AMERICAN GEOLOGICAL SURVEYS

THE United States of America have certainly done noble work in the exploration and mapping of their vast empire. Most of the long-settled States have for many years possessed elaborate maps and reports upon the topography, geology, and agricultural features of their territory. The central Government has likewise carried on extensive and admirable coast surveys, besides innumerable expeditions and surveys for opening up the less known or wholly unvisited regions of the interior of the continent. Were all the literature connected with this subject gathered together it would be found to form of itself a goodly library. Some of it has been published in most costly and indeed luxurious style; other portions, and these sometimes not the least interesting or valuable, have to be unearthed from the pages of flimsily printed "blue-books." But whatever be their external guise, these narratives are pervaded by an earnestness and enthusiasm, a consciousness of the magnitude of the scale on which the phenomena have been produced, and yet a restrained style of quiet description, which cannot but strike the reader. Their writers have evidently had their feelings of awe and admiration worked sometimes up to the highest pitch, yet they contrive on the whole to present just such plain frank statements of facts as to convey clear and definite notions of the regions they describe. Though little is said about hardships and hair-breadth escapes, one can see that these bold explorers could not have accomplished what they so modestly and quietly narrate without a vast amount of privation and danger. Some of them, indeed, like poor young Loring in 1871, have lost their lives by Indian assassins, others have fallen victims to the disease and debility necessarily attendant on so much exposure. But on the whole the work seems to be healthy, and the men engaged upon it like it and keep to it.

Leaving for the present the consideration of what has been done and is now doing in the more settled States, let us turn to those vast territories lying to the west and stretching across the Rocky Mountains to the shores of the Pacific. At the beginning of this century comparatively little was known of these regions. But the Government then resolved to gather some information on the subject, and with that end despatched an expedition in 1804 which penetrated the wilderness, reached the western sea-board, and after much hardship brought back a first instalment of knowledge regarding this part of the continent. During the period preceding the year 1851, somewhere about forty exploring and survey parties were sent by the War Department into the tracts lying to the west of the Mississippi. But in the next twenty years, viz., from 1850 to 1870, the same Department conducted forty-six of these surveys, not merely for military purposes, but to aid in the general opening up of the vast unexplored territories. As a rule, however, and until comparatively recently, these expeditions could make no pretensions to geographical accuracy. Their object was merely to fix as well and as rapidly as might be the positions of main landmarks, and to collect such information as to the nature of the country as was most needful, with the view to its early settlement.

But the discovery of gold in California at once drew attention to the western slope, and awakened a strong desire to open up a better and more expeditious communication with it than had previously been in use. The Pacific Railroad was projected, and surveys were made to ascertain the best routes. In the course of these explorations much additional information was obtained, but still in such necessarily rapid work there could be little done towards accurate geographical and topographical determinations. Hence we find that prominent points were sometimes placed from three to twenty miles out of their true position. Nor could much be attempted of any value in a geological point of view. It is seldom that a single traverse of the rocks of a wide region can be understood without a knowledge of the country lying on either side of it.

In a region of which no reliable maps exist, it is of course impossible to conduct a geological survey except in connection with a topographical one. The geologists must either make their own topographical maps, or be accompanied by surveyors who do that for them. Previous to the year 1867 no special geological exploration seems to have been carried on in the territories as the work of any Government Department. But in that year no fewer than three separate and independent geological surveys were organised. One of these, under the direction of the War Department, but conducted entirely by civilians, with Mr. Clarence King at their head, made a careful examination of a tract about a hundred miles broad, stretching along the fortieth parallel, from the eastern boundary of California to the eastern slope of the Rocky Mountains. A second survey, under the direction of the Smithsonian Institution, with Mr. J W. Powell in charge, had as its task the exploration of the Colorado of the West and its tributaries. A third survey, or series of surveys, has been conducted with great zeal by the Department of the Interior over a vast range of country embracing Nebraska, parts of Colorado and New Mexico, Wyoming, Utah, Montana, and Idaho. These surveys have been under the guidance of Dr. F. V. Hayden.

There appears to have been no concert between the different Government Departments in the organisation and conduct of these various geological explorations. Each survey party was sent out as if it had the boundless wilderness to subdue without the aid of any compatriots or even the chance of seeing human beings save hostile Indians. The Territories, though vast, were not infinite, and it was to be expected that some time or other the independent survey parties should meet. This does not seem to have happened for some years. Meanwhile, however, Dr. Hayden's expedition, supported by increasingly liberal grants from Congress, was doing most excellent work, making a good general map, and at the same time bringing before the world an annual report full of most interesting and valuable and sometimes remarkably novel information regarding the geology and natural history of the regions visited. The War Department, with a far more powerful organisation, and with the help of a staff of trained civilians, was much more deliberate in its movements. Very little of its work had seen the light, though of the excellence and copiousness of that work

there was no reason to doubt. As the Department had been for more than half a century in undisputed command of the exploratory expeditions of those western regions, perhaps some of its more zealous functionaries may have grown somewhat jealous of the increasing popularity of the work done by the Department of the Interior, and may have looked upon that work as an unwarrantable encroachment upon the recognised province of the military corps. Be this as it may, a chance meeting of two independent survey parties in 1873, and the fact that to a certain extent they both surveyed the same ground, led to a battle royal in the spring of last year, wherein appeared the chiefs of the Departments with President Grant at their head, military men, geologists, naturalists, topographers, and several cohorts of professors. Evidently some of the parties knew that the contest would come sooner or later, and were prepared accordingly. The first bomb-shell was thrown as it were by an outsider, on the 15th of April, 1874, when Mr. Lazarus D. Shoemaker carried a resolution in Congress requesting the President to inform the House what geographical and geological surveys were carried on by the Government in the same or contiguous areas of territory lying to the west of the Mississippi, and whether these could not be combined under one Department, or at least have their respective geographical limits defined.

The question thus raised turn out to be really whether the War Department should have entire control of the surveys, both those intended for military and those for purely civil purposes. The President replied that they would be more economically and quite as efficiently carried on by the military authorities. Not content with this recommendation of its military chief, Congress referred the matter to its Committee on Public Lands. A careful investigation followed, and though the military side fought hard for its supremacy, the Committee decided against the purposed consolidation. Their conclusions ran thus: "That the Surveys under the War Department, so far as the same are necessary for military purposes, should be continued; that all other Surveys for geographical, geological, topographical, and scientific purposes should be continued under the Department of the Interior, and that suitable appropriations should be made by Congress to accomplish these results."

There can be little doubt that though it must have chagrined some sanguine partisans whose ebullitions of temper form an amusing feature in the congressional blue-book, this decision of the Committee was in the circumstances a wise one, and one which, followed out by the Government, will have an important influence in the development of the vast and still unexplored regions over which the surveys have yet to extend. It is impossible that the corps of Engineers, weighted with all the numerous and arduous duties which form its ordinary work, should be able to furnish the necessary complement of trained geologists, botanists, naturalists, and other scientific men for the adequate exploration of the territories. In fact, the scientific work of that corps has all along been done in great measure by civilians. But it is neither needful nor desirable that civilians of high training in practical scientific work should be placed under military direction. They move more freely without it. And as in the Western Territories they declare that they no longer need the protection of an escort, the sole remaining reason for a military supervision would seem to be removed.

The Surveys of the Department of the Interior claim the first place from their voluminousness and from the wide area to which they refer. As already mentioned, they have been carried on since their beginning by Dr. F. V. Hayden, to whose skill in geological work, and tact in diplomatic relations with Government bureaux, officials, and fellow-labourers in science, their success is certainly in large measure due. For the last twenty-two years he has given himself to the exploration of the north-western territories. In the spring of 1853 he ascended the Missouri in one of the American Fur Company's steamboats and spent three years up there, during which time he accumulated considerable collections in natural history. In 1856 he joined an expedition of the Engineer Topographical Corps to that region as surgeon and naturalist. On the outbreak of the Civil War he took service in the Federal Army, as Surgeon of Volunteers, and served four years. But when the war ended, finding himself out of employment, he in 1866 returned to the north-west on his own resources, and resumed his researches in the natural history of that region. In the following year, Congress having made a small grant of $5,000 towards a Geological Survey of Nebraska, Dr. Hayden received the charge of it. This was the beginning of his career as Government geologist. But his path was not strewn with roses, either amid the hills of Nebraska or in the Government Offices at Washington. The sum appropriated for his survey in 1867 was the unexpended balance of the grant for the legislative expenses of the territory. He had a sore fight to get it renewed next year. But in 1869 Congress took up the question in a broader spirit, and sanctioned a general geological survey of the Territories of the United States, with an appropriation of $10,000 to be administered by the Department of the Interior. Since that date, owing no doubt to the marked success of the Survey, the gran has grown rapidly in amount, till at present it stands at $75,000.

This great increase in the amount of funds at his disposal has enabled Dr. Hayden to augment and equip his staff to an extent very different from that of his modest beginning in 1867. According to his last published report he organises his force into three geological parties, each completely furnished and able to act independently, so that if desired it could be transferred to any portion of the public domain. Each of these parties consists of a topographer, an assistant topographer, a geologist, two packers, a cook, and usually two or three others as general assistants or collectors in natural history. But besides these he has still three other parties, one for the purpose of carrying on the primary triangulation of the country and thus correcting and harmonising the trigonometrical work of the other or geological explorers, a second for procuring photographs and information likely to be useful to the other parties and the public, and a third, and not least important, the quartermaster's party, for furnishing supplies to all the others. These three last-named parties traverse the entire field of work.

A mere inspection of the catalogue of the publications of the Geological Survey of the Territories is enough to

show what an enormous amount of work has been got through in seven years. First of all there is an Annual Report of Progress, in which, without waiting for completed surveys, the general results of each year's work are given, in geology, palæontology, mineralogy, natural history, meteorology, archæology, and economic products of every kind. Then come what are called Miscellaneous Publications and "Bulletins"—little pamphlets giving data in meteorology, topography, natural history, or other information gathered in the course of the Survey. Next we have large quarto monographs, admirably printed and illustrated, devoted to the discussion of the more technical and matured results, such, for instance, as the palæontology of a wide region or of a formation. Lastly, a series of topographical maps of parts of the districts surveyed has been published. These will be of great value as a basis for the general map to be afterwards constructed. Geologists in this country accustomed to the elaborate geological maps issued by our Government, may perhaps at first wonder why geological maps, properly so called, do not appear among the publications of the Geological Survey of the Territories. But the delay in the issuing of a general map is as necessary as it is prudent. A report may be written of what one sees. It is complete in itself; and if it is found to contain errors, these can be corrected in a subsequent report. But a sheet of a geological map must fit accurately to its neighbours. If it is surveyed and published without waiting for the investigation of the surrounding area, it will most probably be found somewhere, at least, erroneous; and to make it harmonise with adjoining sheets may require so much alteration as to demand, perhaps, even the cancelling of the old and the engraving of a new plate. Therefore we are content to wait for Dr. Hayden's geological map of the Territories in confident anticipation that it will be worthy of the high reputation which he and his staff have already gained.

It should be added, that with the most praiseworthy liberality the publications of the Survey are distributed as gifts to learned bodies and scientific men all over the world. All that is asked is that, where possible, the scientific publications of the recipients of the volumes may be sent in exchange. It is to be hoped that this generous spirit has called forth a similar feeling elsewhere, and that the library of the Geological Survey of the Territories is continually augmented by presents from all parts of the world.

ARCH. GEIKIE

FISKE'S "COSMIC PHILOSOPHY"

Outlines of Cosmic Philosophy, based on the Doctrine of Evolution, with Criticisms on the Positive Philosophy. By John Fiske, M.A., LL.B., Assistant Librarian, and formerly Lecturer on Philosophy, at Harvard University. 2 vols. (London: Macmillan and Co., 1874.)

WE have repeatedly expressed our admiration of the system of philosophy which Mr. Spencer is engaged in working out. Mr. Fiske, in giving an outline of this philosophy, has called it *Cosmic;* a name which he thinks peculiarly fitting, because "the term 'Cosmos' *connotes* the orderly succession of phenomena quite as forcibly as it *denotes* the totality of phenomena; and with anything absolute or ontological, with anything save the 'Mundus' or orderly world of phenomena, it has nothing whatever to do." But Mr. Spencer is far from ignoring the absolute, and the ontological element in his speculations has frequently been the subject of criticism; and surely Mr. Fiske goes beyond an account of the orderly succession of phenomena in all that he has to say about the "Infinite Power manifested in the world of phenomena," which he finds that we are clearly bound to symbolise as quasi-psychical rather than as quasi-material, so that we may say with meaning, "God is Spirit, though we may not say, in the materialistic sense, that God is Force."

As the Evolution-Philosophy, which is for the most part but higher science, has swallowed up the rival systems of former times, and now stands itself without a rival, we need not pause to speak of its merits. Our first duty then is to acknowledge that Mr. Fiske has succeeded in giving a very faithful and attractive sketch of Mr. Spencer's philosophy. He has made all the thoughts his own, and has, we should think, secured for himself a recognised place among the most advanced thinkers of our time. But Mr. Fiske claims that his work shall be regarded as more than a mere reproduction of Mr. Spencer's thoughts. It contains "much new matter, both critical and constructive." In relation to the evolution of society, the author supposes he has anticipated what "will doubtless be much more thoroughly and satisfactorily presented by Mr. Spencer in his forthcoming work on Sociology." Without stopping to inquire whether a love of system may not here, as elsewhere, have led to a slight waste of energy and a straining of words, it must without doubt be recognised that Mr. Fiske has expressed with clearness and ability many large and important truths, the recognition of which must have a very healthy and elevating effect. Nothing can be better than for people to reflect that moral progress consists in the continual "adaptation of the desires of each individual to the requirements arising from the co-existent desires of all neighbouring individuals." Again, the superiority of a true philosophy over some modes of thought which still claim to be the most advanced, may be learned from Mr. Fiske's profound appreciation of the vital part played by the Roman Church in the evolution of European civilisation.

The original matter, however, on which the author lays most stress, refers to the genesis of man. He works out a theory as to the part taken by the prolongation of human infancy in originating social evolution, which, in his own words, "is entirely new in all its features." To account for the passage from mere gregariousness to sociality as marked by permanent family groups, is the problem Mr. Fiske has set himself, and his solution is this:—Mr. Wallace has given a most beautiful exposition of the operation of natural selection at that point in the evolution of man from a lower form when variations in intelligence began to be seized on and preserved rather than variations in bodily structure. It was then that our remote progenitors began to clothe their bodies and to prepare their food, that the ape of many devices survived where his perhaps stronger or swifter contemporaries perished. Now, increase in intelligence, says Mr. Fiske, implies increase in size and complexity of brain; and, as a matter of observation, this structure, as it becomes more and more complex, is less and less definitely organised at

birth; then arises the phenomenon of infancy. The orang-outang, until about a month old, "lies on its back, tossing about and examining its hands and feet;" with the lowest savages the period of helplessness is much longer, and as civilisation advances, the period during which the child must depend on the parent for support, becomes still longer. Mr. Fiske believes that these considerations supply "a very thorough and satisfactory explanation of the change from gregariousness to sociality." "The prolonged helplessness of the offspring must keep the parents together for longer and longer periods in successive epochs; and when at last the association is so long kept up that the older children are growing mature, while the younger ones still need protection, the family relations begin to become permanent. The parents have lived so long in company that to seek new companionships involves some disturbance of ingrained habits; and meanwhile the older sons are more likely to continue their original association with each other than to establish associations with strangers, since they have common objects to achieve, and common enmities, bequeathed and acquired, with neighbouring families. As the parent dies, the headship of the family thus established devolves upon the oldest, or bravest, or most sagacious male remaining. Thus the little group gradually becomes a clan, the members of which are united by ties considerably stronger than those which ally them to members of adjacent clans, with whom they may indeed combine to resist the aggressions of yet further outlying clans, or of formidable beasts, but towards whom their feelings are usually those of hostile rivalry." "In this new suggestion," says Mr. Fiske, "as to the causes and the effects of the prolonged infancy of man, I believe we have a suggestion as fruitful as the one which we owe to Mr. Wallace," and "the clue to the solution of the entire problem" of the origin of the human race.

Towards the end of the second volume there is a good deal of more or less original matter relating to religion, much of which we think open to serious criticism, but on which we cannot enter here. There is, however, in the writings of Mr. Spencer, a view (adopted by Mr. Fiske) with respect to the relation of feeling to movement which appears to us to be nothing more than a popular fallacy, and which, as it seems to us, spreads much confusion through the psychological part of his system. The assumption against which we would direct some criticism is, that feelings stand in a causal relation to bodily movements. The point has recently occupied some attention, but we must reserve our remarks for another article.

Though we admire the far-reaching speculations of Mr. Spencer as more wonderfully consistent than the thoughts of any other thinker of equal range, we cannot regard his writings as criticism-proof at all points. Mr. Fiske, in arguing against the volitional theory of causation, says: "Phenomenally we know of will only as the cause of certain limited and very peculiar kinds of activity displayed by the nerves and muscles of the higher animals. And to argue from this that all other kinds of activity are equally caused by will . . . is as monstrous a stretch of assumption as can well be imagined." "Because this is the only cause of which we are conscious, . . . we are asked to assume, without further evidence, that throughout the infinitely multitudinous and heterogeneous phenomena of nature no other kind of cause exists. A more amazing example of the audacity of the subjective method could hardly be found." We hope soon to see the evolution philosophy rendered at once more consistent with itself, and able to give to the volitionist a more complete answer than is to be found in this "crushing refutation;" at which the volitionist will but smile, believing the strong language to be but a make-weight to the weak argument. The argument, as it stands, is Mr. Fiske's; it is in the admission made to the volitionist, viz. that certain movements are caused by feeling, that he follows Mr. Spencer. We contrariwise maintain that an antecedent feeling is never the cause of any movement whatever, that there is no evidence of its being so, that the phenomena of life and motion can be wholly accounted for without such assumption; that the assumption, that feeling causes movements, though it can be expressed in words, cannot be represented in thought; and that the thing asserted is inconsistent with the physical explanation of the objective side of the universe—of all physical phenomena, and movements are such—which is a fundamental idea in Mr. Spencer's philosophy. When this is accepted, the answer to the volitionist will be, that he takes for the cause of all action not that which is phenomenally known "only as the cause of certain limited and very peculiar kinds of activity," but that which is not known to be, and cannot be conceived of as, the cause of any activity.

Justice cannot be done to this criticism in a review article in these columns. We shall therefore content ourselves with calling attention to some of the confusion which, as it seems to us, this popular fallacy introduces into the philosophy Mr. Fiske expounds in these volumes. First, let us have no misunderstanding, if that be possible among philosophers. Certain states of consciousness, which precede certain bodily movements, and which are called by the learned "volitions," have in all ages been believed to be the cause of these movements. This opinion is perhaps as ancient as the human mind, more ancient than, and the father of, the earliest conceptions of deity. It is still the all but universal opinion, not of the vulgar, but of the most cultured. Quoting from Mr. J. S. Mill, Mr. Fiske says: "Our will causes our bodily actions in the same sense (and in no other) in which cold causes ice or a spark causes an explosion of gunpowder." In a passage quoted from Sir William Hamilton, also with approval, we have this definite expression: "A multitude of solid and fluid parts must be set in motion by the will."

Now let us in effect deny all this in Mr. Fiske's own words. Speaking of what he calls "the closed circuit of motion, motion, motion," he says: "No conceivable advance in physical discovery can get us out of this closed circuit, and into this circuit psychical phenomena do not enter. Psychical phenomena stand *outside* this circuit, *parallel* with that brief segment of it which is made up of molecular motions in nerve-tissue." "However strict the parallelism may be, within the limits of our experience, between the phenomena of mind and this segment of the circuit of motions, the task of transcending or abolishing the radical antithesis between the phenomena of mind and the phenomena of motions of matter must always remain an impracticable task. For in order to transcend or abolish this radical antithesis we must be

prepared to show how a given quantity of molecular motion in nerve-tissue can become transformed into a definable amount of ideation or feeling." Strange that it does not occur to our philosophers that they just leap this impassable gulf from the other side when they talk about a multitude of solid and fluid parts being set in motion by the will, in the same sense in which a spark causes an explosion of gunpowder. Either the volition is itself a mode of motion, which Mr. Fiske solemnly denies, or the circuit is not closed, which he as solemnly asserts it to be.

The inconsistency and consequent error, to which we have called attention, cause much more widespread confusion than might at first be supposed. In one direction we have seen the closed circuit of motion broken in on. In the opposite direction we have elaborate attempts to evolve mind out of matter, all specific and impressive declarations to the contrary notwithstanding. In this direction Mr. Lewes has gone forward with a more uncompromising logic than is to be found in the volumes before us. Mr. Fiske agrees with Mr. Lewes that both "life and mind are processes," but we do not find that he goes on to picture consciousness "as a mass of stationary waves formed out of the individual waves of neural tremors." The evolution philosophy, starting from the primeval nebula, finds every science a specialised part of some more general science. Biology is a specialised part of geology, and psychology is a specialised part of biology. "Mind here appears," says Mr. Fiske, "to be but the highest form of Life," and life, as admirably defined by Mr. Spencer, "is the definite combination of heterogeneous changes, both simultaneous and successive, in correspondence with external co-existences and sequences." Truly the study of the higher forms of these phenomena may be called a specialised part of biology. But may we call any adjustment of internal relations to external relations *Mind?* We think not, and in this Mr. Fiske heartily agrees with us, for he hastens to tell us that "push our researches in biology as far as we may, the most we can ever ascertain is that certain nerve-changes succeed certain other nerve-changes or certain external stimuli in a certain definite order. But all this of itself can render no account of the simplest phenomenon of consciousness." And Mr. Spencer is equally emphatic:—"The thoughts and feeling which constitute a consciousness form an existence that has no place among the existences with which the rest of the sciences deal." But where are we now? If in psychology any part of the phenomena studied are those given directly in consciousness, then they are not the phenomena which form a specialised part of biology. Consciousness, then, is not evolved out of the primeval nebula. It creeps in surreptiously somewhere in the course of the evolution of organised beings, and appears in man, the highest product of evolution, as a power guiding his movements. This, to our mind, is the weak point in Mr. Spencer's philosophy.

Let us glance at Mr. Fiske's chapter on the Evolution of Mind, which he tells us "was mostly written, and the theory contained therein entirely worked out, before the publication of Part V. of the second edition of Mr. Spencer's 'Principles of Psychology.'" In so far as this so-called theory of the evolution of mind is an account of the evolution of the nervous system, it may be open to no serious criticism. But what happens is this: From talking of waves of molecular disturbance passing along finished channels and finding for themselves new courses in lines of least resistance, the language gradually changes; a process entirely physical, "reflex action, which is unaccompanied by consciousness," is called "the simplest form of psychical life." Instinct is found to be compound reflex action. And in the higher organisms "there will be a number of permanent transit-lines and a number of such lines in process of formation, along with a continual tendency towards the establishment of new ones. The consequences of this are obvious. In becoming more and more complex, the correspondence becomes less and less instantaneous and decided. 'They gradually lose their distinctly automatic character, and that which we call instinct merges into something higher.'" What is the something higher into which all these nervous operations merge? Into mind as we see it in man, who is supposed to perform actions "with the assistance of reason, volition, and conscious memory."

It is, however, when specially engaged with the consideration of voluntary action that the confusion may be said to reach a climax. But Mr. Fiske has no misgiving; he proceeds, confident that he has clear ideas to expound, and that he is expounding them in clear and consistent language. "Volition," he tells us, "is that transformation of feeling into action which is attended by a conscious comparison of impressions." If *feeling* may be transformed into *action*, why may not motion be transformed into feeling? Having written this he cannot well afford to sneer at the materialist. Though mind and motion, as we are often told, have no kinship, yet here are a few sentences which are perhaps expected to help us towards a mental picture of the curious "dynamic process" "whereby feeling initiates action."—"In a complex aggregate, like the human or animal organism, such a state of equilibrium (as the ass between the two bundles of hay) cannot be of long continuance. Sooner or later—either from the greater vividness with which one of the desired objects is mentally realised, or from any one of a thousand other disturbing circumstances down to those of a purely physical nature—one desire will become stronger than the other, and instantly thereupon, the surplus nervous tension remaining after the weaker desire is neutralised, will pass into nervous *vis viva*, or, in other words, volition will take place." It will be almost a sufficient criticism of these statements to place alongside of them a sentence from Mr. Fiske's next paragraph. "To say explicitly that volition does not follow the strongest motive, is to say implicitly that motion does not always follow the line of least resistance; which is to deny the persistence of force." With this last statement we agree; but how is it to be reconciled with the preceding sentences? Can mental vividness, or anything else not purely physical, either help or hinder motion in following the line of least resistance? To say so is to deny the persistence of force.

Having found that philosophers are very like other people, that they are sometimes almost as anxious to be thought infallible as to have any inconsistency in their writings pointed out (Mr. J. S. Mill was a grand exception), it may perhaps be as well to say that in bringing together a few passages which seem to us after careful

consideration to be hopelessly inconsistent, we have been inspired by no other feeling than a desire to see the philosophy we admire purified from an error that greatly mars its beauty. Let it be accepted that states of consciousness really stand outside the circuit of motions and therefore can never be a cause of any movement, and the occasion of all the confusion of which we have spoken disappears.

Mr. Spencer, who has been so kind as to read the proof of this article, tells me by letter that he thinks I have not quite remembered his point of view and its implications. He says:—"The implication of your argument seems to be that I identify motion as it actually exists with motion as manifested to our consciousness. Did I do this there would be the inconsistency you allege in the supposition that feeling is transformable into motion and motion into feeling. . . . But that transformation which I assume to take place (though without in the least understanding how) is the transformation of the subjective activity we call feeling (unknowable in its ultimate nature) into the objective activity we call motion (also unknowable in its ultimate nature)." On the metaphysical question my own view probably does not differ much from Mr. Spencer's; but I would have it kept distinct from the question of ordinary science, which deals only with the relations of things as manifested to our consciousness. And I leave it to Mr. Fiske and his readers to determine whether in the passages I have quoted from his work he means motion and feeling as known to us—the motion and feeling of science, or the ontological entities of the metaphysician, with which in his preface he has told us his system "has nothing whatever to do."

DOUGLAS A. SPALDING

OUR BOOK SHELF

Notes on the Fertilisation of the Cereals. By A. S. Wilson. (Reprinted from the "Transactions of the Botanical Society of Edinburgh.")

NOTWITHSTANDING the practical importance to the farmer of a knowledge of the mode in which our cereal crops are fertilised, it is singular that different views still prevail on several essential particulars. One point appears to be generally conceded, that insects have nothing to do with it; the ovules are either self-fertilised, or cross-fertilised by the agency of the wind. Dr. Boswell-Syme and the present author incline towards the former; Delpino and Hildebrand to the latter view, at all events in the case of wheat; and Belgian farmers still trail ropes over their flowering wheat to insure complete fertilisation. Although we cannot altogether agree with Mr. Wilson's conclusions, he has added some most valuable observations to our knowledge of the subject, especially with regard to the remarkable extension of the filaments immediately previous to, or concurrently with, the discharge of the pollen. If a rye-flower, he states, is opened a moment before the natural time of flowering, the filaments will be found to measure about one-sixteenth of an inch in length. In the course of five minutes, or less, from the instant the pales begin to open, the filaments will, in many cases, have grown to twelve-sixteenths, and the whole of the pollen will have fallen out; and this rapid extension is not a mere straightening out of a doubled-up thread, but an actual growth. In oats and barley a similar extension takes place; in the latter case the filaments may be seen, under an ordinary pocket lens, to be visibly growing at the rate of six inches an hour. The result at which Mr. Wilson arrives is, that the "European cereals are self-fertilised, and that the act of fertilisation, in those cases in which the flower opens, is probably performed in the opening, and is necessarily confined to the twenty or thirty minutes during which the flower remains open." We must confess that we are not convinced of the validity of the train of reasoning which led the author to this conclusion. The remarkable phenomenon of the extension of the filaments would appear to be quite useless for this purpose, Mr. Wilson's drawing showing that its effect is to remove the anthers from the immediate proximity of the stigmas to a considerable distance from them. The whole mechanism of the "versatile" anthers, lightly suspended at the end of very slender filaments, the immense quantity of light dry pollen, and the sudden jerk by which the flowers are opened, appear to lead *primâ facie* to an opposite conclusion, and to suggest the agency of the wind. On two other points Mr. Wilson seems to us to have been led into some confusion by an incorrect use of terms. He speaks of the meaning of the word "fertilisation" as being "partly a matter of convention; it may mean that act of the anthers by which they project or discharge the pollen, which, falling directly on the pistil, shall produce the embryo; or it may mean the falling of the pollen on the ovule after being carried a distance by the wind; or it may apply to the instant in which the elements of the pollen set up that action in the ovule which produces a new plant;" and he employs the word throughout in the first of these meanings. Now we believe that all our best writers use the term as synonymous with "impregnation" or "fecundation;" and that the correct expression for the falling of the pollen on the stigma—the German "Bestäubung"—is "pollination"; Mr. Wilson's "fertilisation" being simply the discharge of the pollen from the anther, which may or may not "pollinate" the stigma and "fertilise" the ovules. He also finds fault with those botanists who distinguish between "cross-fertilisation" and "self-fertilisation"—the fertilisation of ovules by pollen from a different or from the same flower—without being able to define accurately the physiological difference between the two processes. The terms are, however, currently used, and we think quite correctly, to express an actual external difference, which we know from experience to be frequently accompanied by results of a different character; even though we are not at present able to trace this difference to its physiological causes. Notwithstanding these points, to which we have felt bound to call attention, the present treatise is one of the most important contributions yet made to our knowledge of the remarkable phenomena connected with fertilisation.

A. W. B.

Official Guide to the Kew Museums; a Handbook to the Museums of Economic Botany of the Royal Gardens, Kew. By Daniel Oliver, F.R.S. Sixth edition, with additions by J. R. Jackson, A.L.S., Curator of the Museums. (J. R. Jackson, Museum, Kew. 8vo., 92 pages.)

ALTHOUGH this is by no means a complete catalogue or guide to all the objects exhibited in the museums at Kew, very few substances of commercial importance have been overlooked. Necessarily in so small a book, little is said of the relative value, &c., of different fibres and other vegetable substances; but it will be found useful to all interested in applied botany, inasmuch as it embodies all recent discoveries of interest to the druggist, manufacturer, or artist. The products are arranged in families according to their affinities, and by means of this guide, which has a complete index of trivial and technical names, the visitor can readily find any article of which he may be in search. One thing, however, is certain, the Government might, by a small grant in aid of a more comprehensive publication, render the fine collection of vegetable products at Kew of infinitely more service to the general public.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.]

On the Mechanical Work done in exhausting a Muscle

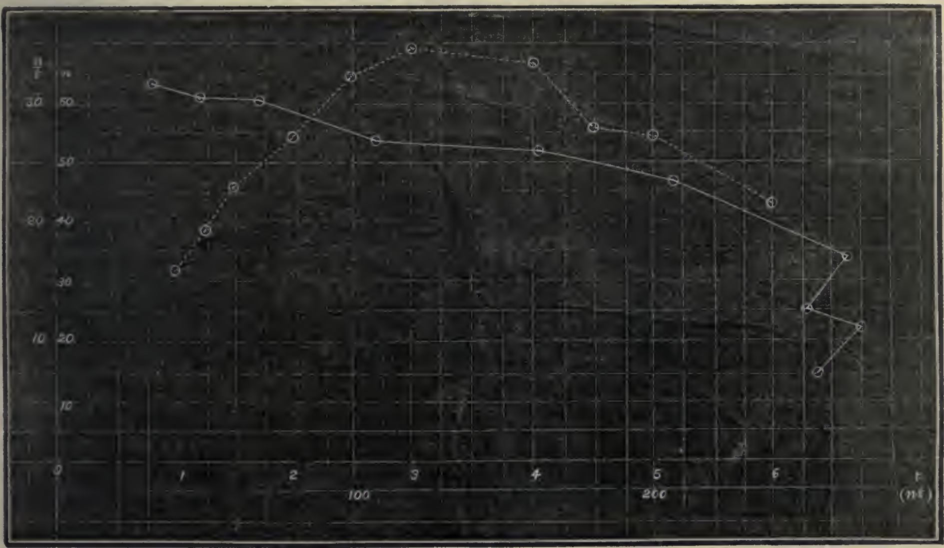
I BEG leave to make some reply to the comments (NATURE, vol. xi. pp. 464, 488) of Prof. Haughton on my paper.

1. In regard to the relative value of my earlier and later experiments, it is to be said, that in one sense they are all equally valuable. My object, however, was to find the work of exhaustion when the intervals of work and rest were equal, the work to be expended only in lifting the weight. Hence the experiments were made in such a way as to eliminate the fatigue caused by the falling weight. Prof. Preston and myself practised for several weeks, until we were able to keep accurate time, before the published series was begun. All who saw the experiments were then satisfied that the later method of experiment was an improvement. The two series first published were made with equal care, and I am therefore at some loss to know what has been Prof. Haughton's criterion in deciding that one was good and the other bad.

2. In dealing with Prof. Haughton's equation—

$$n = \frac{A.t}{1 + \beta t^2} \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

when it was said that the co-ordinated values of $\frac{n}{t}$ and $n{\cdot}t$ formed a curve, the meaning could only have been that β is not a constant. Prof. Haughton is of course right in saying that the observations thus co-ordinated "may be represented by a straight line." He might also have added that for properly chosen limits, any other observations may also be represented by a straight line. The point is, whether these lines give any evidence of regular deviations. It seems to me that "any one accustomed to such observations" ought to be able to see such evidence in the diagrams of Prof. Haughton in NATURE, *loc. cit.* In this connection I wish to give a series of experiments, the time of lift t being variable and equal to the interval of rest. The values of n are the means of four experiments, and are uncorrected for variations in strength. The experiments were made with the apparatus described in my last paper (NATURE, vol. xi. pp. 256, 276) and my right arm.



Raising weight of 4·5 *kgr. through* 0·70 *in* t *sec.*

t	n	$\frac{n}{t}$	$n{\cdot}t$
1·00	31·7	31·7	31·7
1·25	38·7	30·6	48·4
1·50	45·5	30·3	68·3
2·00	54·0	27·0	108·0
2·50	64·7	25·9	161·8
3·00	69·2	23·1	207·6
4·00	66·5	16·6	266·0
4·50	56·0	12·4	252·0
5·00	54·0	10·8	270·0
6·00	42·5	7·1	255·0

The values of n and t are represented in the diagram by the dotted line. It will be seen that n reaches a maximum where $t = 3{\cdot}4$.

The values of $\left(\frac{n}{t}\right)$ and $(n{\cdot}t)$ are also represented by the full line. It will be observed that the observations on opposite sides of the maximum n are not continuous. A comparison of this line with those given by Prof. Haughton in NATURE, vol. xi. p. 465, will be found instructive.

3. In the case just considered, the time of exhaustion depends upon the velocity of disintegration and recuperation of the muscles. It is well known that the velocities of such operations, taking place in time, are represented by the binomial curve. I have satisfied myself that the values of n in the above series are represented by the terms of the expanded binomial $(p + q)^m$ where $p + q = 1$; where p and q are unequal, and where $m = 1$ represents the total number of chances. This point is reserved for future investigation.

4. In my paper in the *American Journal of Science* (Feb. 1875, pp. 130–137), the accuracy with which Prof. Haughton's formula represents my experiments, was shown. Assuming

$$(w + a)\,hn = \frac{A}{(w + a)^v}$$

where a is the reduced weight of the arm, and Prof. Haughton's law demands that $v =$ unity. It turns out to be 2·6. Prof.

Haughton refers the difficulty to my experiments, and I refer the difficulty to his theory.

5. Prof. Haughton objects to my reduction for variations in strength. In reply, it is to be said that an increase of from 13·66 kgr. to 14·84 kgr. in the strength of Mr. Myer's arm, caused *n* to vary from 78 to 1366. The weight used was 5·00 kgr. For a weight of one or two kgr. my own arm also varies thus greatly. I therefore conclude that this reduction is not only not improper, but that it is essential.

6. I beg leave to state that I alone am responsible for the paper published in NATURE, vol. xi, pp. 256–276. I acknowledged therein all the aid that I am conscious of having received. F. E. NIPHER

Washington University, St. Louis

P.S.—I find that one important point in Prof. Haughton's paper has been overlooked in my reply. Objection is made to my last series of experiments, on the ground that all the muscles thrown into action are not exhausted. If this objection is well taken, it applies also to the former series of mine, so "highly confirmatory of the Law of Fatigue," the agreement of which with Prof. Haughton's formula is so "complete and satisfactory." The *lifting* of the weight was done in precisely the same way.

Domestic Economy of Blackbirds

TWO Blackbirds having built their nest in full view of my bedroom window, I have been much interested in watching the process of feeding their young, &c. The cock bird is the principal forager, and the food generally brought are worms. My object in writing is to draw attention to one feature which may be unknown to most of your readers as relates to the disposal of the young birds' droppings. If left in the nest, it would become filthy, if thrown aside the accumulation would lead to detection, and I believe the general impression is that the old birds carry the soil away; but on watching them closely I never saw the droppings carried away but on one occasion, and that by the hen; in every other instance after being fed, the young birds in turn lift up their tails and the droppings are taken by the old bird and actually swallowed. On the 15th July the young birds being fully fledged, were literally washed out of their nest by the downpour of rain on that day, but, with a little care, they all survived. On the 22nd the hen again returned to her nest, and she is now sitting closely on three eggs, and I hope to get the next brood photographed. I enclose my card and address, and should any readers of NATURE desire to witness what I have described, I shall be very glad to afford them an opportunity.

Woolwich Common, 2nd Aug., 1875 E. R. W.

Scarcity of Birds

MR. BARRINGTON, writing from the Co. Wicklow, in NATURE, vol. xii. p. 213, says that he finds Blackbirds and Thrushes unusually scarce this year. I have not heard of this anywhere else, and certainly it is not the case here.

Old Forge, Dunmurry, JOSEPH JOHN MURPHY
Co. Antrim, July 26

Hay Crops of 1875

LET me record in NATURE the extraordinary fact that on Monday, July 26, in one of my meadows here, the first crop was carried while the second crop, or after-math, was being cut.

Valentines, Ilford C. M. INGLEBY

OUR ASTRONOMICAL COLUMN

VARIABLE STARS.—The last number of *Vierteljahrsschrift der Astronomischen Gesellschaft* (x. Jahrgang, weites Heft), received within a few days, contains an ephemeris of most of the known variables, including those of short period, for the year 1876, drawn up by Dr. Schœnfeld, chiefly from the data in his catalogue of 1875. This early publication will, no doubt, be very acceptable to observers who are devoting attention to these interesting and puzzling objects.

THE GREAT CLUSTER, MESSIER 11.—As the first special publication of the Observatory of Hamburg, we have Prof. Helmert's memoir detailing the results of his micrometrical observations on the components of this well-known cluster in the constellation Aquila, or in *Clypeum* or *Scutum Sobieski*, as many of the Continental astronomers continue to call that part of the heavens in which it is situate. The memoir has a particular interest from the circumstance of Dr. Lamont having similarly employed the Munich refractor in the years 1836-39. The investigation of any changes that may take place in the constituents of these groups of stars, as regards position or brightness, becomes a very attractive one, and as we know from the excellent work of Herr Pihl on the Perseus cluster, it is not one always requiring the use of large instruments, such as have been employed in the hands of Lamont and Helmert, upon Messier 11. D'Arrest terms this cluster "magnifica innumerabilium stellarum coacervatio"; the amateur will remember Admiral Smyth's comparison of the configuration of the components to "a flight of wild ducks."

NEW MINOR PLANET.—No. 147 of this group was detected by Herr Schulhof, at the observatory of Vienna, on July 10, in the vicinity of β Capricorni. It is of the twelfth magnitude, and Prof. Littröw, the director, proposes to call it "Protogeneia," perhaps in allusion to it being the first minor planet discovered at this observatory. It may be presumed that he has satisfied himself of its distinctness from any of the minors which are now adrift.

THE GREAT COMET OF 1843.—The elements of the orbit of this remarkable body, finally derived by the late Prof. Hubbard, of the Naval Observatory, Washington, after a very masterly discussion of the whole series of observations, are as follow:—

Perihelion Passage 1843 February	27·41051	G.M.T.
Longitude of Perihelion ,,	278° 40′ 17″	M. Eq. 1843.
,, Ascending Node	1 14 55	
Inclination of Orbit	35 40 39	
Excentricity	0·9999915717	
Perihelion Distance	0·0055383	

Motion—retrograde.

From which we have the following additional figures:—

Mean Distance from the Sun ...	65·711	
Aphelion Distance	131·42	
Period of Revolution	532·7	years.

The distance from the sun at the perihelion is less than that of any other comet so far computed; the famous comet of 1680, according to Encke's definitive calculations, making also a very close approach, though not so near as in the present case. If Leverrier's semi-diameter of the sun be adopted, with 8″·875 for the solar parallax, we find—

Sun's semi-diameter	428,710 English miles.
Comet's perihelion distance ...	510,140 ,,

Whence it would appear that a little before 10 P.M. on February 27, the comet passed within 81,500 miles from the sun's surface, and if we compute the orbital velocity at the time, we find it 348·5 miles per second. The comet was less than $2\frac{1}{4}$ hours on the north side of the ecliptic, passing from ascending to descending node in 2h. 13·4m.

On examining with the above elements the track of the comet on the day of perihelion passage, it results that a transit over the sun's disc must have taken place at the descending node, the ingress (geocentric) occurring at 11h. 28m. Greenwich time, 241° from the sun's N. point towards E., and the egress at 12h. 29m., at 187° similarly reckoned. The transit might have been observed in Australia; the times for Sydney being, Feb. 27, 21h. 33m. for ingress and 22h. 34m. for egress. Such a transit brings to recollection an observation recorded in the Paris Astronomical Bulletin at the time as having been made by M. Aristide Coumbary at the observatory of Constantinople, on the morning of the 8th of May, 1865, from which it would appear that a dark spot moved over a space of 21′ upon the sun's disc, in a little over three-

quarters of an hour. From the data published by Coumbary we might infer on the hypothesis of circular motion, that the body, whatever its nature, had moved at a distance of about 415,000 miles from the sun's surface, and as we know from the experience afforded by the great comet of 1843, there is nothing improbable in a comet having so passed. Perhaps when the sun's disc is more systematically and widely watched, a comet may be caught in transit and properly observed. The case of the comet of 1819 is not a satisfactory one, Pastorff's observation at least attributing to it a position upon the sun's disc which it could not have occupied at the time he assigns to his observation.

COMET 1874 (II).—The comet detected by M. Coggia at Marseilles on April 17, 1874, which presented so fine an appearance in our northern heavens in July, was observed at Melbourne, and by Mr. Tebbutt, near Sydney, until the end of the first week in October. Comparing the Melbourne observation on the 6th of this month with the place given by the elliptic elements of Prof. Tietjen, the difference is found to be less than a minute of arc, and the European observations to the middle of July are very accurately represented by these elements. Between April 17th and October 6th the comet traversed an arc of 205° of true anomaly, and the near agreement of Prof. Tietjen's orbit throughout, shows that the comet when it attracted so much attention was really moving in an ellipse of very long period, though no doubt this element may be considerably varied without largely increasing the differences between calculation and observation. The period of revolution in Tietjen's ellipse is nearly 9,000 years. When a similar complete investigation has been made for this comet to that so skilfully performed by Dr. von Asten in the case of Donati's great comet of 1858, some kind of limits may be assigned to the time of revolution, but in all probability it must extend to some thousands of years. We remark that the Melbourne observations of Coggia's comet were made with a telescope of only $4\frac{1}{2}$ inches aperture; no doubt the comet might have been followed some time longer with larger instruments, but it is possible that the Melbourne reflector may have been under preparation for the transit of Venus, and not conveniently available for cometary observations.

PROF. LOOMIS ON THE U.S. WEATHER MAPS *

THIS paper is in continuation of a similar paper published in July last year, in which the American Weather Maps for 1872-73 were discussed. The results then arrived at are compared with the observations of 1874, and the whole is thereafter combined into a three years' average.

The principal conclusions from the three years' observations are these :—

The mean direction of the onward course of storms is N. 81° E., or a little to the north of east, being most southerly in July (E. 7° S.), and most northerly in April and October (N. 72° E. and N. 74° E.). The mean velocity is 26 miles per hour—the maximum monthly velocity, 32 miles, being in February, and the minimum 18·4 miles in August. As regards particular storms, wide deviations from these figures take place, it being found that the actual motion of the storm's centre may have a path in any direction whatever, and the velocity of progress may vary from 15 miles per hour towards the west, to 60 miles per hour towards the east. From the tri-daily observations it is found that the average velocity of storms from 4·35 P.M. to 11 P.M. is about 25 per cent. greater than for the rest of the day, and that while this varies in different months from 14 to 32 per cent., the most rapid progress occurs in every month during this portion of the day. Prof. Loomis suggests that as this is the time of the day when the temperature is falling most rapidly, the fall of rain may be thereby accelerated, and the velocity of the storms' progress be increased by the more rapid extension of the rain-area which would follow. The meteorological system of the States fortunately furnishes the required data for the examination of this important point, and we shall look forward with great interest to discussions of the daily rainfall of the States in this connection.

It would appear that an unusual extension of the rain-area of a storm is generally accompanied by a velocity of progress greater than the mean. The average extent of the rain-area eastward from the centre of the storm is 542 miles; but when the eastern extent of this area is 100 miles greater than the mean, the hourly velocity of the storm's progress is increased $13\frac{3}{4}$ miles; and when on the other hand, the eastern extent of the rain-area is 100 miles less than the mean, the hourly velocity of progress is diminished $9\frac{1}{2}$ miles. Whilst the extent of the rain-area exercises an important influence on the storm's progress, the inclination of its axis would also appear to influence to some extent the course of the storm. Professor Loomis is of opinion that the direction and velocity of the storm's progress may be predicted with some confidence, in cases when the precise limits of the rain-area are known. It is thus most desirable that rain observations form an integrant part of all weather telegrams.

The influence of areas of high barometer on the velocity and direction of a storm's course is important in connection with the prediction and theory of storms, but further observations are required for its elucidation, among the more important of which are the movements of the upper currents of the atmosphere as disclosed by observations of the cirrus cloud.

The reports of General Myer, Chief Signal Officer, for 1872-73-74 show by the barometric results for Denver and the other elevated stations on the spurs of the Rocky Mountains, that the relative distribution of atmospheric pressure at these great heights is just the reverse in summer and winter of what obtains at lower levels to eastward in these respective seasons. The point is a vitally important one in its bearings on the weather and meteorology of the States. In connection with it, we have examined with much interest the tables at pp. 10 and 11 which give the number of times during 1873 and 1874 on which the daily change of temperature amounted at the different stations to 40° and upwards. This large temperature fluctuation occurs most frequently at Colorado Springs, Denver, and the other high stations in the west. The most remarkable of these changes occured at Denver on the 14th of January 1875, at which place the temperature was below zero all day, and the wind N.E. At 9 P.M., the temperature was 1°.0 and the wind suddenly shifted to S.W.; at 9.15 P.M., the temperature had risen to 20°.0 at 9.20 P.M. to 27°.0; at 9.30 P.M., to 36°.0; and at 9.35 P.M., to 40°.0, after which there was little change till the following morning. At 11.30 A.M. of the 15th, the temperature was 52°.0 and at this time the wind suddenly backed to N.E.; at 12.30 P.M., the temperature had fallen to 4°.0 Thus in the evening of the 14th, the temperature rose 39°.0 at Denver in the short space of 35 minutes, and about noon of the following day fell 48°.0 in one hour.

* Results derived from an examination of the United States Weather Maps for 1872-73-74. By Prof. Elias Loomis, Yale College. From the *American Journal of Science and Arts*, vol. x., July 1875.

ON THE HORIZONTAL PHOTOGRAPHIC TELESCOPE OF LONG FOCUS *

IN what I have now to say in regard to the methods of Photography employed in observing the recent Transit of Venus, I shall confine myself to the subject of

* This paper was read by the late Prof. Wenlock to a private scientific Club in Cambridge, U.S., shortly before his death; it has been forwarded to us for publication, at the request of the Club, by Prof. Asa Gray.

the instruments used, having especially in view the explanation of the advantages of the horizontal telescope and its origin.

I should not have thought it worth while to make any communication on this subject, but since it has been a matter of discussion in the French Academy, and several pamphlets have been written on the subject, it may not be uninteresting to explain here the connection of the Observatory of Harvard College with it.

In the spring of 1869, when it became necessary to begin preparations for observations of the Solar Eclipse of August 7th of that year, my attention was called especially to the subject of Solar Photography for the first time. Mr. Warren De La Rue in England, and Mr. Rutherford in America, had devoted themselves almost exclusively to astronomical photography for many years, and they were the authorities on this subject. The methods employed by them were substantially the same; each used an equatorial telescope with clock movement, and enlarged the image formed by the object-glass by means of another system of lenses, and photographed this magnified image. Mr. De La Rue corrected his object-glass to secure as nearly as possible the foci of chemical and visual rays, and Mr. Rutherford corrected his so as to obtain the best echromatic combination of the chemical rays without regard to the visual focus.

Mr. De La Rue first undertook a series of daily photographs of the sun at Kew some time previous to 1860. In making my own preparations for the Solar Eclipse of 1869, I collected what information I could about the extent and brightness of the corona, and the nature of Mr. De La Rue's photoheliograph which he employed in observing the total eclipse of 1860 in Spain. In the first part of the volume of the "Philosophical Transactions" for 1869, I found a paper which was read May 31, 1868, which contains the results of the first attempt to measure the heliographical positions and areas of sun-spots observed with the Kew photoheliograph. From the examinations of the measurements in this paper I became convinced that no trustworthy measures of photographs taken in this way could be made. The magnified image is so much distorted by the eyepiece, or the equivalent system of lenses used to form the image in the camera, that no satisfactory scale could be obtained; in fact the scale was found to vary irregularly from the centre to the circumference of the image; and even if this irregular scale could be investigated, a slight displacement of the centre of the picture from the axis of the telescope would introduce confusion. Mr. De La Rue's method of investigation consisted in photographing the pinnacle of a pagoda which was composed of rings and chains of known dimensions, and then attempting to find the scales of the different parts of the pictures from the images of this pinnacle.

The result, as I have said, satisfied me that this was a method to be avoided. The difficulty arising from the distortion of the image, and the apprehension that the light of the corona might be so enfeebled by enlargement that it would not make an impression on the plate, determined me to photograph the image in the principal focus of the object-glass.

All of the many other parties fitted out for photographing the total phase of this eclipse followed the method of De la Rue and Rutherford; the expedition from the Observatory of Harvard College was the only one that succeeded in getting a picture of the corona. The method of De la Rue was employed in the preceding eclipse of 1868, and no photograph of the corona was secured. I mention these facts simply to show how little the disadvantages of enlarging the image by an eye-piece were appreciated. In the next eclipse no party went into the field with De la Rue's plan; every one of them photographed in the principal focus, but this time, on account of the weather, the American party in Spain alone succeeded in getting the corona.

In 1871, in India, this method was again followed by all the parties, and was successful. My preparatory experiments in 1869 were made with an equatorial of 7 feet focal length, which gave an image of about three-fourths of an inch, and with the great equatorial of 24 feet, which gave an image of $2\frac{1}{2}$ inches diameter.

Measurements of photographs of the smaller image seemed to indicate that under a microscope an accuracy comparable with that of the best meridian circles was attainable; but believing that a larger image would be better, I thought that four inches would be a convenient size. In order to get such an image free from the distortion of the eye-piece, I must have a telescope 40 feet in length. Immediately on my return from the eclipse of 1869, I ordered a lens of Messrs. Clark and Sons, of 40 feet focus, and a micrometer capable of measuring conveniently an image of four inches diameter. Thus the long telescope was adopted to escape the distortion.

Then of course the difficulty of mounting and handling a telescope of this length, especially when extreme precision in measuring was the main object, naturally presented itself. To obviate this I resorted to the very simple expedient of placing the telescope horizontally, so that it need not be moved at all, and reflecting the light of the sun through it by means of a plane mirror. This seemed likely to meet all of the difficulties of the case; the well-known methods of mounting and directing collimators rendered the utmost degree of accuracy attainable in directing such a telescope, and by putting the object-glass on one pier and the camera on another, using a tube which should touch neither, only for excluding the light, all disturbance of the focus by the expansion of the long tube was avoided.

Other information obtained by my preparatory experiments had an important bearing upon my plan at this time. I had found how difficult it was to get an exposure of the plate short enough. It became necessary to reduce the apertures of the equatorials to one or two inches, and then throw the slide across with a strong spring. From this I derived two important suggestions: one, that a heliostat driven by clockwork was not indispensable, as the picture would be instantaneous, so that the motion of the sun during the exposure would be of no consequence. The other was that I might reduce the light by using a transparent glass reflector, and not be compelled to reduce the aperture of the telescope so much. By these means the cost of the experiment was greatly reduced, saving the expense both of a heliostat and of a silvered mirror. Messrs. Clark and Sons did not get the apparatus ready for use at the Observatory until July 1870, although it was tried at their shop previously. A series of daily photographs was begun with it, July 4, 1870, and has been kept up with little interruption to the present time.

At this time and for a year or two after, I had not heard of this method being thought of by any one. No one of my acquaintances seemed to have any knowledge of any other claimant of the method. Mr. Rutherford, with whom I had frequent communication, and who had been occupied with the subject for twenty years, regarded it as new and original. It was described in Mr. Lockyer's paper in 1870, and attributed to me; Mr. Newcomb, in the latter part of 1872, speaks of it as a method devised by me, and in successful operation for several years, and also independently proposed by Faye. Lord Lindsay adopted it for his expedition to the Mauritius. Mr. De La Rue in several communications down to 1873 spoke of it as the method of the American Astronomers. It was afterwards, about this time, called the method invented by Foucault and Prof. Winlock independently. Then, in 1873, I received a book by M. Edmond Dubois, claiming it as a French

invention, and giving the whole credit to Capt. Laussedat, closing with the remark that if it should be successful the glory would belong to France. Afterwards I received a pamphlet of twenty-six pages, by Capt. Laussedat, in which, ignoring me entirely, he tried to sustain his claims against those of Faye, Foucault, and Fizeau.

In 1873, after the horizontal telescope had been in successful operation for three years, after specimens, both negatives and lithographic copies had been distributed in Europe, the French Commission, which had up to this time been making their preparations to use the method of de La Rue, adopted the horizontal telescope. It would appear from this, that whatever might have been done or said on this subject by the Frenchmen named above, it had not contributed much to a clear appreciation of the advantages of the method until after they had been demonstrated here.

Without caring anything about credit for priority of suggestion in such matters, being satisfied that no similar instrument was in use or had been used before the one at Harvard College, I was yet interested enough in the matter to look up the claims put forth by these gentlemen, and to see why they happened to be overlooked for so long a time, even by their own countrymen. I find that credit is accorded to Foucault, mainly for his perfection of the heliostat, both for the plane mirror and for the uniform motion. He published nothing in regard to its application to photography. After his death his friend, St. Claire Deville, spoke of it as one of the things that Foucault intended to do. He at the same time contemplated the use of the siderostat in all kinds of astronomical observations. M. Laussedat is unwilling to give him any share of credit for the horizontal telescope. M. Faye gives him credit only for the heliostat.

M. Faye himself took some photographs of the sun with a very long telescope of one M. Porro, of 15 meters focal length. The telescope was pointed directly at the sun. M. Faye's remarks on them before the Academy related only to the advantage of their size and their distinctness. He had nothing to say about the peculiar advantages of the long telescope, but he anticipated all succeeding inventions in the application of Photography to astronomy by predicting its early use in meridian and every other class of observations.

His next communication on this subject was on March 14, 1870, on the occasion of presenting a letter from M. Laussedat on the subject of a horizontal telescope. This was six months after my apparatus was ordered, and after some experiments had been made with it. In this communication he appears at first glance to have suggested the whole arrangement now adopted; but on closer examination he does not seem to have had any clear ideas about it. He recommends the use of a long telescope because he had seen good pictures with a long telescope; he nowhere speaks of his reasons for dispensing with the eyepiece, and in fact it does not clearly appear that he did dispense with it. In September, 1872, after it had been in use for two years and several accounts of it had been published, in his comments before the Academy on a paper of Warren De la Rue's, he seems to have understood for the first time the true theory of the long horizontal telescope.

Capt. Laussedat appears to have the most substantial claim of any that have been mentioned thus far. He used a horizontal telescope in Algeria in 1860, in observing the total eclipse of that year; but he used a very short telescope and had an eyepiece to enlarge and distort the image. His own account of what led him to this method was that he had no equatorial mounting for his little telescope and that no means were furnished him to buy one, but he had a good heliostat, and he resorted to the method as a makeshift. He fully appreciated, however, the advantages over the other method in the accuracy of orientation and in the certainty with which fixed lines of reference could be had on the plates.

M. Faye, in his communication of Sept. 1872, seriously claims that his use of the long telescope pointed to the sun in 1858—because M. Porro happened to have one, and Capt. Laussedat's use of a short one, placed horizontal, because he had no equatorial stand and clock movement—together make up the invention of the telescope as it is now used.

But, after all that has been said about the priority of suggestion, that question is settled finally by some one * in England finding that the wole arrangement was suggested by Hooke in 1676. A late communication on the subject in the *New York Times* calls it a method suggested by Hooke and perfected by Foucault.

In Hooke's day they had none but very long telescopes, but they had no heliostats. No practical application of his suggestion, however, seems to have been made.

* A correspondent in NATURE.—ED.

ON THE CARDIOGRAPH TRACE

BY placing the sphygmograph, as constructed by M. Marey, over that portion of the chest where the heart can be best felt beating, instead of on the wrist-pulse for which the instrument is constructed, tracings called cardiograms can be obtained which bring to light physiological facts not otherwise ascertainable. In the last-published volume of the Guy's Hospital Reports there is a paper by Dr. Galabin, on the interpretation of these tracings, which will be read with interest by physiologists on account of the considerable difficulty there is connected with all attempts to explain the numerous ups and downs which they present between any two pulsations of the heart, and also because of the comparatively slight attention which they have had paid to them.

Dr. Galabin, in the paper under consideration, limits his observations almost entirely to the vertical variations in the curves under consideration, paying but little attention to the differences in the relative lengths of systole and diastole which they so clearly indicate, and which cannot be recognised with any degree of accuracy by any other means at our disposal. From a study of the cardiograph trace, he is led to the conclusion that the two most important elevations in the systolic portion of each curve are produced by the muscular movements in the heart itself, because "the more the heart is hypertrophied (by disease) the more prominent in comparison do these two become," and under these circumstances, "the effect of any oscillations, either of the blood or of any solid structures, would become less noticeable in proportion." It is remarked that "Marey's figures (of tracings indicating intracardial pressures) prove that the first, at any rate, of the cardiac impulse is not due to any stroke against the ribs caused by locomotion of the heart as a whole, which could only commence after the opening of the semilunar valves," because "the aortic valves do not open until the ventricular pressure has nearly reached its first maximum." It must, however, be noted that other tracings, obtained by the same illustrious physiologist, demonstrate equally clearly that the maximum of intracardial pressure is reached some appreciable time before the first major systolic cardiograph rise in the trace from the chest-wall, so that it may still be reasonably argued that the rise referred to depends upon the locomotion of the heart *en masse*.

To explain the second main systolic rise, Dr. Galabin makes a statement which needs considerably more demonstration before it can be considered to be proved. He refers to "inverted tracings," by which are understood curves in which all the rises in an ordinary trace are represented by depressions, in such a way that "to see more clearly their correspondence with positive tracings

they should be turned upside down and read from right to left," instead of from left to right. Are we to believe, on the simple dictum of Dr. Galabin that *inverted tracings*, as above explained, are developed; that every elevation in the apex cardiograph trace is the result of a movement which is represented by a fairly proportionate fall in a trace a little distance from that spot; that every apical propulsion is a lateral suction? This may possibly be the case, but it requires a considerable amount of proof before it can be accepted as true. The relative duration, or, in other words, the horizontal projections of the different undulations, is not in favour of the assumption, which seems to be based on an accidental similarity between that apex trace and the reversed one from its neighbourhood. Till Dr. Galabin introduced his view, it has been assumed that the negative trace differs from the other positive trace in the fact that in the latter some of the undulations are longer in the up than in the down stroke; whilst in the former the reverse is the case. There is need for positive disproof of this explanation before the other is even considered.

Dr. Galabin concludes that the second main systolic rise "corresponds in time to the maximum contraction of the ventricle," and that it is due to the locomotion of the heart, dependent on the consequent injection of the aorta and the propulsion of the blood. This explanation might be tenable were it not for the results obtained by the employment of the hæmodromometer of Chauveau, tracings taken with which can be found in Marey's "Circulation du Sang" (p. 273). These show that there is a regurgitant current in the carotid arteries for some appreciable period *before* the closure of the aortic valve, which can only exist in connection with a similar one in the ventricular cavity. It is the hæmodromometer trace which has led the writer of this article to lay more than usual stress on the interval between the termination of the cardiac systole and the moment of closure of the aortic valves, termed by him the diaspasis.

Dr. Galabin remarks, "Mr. Garrod attributes the elevation d (the first main systolic rise), solely to the locomotion of the heart caused by the lengthening of the aorta. The rise f (the second main rise) he considers to intervene between the end of systole and the closure of the aortic valves, and to be due to the initial relaxation of the ventricle. It appears to be impossible that the relaxation of the ventricle, apart from its repletion, could produce an elevation in the curve except in those cases in which its hardening produces a depression either at the commencement or towards the conclusion of systole." In the explanation here referred to the elevation under consideration is, however, not supposed to be the result of the relaxation of the muscular walls of the ventricles, or to have anything to do with that phenomenon, but to be caused by the reflux of blood from the aorta and pulmonary artery into the ventricles which, when it has attained a sufficient velocity, closes the semilunar valves.

Dr. Galabin, by employing the stethoscope in conjunction with the cardiograph, watching the development of the trace whilst listening to the heart-sounds, has been able to satisfactorily verify the observation that the first sound occurs during the primary up-stroke, and that the instant at which the second sound is heard corresponds to a point on the principal down-stroke, and before the succeeding small and constant rise. This is further verified by the superposition of the sphygmograph trace on the cardiograph trace taken at the same time, a method which has elsewhere been shown to lead to particularly important theoretical results.

No particular stress is laid by Dr. Galabin on the peculiarities of the cardiograph trace associated with different rapidity of pulse and nothing else. The thorough study of the subject necessitates this point being taken into consideration, as is demonstrated by the great differences there are always found in the curves derived from the same individual when the heart beats at say 45 and 125 a minute.

Most of the paper under consideration is devoted to pathological points, especially mitral stenosis or contraction. With this we cannot here deal. One particularly interesting tracing proves that in some extremely slow pulses (*e.g.* twenty-five a minute) there may be an abortive attempt towards an intermediate contraction, perceptible in the cardiograph tracing, but not seen in that from the arterial pulse.

Whilst on this subject it may be mentioned that Dr. C. Hanfield Jones has recently read a paper before the Royal Society on reversed sphygmograph tracings, or tracings in which the systole is represented by a fall instead of a rise. These he explains on the assumption that they are produced by the brass end-pad of Dr. Sanderson's modified instrument resting on the artery instead of the spring-pad. This is no doubt the true cause in many cases; these tracings are, however, in our experience sometimes produced when Marey's unmodified instrument is employed. They may sometimes result from the fact that a curved artery is, during systole, rendered part of a larger curve, and so slips from under the spring-pad at that time.

A. H. GARROD

SIR JAMES KAY-SHUTTLEWORTH ON SCIENTIFIC TRAINING

ON the occasion of presenting the prizes to the successful students at the Giggleswick Grammar School, near Settle, on July 28, Sir J. Kay-Shuttleworth made some forcible remarks on the above subject. Sir James points out with so much wisdom the relative position which science and literature ought to hold in the training of youth, that his remarks deserve the serious attention of all interested in education. Our columns constantly bear witness to the increasing prominence given to science in education, both at the higher schools and universities. Sir James, after noticing this and other features in the progress of the Giggleswick School, and referring to some of the results of the training of the school, went on to say:—

"You will perceive that among them are proofs of the influence of the practical teaching in natural science in opening a career to our pupils in the universities. In the growth of any institution on a new basis, time must be allowed for its development. Difficulties will be encountered in discipline, in domestic management, and in the attainment of the ideal to which its course of studies is expected to rise. Yet it is well to keep that ideal closely in view as the goal of all efforts; to retain a firm hold on the principles of action, and while confessing the length and the arduous character of the way, to press forward, undismayed by any partial failure, towards the summit of our hopes. I find in the examination papers a continually higher standard. They embrace a wide range of studies. But it must not be supposed that we are so presumptuous as to expect that even the *élite* of the school could attain a high degree in the whole range of these studies. No error could be more fatal than that they should be obligatory on all our pupils. Indeed, we must, in the first place, point out that in consideration of the prominence given to modern languages and to practical instruction in natural science, Greek is not among the subjects comprised in the scheme of the school, though it will be taught to all boys preparing for the universities, or for any of the public examinations. To determine how best the faculties of those not gifted with average energy and capacity can be developed requires a delicate and thoughtful discrimination. But the curriculum is open to boys in proportion to the mental and physical vigour which they bring to the task. I have said that Greek is not one of the subjects of instruction made obligatory by the scheme, and the reasons for this will become more apparent as I proceed, but among these reasons is

no want of appreciation of the ancient classical literature, or of the classical languages as means of mental culture. It may, therefore, be desirable to say that we appreciate the treasures bequeathed to us by them in philosophy, poetry, history, and art, and in the principles of jurisprudence." After speaking in high terms of the value of the classical languages as pedagogical instruments, Sir James went on :—

"But while we thus emphatically express our sense of the value of the classical languages as instruments of mental training and sources of the highest literary culture, the curriculum of this school includes pure and applied mathematics. These studies, which stretch back to the period of Greek civilisation, have grown with the development of astronomical and physical research. They are the instruments of the abstract investigation of physical laws. But we have also sought to place the school practically in relation with natural science. The question has been much discussed whether science should be thus taught through the whole school course, or whether it should be interstratified with the other studies. We shall endeavour to solve these questions by introducing in the junior forms the cultivation of the faculties of observation by the practical study of botany and physical geography, for both of which this neighbourhood affords considerable opportunities. For somewhat more advanced students we have built a good chemical laboratory, and we are about to extend this building so as to provide separate rooms and apparatus, and for the practical study of experimental physics. The thorough knowledge of any branch of experimental science involves an acquaintance with the instruments and modes of investigation, as well as skill in manipulation. These are not to be acquired from books. It is indispensable that pupils should become familiar with the phenomena of the operation of natural forces. They must learn to observe, to practise the philosophy of induction by following the footsteps of the great masters of research in preparation for independent efforts. The faculties exercised in such pursuits are not altogether the same as those employed in literary studies. They may be compared without the depreciation of either. The student of literature has opportunities to cultivate what is metaphysical—whatever relates to art, to poetry, to history, philosophy, or language; while the student of nature may more successfully develop the faculties of observation and those brought into play in the processes of inductive and deductive reasoning. The search for hidden truths trains the ripe student in habits of scrupulous exactitude. To record such observations is an exercise in accuracy of thought and language.

"The scientific habit of mind which is the result of a thorough practical training in one or more branches of science is not to be attained by any devotion to language or literature, just as the development of taste in literature, or of critical skill, or of the power of philological research and discovery cannot be gained in the laboratory. These distinctions between literature and science are in harmony with the diverse capacities of boys, and they may be employed as auxiliaries in the development of boys of limited or one-sided capacity. Some pupils who have low grammatical and linguistic power may yet exhibit facility in mathematical processes. Others in whom both these faculties are feeble, awaken to intellectual life as observers of nature. To some minds the facts and principles of science become easy only when they are in contact with the actual phenomena. Hence one part of the value of practical studies in the field and the laboratory. It may be confidently asserted that when any of these classes of mental power is feeble, the development of that part of the brain which is most easily awakened to activity will communicate vigour to the rest; the whole brain will become more healthy and active. A boy incapable of successful literary effort, but who has power as an observer, may, by that form of mental culture, by-and-by become more capable of literary application and success. Thus the literary, the mathematical, and the practical scientific studies of schools become, in the hands of a thoughtful and skilful master, preparatory or co-ordinate instruments of mental development.

"There has been of late a new era in the development of the natural sciences. This commenced with the discoveries of great mathematicians and astronomers, and extended to every department of physical research. After Kepler and Newton, mathematics in their application to experimental physics and astronomy established themselves, especially at Cambridge, as a prominent part of the studies of the European Universities. But during the present century, the rapid development of every department of natural science has created new claims for the introduction of new courses of study, for which the universities are gradually increasing their means and appliances, and towards the successful cultivation of which they are extending their honours and rewards. What happened at the revival of learning with respect to the classical literature is about to happen in the fuller recognition in the universities of every department of natural science. The Chancellor of the University of Cambridge has recently munificently founded a physical laboratory in that university. Certain of the colleges have established chemical and biological laboratories. The Geological Museum lectures and fieldwork continue to develope. These are preliminary steps towards practical instruction in every department of natural science. At Oxford, the university has built an admirable museum, with which are connected laboratories for chemical and biological studies, and for those of experimental physics and geology. Certain of the colleges have also laboratories, and readers or demonstrators of practical science. The Commission on Scientific Instruction, which has just closed its five years' labours, has made many suggestions as to the facilities to be granted to students of natural science in both universities. For example, it recommends the freer admission of those who are successful to the honours of the university, as well as to the scholarships, fellowships, and government of the colleges. The Commission had such opportunities of ascertaining to what extent these recommendations expressed the opinions of the governing minds of the universities, that there can be no doubt that no insurmountable obstacle will be encountered in the establishment of studies in natural science in a position, in relation to their honours and rewards, which will duly represent the part which science has to play in the education of the country.

"The methods and results of natural science have now so far affected all our modes of thought that they claim their place in the arena of all forms of discussion. They must, therefore, also take their place in the studies of the public and grammar schools, and of the colleges and universities which would fitly train men for the work of life. It would be a grave disadvantage to this nation if its rulers in Parliament and in the Cabinet should represent chiefly literary culture, without a familiarity with the physical sciences. Such a result could not now long exist without a neglect of opportunities of promoting scientific culture and research, which would be injurious to the education of the country and prejudicial to the development of its material resources. Perhaps it would be a much graver misfortune if there should grow up in the country two forms of thought—one derived from the exclusive contemplation of the metaphysical, and the other resulting from purely physical and materialistic studies. Moreover, to a man of education, however ripe and complete may be his classical accomplishments, it must be a great misfortune to have had no training in the natural sciences. He must have a sense of partial development, and of the deprivation of a great source of mental pleasure. These are, doubtless, among the reasons why, in the great public schools, instruction in natura

science has recently been introduced by the appointment of skilled teachers, by the building of laboratories and the establishment of museums, and by the regulations of the commission of public schools as to the time to be allotted to such studies. Among our provincial grammar schools Manchester has provided laboratories and the means of highly skilled scientific instruction. At Burnley, also, laboratories have been built, and the head master, Mr. Hough, is distinguished by his scientific knowledge and practical skill. He, doubtless, will diligently employ the means at his command. The Commission on Scientific Instruction has carefully collected the experience of the schools which have introduced practical scientific teaching. They strongly recommend that such instruction should take its place at the side of that which is literary throughout the whole school course. We had practically anticipated this suggestion at Giggleswick. I do not prominently put forward the adaptation of such studies to the wants of the great manufacturing districts of Yorkshire, Lancashire and Cumberland, which are contiguous to us, or of the Durham and Northumberland coalfield. Yet many of the sons of wealthy men in these districts, as well as of those engaged in scientific professions, will complete their education at school. In these trades and professions the practical commencement of a scientific training is often of great value. As I have already said, it forms the scientific habit of mind; it familiarises the youth with the phenomena of the operation of natural laws, and with the manipulation of instruments. It develops the faculty of observation and the power of inductive and deductive reasoning. Moreover the facts of physical science learned in the laboratory are an invaluable possession to the engineer, the chemist, the miner, the physiologist, and to every professional man who has to use these facts, principles, and processes as a part of his daily occupation. This school is intended to offer, in the first place, a sound preparation in elementary knowledge in the English language, its grammar, composition, and some acquaintance with English history and literature. Within the range of its studies are the ancient classical literature and modern languages. It would fail in its purpose if the humble elements of arithmetic were not faithfully cultivated as the basis of mathematical knowledge and scientific calculation. It is on this broad basis that we wish and hope to rear the structure of a sound and scientific culture.

"The questions which the governors of this school have attempted, through years of patient labour, to solve, are also awaiting solution in all similar schools. What are in future to be the relative positions of the literary and scientific education of our youth? How, as in this school, can the financial resources be developed so as to provide laboratories, and a larger skilled staff of teachers, in order to ensure a sound literary culture, together with scientific instruction? Inseparable from these questions is the formidable one, Whence are the skilled teachers of science, capable of giving practical instruction in laboratories to be provided, if science in this sense is to form part of the curriculum of all schools? Where the income of the school is small, that difficulty is at present insurmountable, for a separate science master cannot be afforded in such schools. Nor will it be removed until some means be devised for the training of teachers by which they will be enabled to add practical skill in scientific instruction to a sound basis of literary culture. Then a single master may fulfil the double function in a school. The commission on scientific instruction points to this, among many other reasons, for the establishment, within the universities and elsewhere, of a system of training for masters of schools above the elementary in the art and practice of teaching, and in a practical knowledge of science. The governors of this school of King Edward the Sixth of Giggleswick have not been negligent of the bearing of their labours on these wide general questions. So far as they have proceeded, they are satisfied that a sound literary culture may not only subsist with practical instruction in science, but that, under earnest and thoughtful guidance, these departments of instruction may each contribute to the intellectual activity and to the success of every form of teaching in the school."

THE INTERNATIONAL GEOGRAPHICAL CONGRESS AND EXHIBITION

THIS Congress, which has been looked forward to with considerable expectation, was opened in the Salle des Etats of the Tuileries, on Sunday last, in presence of the President of the French Republic, many of the dignitaries of State, foreign ambassadors, and other eminent persons. There was a large attendance of the general public, and addresses were given by the President of the Congress, Admiral de la Roncière le Noury, Baron von Richthofen, Sir Henry Rawlinson, and other delegates of the various nations represented at the Congress.

The regular work of the Congress commenced on Monday, and the sittings will be continued till the 11th inst., when a distribution of medals will take place. We believe a few prizes will be awarded to England, but not many, as our country has contributed but scantily to the exhibition. To-day a visit will be made to the Paris Observatory, and to-morrow one to the Historical Museum of National Antiquities (mostly pre-historic) at St. Germain.

Juries have been appointed to decide on the awards in the various sections of the Exhibition, and a notable feature of these is that not a single Frenchman has been appointed a president; this, we believe, is the result of characteristic delicacy on the part of the French authorities. Col. Montgomerie and Major Wilson are the English representatives.

The Exhibition continues to be well attended, and we hope the receipts will be sufficient to reimburse the Committee, who have become responsible for a large sum, the French Government and Geographical Society having contributed a very small amount.

In the English Section the books of photographs illustrating the people of India and China and the Chinese have proved very attractive. The photographs exhibited in the Russian annexe are very numerous, and relate to people of every tribe and condition inhabiting the empire. Austria has also been very successful in this respect, having exhibited photographs and drawings illustrating the chief incidents of the *Tegethoff* Polar Expedition.

A special room has been set apart for the several Alpine clubs, which have been created in imitation of the English Alpine Club. The publications of the parental association, and the scientific and other apparatus used in Alpine climbing by the English, French, and Italian clubs, are exhibited, and are inspected with evident interest.

The French Government exhibits the results of the missions sent out by the Ministry of Public Instruction. These have been numerous and successful. Independently of the Transit of Venus Expedition, we must mention a series of pictures showing the Bay of Santorin, in the several successive stages of creation of the new volcanic island. These illustrate happily how continents come into existence.

The Hall of National Antiquities (Pre-historic) is a compendium of the Saint Germain Museum, which will be visited by the Congress. A number of highly instructive maps, showing the distribution of relics of the Stone Age, Iron Age, &c., have been published, and are exhibited by the Historical Commission on the Gauls, which was created by Napoleon III. while writing his "Life of Cæsar," and will be continued for a lengthened period.

Amongst the real curiosities of the Exhibition, we must mention a microscopic photograph of the French map by the staff. This photograph was executed by M. Dagron,

the inventor of microscopic photographs for carrier pigeons during the war. The 250 maps, covering a space of more than a hundred yards square, are so reduced on glass, that they can be packed in a portfolio weighing half a pound when full, and examined with a small microscope with perfect facility and clearness.

M. Bouvier, a French naturalist, has presented a collection of almost all the known species of *Algæ* collected in the fish market at Paris.

NOTES

THE following are the officers of the forty-fifth meeting of the British Association which will commence at Bristol on Wednesday, August 25, 1875 :—President-elect—Sir John Hawkshaw, F.R.S. Vice-Presidents-elect—The Right Hon. the Earl of Ducie, F.R.S., the Right Hon. Sir Stafford H. Northcote, Bart., F.R.S., the Mayor of Bristol, Major-General Sir Henry C. Rawlinson, F.R.S., Dr. W. B. Carpenter, F.R.S., W. Sanders, F.R.S. General Secretaries—Capt. Douglas Galton, F.R.S., Dr. Michael Foster, F.R.S. Assistant General Secretary—George Griffith, F.C.S. General Treasurer—Prof. A. W. Williamson, F.R.S. Local Secretaries—W. Lant Carpenter, F.C.S., John H. Clarke. Local Treasurer—Proctor Baker. The sections are the following :—Section A : Mathematical and Physical Science. President—Prof. Balfour Stewart, F.R.S. Section B : Chemical Science. President—A. G. Vernon Harcourt, F.R.S. Section C : Geology. President—Dr. T. Wright, F.R.S.E., F.G.S. Section D : Biology. President—P. L. Sclater, F.R.S. Department of Zoology and Botany, Dr. P. L. Sclater, F.R.S. (President), will preside. Department of Anatomy and Physiology. Prof. Cleland, F.R.S. (Vice-President), will preside. Department of Anthropology. Prof. Rolleston, F.R.S. (Vice-President), will preside. Section E : Geography. President—Major-General Strachey, F.R.S. Section F : Economic Science and Statistics. President—James Heywood, F.R.S., Pres. S. S. Section G : Mechanical Science. President—William Froude, F.R.S. The First General Meeting will be held on Wednesday, August 25, at 8 P.M. when Prof. Tyndall, F.R.S., will resign the chair, and Sir John Hawkshaw, C.E., F.R.S., President-elect, will assume the presidency, and deliver an address. On Thursday evening, August 26, at 8 P.M., a *soirée;* on Friday evening, August 27, at 8.30 P.M., a Discourse by W. Spottiswoode, LL.D., F.R.S., on "The Colours of Polarised Light;" on Monday evening, August 30, at 8.30 P.M., a Discourse by F. J. Bramwell, C.E., F.R.S., on "Railway Safety Appliances;" on Tuesday evening, August 31, at 8 P.M., a *soirée*; on Wednesday, September 1, the Concluding General Meeting will be held at 2.30 P.M. A special lecture to working-men will be given by Dr. Carpenter, F.R.S., on the evening of Saturday, Aug. 28; the subject will be "a piece of limestone." The Local Committee have done everything in their power to make the Bristol meeting a success. All the non-local sectional secretaries will be lodged at the Queen's Hotel, close to the reception-room, at the Local Committee's expense; this will no doubt conduce much to the easy working of the meeting. The experiment of a room for the exhibition of specimens and apparatus, tried first last year at Belfast, will be repeated this year. The President will be the guest of the Mayor, who will occupy for the first time the new Mansion House just given to the city by Thos. Proctor, Esq. Most of the other office-holders, as also all the foreign members, who have intimated their intention of being present, and several English members, have received private invitations from gentlemen resident in Bristol and neighbourhood. Many other hospitable arrangements have, we believe, been made, and altogether, so far as enjoyment and comfort are concerned, this promises to be one of the most satisfactory meetings of the Association. As we previously intimated, a specially prepared Guide, compiled by several gentlemen, will be published by Wright and Co., of Bristol; a lodging list with useful map will be issued this week. The whole of the Victoria Rooms, Clifton, will be used as a reception-room. All the evening meetings and *soirées* will take place at the Celston Hall, and satisfactory arrangements have been made for the meetings of sections. Several interesting excursions have been arranged for, including two to the Mendips, and handsome offers of entertainment have been made by those gentlemen to whose neighbourhood the excursions are to be made.

A NEW physical observatory is to be erected at Fontenay, the head of which will be M. Janssen. It will be erected on the very spot where it was intended to build one when it was proposed some years back to remove the Paris Observatory. In a few months, then, Paris will have four observatories—the National, the Physical, and two meteorological observatories—one at Montsouris under M. Marie-Davy, and another which is being built at the Acclimatisation Gardens. It is said that some members of the Municipal Council will propose to connect all these observatories with the National one by a special wire to register automatically all the meteorological observations by the Rysselberghe process, which we noticed last week in connection with the Geographical Exhibition.

THE Smithsonian Institute and the Indian Bureau are engaged in forming for the U.S. Centennial, a collection exhibiting the past and present history of the Aboriginal races of America.

"THE German Abyssinian Company."—A company has been incorporated in Berlin which proposes to found at Choa, the most southern province of Abyssinia, a permanent settlement, in order from thence to send out scientific expeditions into the unexplored portion of Africa, and to develop the commerce of the country. The objects of the Company are, however, supposed to be more commercial than scientific.

THE Khedive has issued a decree ordering the enforcement of the metrical system in Egypt from the 1st of January, 1876.

DR. HAWTREY BENSON, of Dublin, writing to the Dublin *Daily Express* under date July 27, describes a remarkable shower of small pieces of hay which he witnessed at Monkstown that morning. It appeared in the form of "a number of dark flocculent bodies floating slowly down through the air from a great height, appearing as if falling from a very heavy dark cloud, which hung over the house." The pieces of hay picked up were wet, "as if a very heavy dew had been deposited on it. The average weight of the larger flocks was probably not more than one or two ounces, and, from that, all sizes were perceptible down to a simple blade. The air was very calm, with a gentle under-current from S.E.; the clouds were moving in an upper-current from S.S.W." The air was tolerably warm and dry, and the phenomenon is thus accounted for by Dr. J. W. Moore: "The coincidence of a hot sun and two air currents probably caused the development of a whirlwind some distance to the south of Monkstown. By it the hay was raised into the air, to fall, as already described, over Monkstown and the adjoining district."

IN the Paris *Bulletin International* for July 30 last Prof. Raulin of Bordeaux gives the result of an examination of a comparison of the gross amount of the rainfall for the ten years 1851-60 with that for the ten years 1861-70, from which it is shown that, as regards the southern half of France, the rainfall during the former of these decennial periods exceeded that of the latter at forty-six out of the fifty-three stations at which observations were made for the twenty years. A similar distribution of the rainfall during these two decennial periods appears to have taken

place, with few exceptions, over a large area, embracing the British Isles, France, Germany, Italy, Spain, the basin of the Mediterranean, and Algiers. The point is an interesting one, and we hope that meteorologists will inquire how far the rainfall observations of their respective countries agree with the result obtained by Prof. Raulin for the southern half of France.

In the *Journal* of the Scottish Meteorological Society for 1874-5, just published, will be found a long and elaborate paper by Mr. A. Buchan and Dr. Mitchell, on the Influence of Weather on Mortality from different diseases and at different ages; some of the results which have been arrived at will be found in an abstract by Mr. Buchan, which we publish to-day. Other papers in the *Journal* are on proposed portable Iron Barometers, and on a simple form of Anemometer, by Mr. T. Stevenson, C.E.; Meteorological Register at Inveresk for 1874; Table of Observations connected with the periodical return of the Seasons; Additional Rainfall returns for 1874; and Meteorological returns, with notes of the prevailing weather and state of vegetation at the Society's stations for the year; besides reports of the general meetings of the Society held on July 3, 1874, and February 10, 1875.

It is expected that an important meeting of the Council of the Paris Observatory will be held to-day, a member of the Academy having been desired to explain his assertions relating to astronomical observations. The results will very likely be made public.

The recent French inundations have recalled to memory an experiment which was tried twelve years ago before Napoleon III. The design was to manufacture mattresses of cork, so that any one on board a ship or in a house which could be flooded would have in his bed a ready-made raft capable of floating under a weight of more than 1 cwt. for any length of time. Cork is a material so soft that mattresses made of it are not inferior to any other for comfort.

A memorial in marble of Sir John Franklin was uncovered on Saturday by Sir George Back in Westminster Abbey. The monument has been erected by the late Lady Franklin, and contains some appropriate lines by Mr. Tennyson.

The recent attack upon Lieut. Conder's Palestine exploring party occurred near Acre. Lieut. Conder was badly, but not dangerously, wounded.

The election to the vacant Professorship of Medicine in the University of St. Andrews will take place on Sept. 22 next.

The *Shearwater*, which was commissioned by Capt. Nares (now commanding the Arctic Expedition) on July 20, 1871, for surveying service on the Mediterranean Station, arrived at Sheerness on July 23 last. In Saturday's *Times* will be found a brief account of the work done by the ship during her four year's service. During part of the cruise in the Mediterranean Dr. Carpenter was on board to investigate the results of soundings and dredgings. Commander W. J. L. Wharton took command of the ship on Capt. Nares leaving to join the *Challenger*. After having been two years in the Mediterranean the *Shearwater* proceeded to Zanzibar, in order to survey the island and the opposite coast. In February 1874 the ship proceeded to the Cape of Good Hope, leaving Cape Town on July 14 with the Rodriguez Transit party. At Rodriguez the ship was constantly employed on work connected with the Transit, running meridian distances, surveying the island, and assisting the shore party in various ways. After landing the Transit party at Mauritius, the *Shearwater* again proceeded to Zanzibar to continue surveying work, officers and men, however, suffering greatly from fever. Zanzibar was left on May 8, and the *Shearwater* reached England as we have said on July 23 last. During the four years the ship has been in commission, she has surveyed in detail 790 miles of coast line and sounded closely over an area of 5,900 square miles. Most of the earlier surveys have been published.

In the new part for May 1875 of Hoffmann's *Niederländisches Archiv für Zoologie* there are two papers of interest—one by Dr. A. A. W. Hubrecht, on the Nemertines of the Gulf of Naples, the other by Prof. P. Harting, on the eggs of Cyanea-Otoliths of Cyanea, and Chrysaora-nerve ring and organs of sense of Eucope-Chromatophores of the embryonic Loligo; being notes made during a stay at Scheveningue.

The following candidates have been successful in the competition for the Whitworth Scholarships, 1875:—Joseph Harrison, 21, Mechanical Engineer; George Goodwin, 20, Mechanical Engineer; John Alldred, 21, Locomotive Engine Fitter; Franklin Garside, 20, Pattern Maker; Frank W. Dick, 21, Mechanical Engineer; Joseph Poole, 20, Fitter and Turner.

The forty-third meeting of the British Medical Association opened on Tuesday in Edinburgh. Sir Robert Christison, the President, in his inaugural address, treated of the subject of Medical Education, entering into a complete history of the Medical School of Edinburgh.

The twelfth number of Mr. Hermann Strecker's quarto work upon indigenous and exotic lepidoptera has lately been published by him at Reading, Pennsylvania, and contains, as usual, one plate filled with figures of butterflies. Among them are several very conspicuous forms, the most prominent being that called by him *Eudamonia Jehovah*, a term to which very serions objection has been raised on account of its apparent irreverence, but which he stoutly defends. Several new species are described; one of them being figured under the name of *Hepiolus thule*.

The Report of the Agri-Horticultural Society of Madras, for 1874, shows that the Society is effecting much substantial benefit in its district, especially in the assistance and encouragement it offers in the introduction and cultivation of useful plants, that will thrive in the different climatal regions of Southern India, European vegetables, fibre-producing plants, coffee, tea, tobacco, indigo, &c. The cultivation and preparation of tea is strongly encouraged, and substantial prizes awarded for the best sample of different sorts. Some of the samples submitted to the brokers at Calcutta for their judgment are described as being of superior quality. A flower, fruit, and vegetable show is held annually, and it is worthy of note that all the prizes for ferns and other plants with ornamental foliage were gained by native gentlemen. There was last year a special class for the vegetable productions of native market gardeners, and the European vegetables exhibited are reported to have been of fair quality. The "list of new plants introduced in 1874" is remarkable for the very small proportion of correctly spelt names.

In reference to Tidal Mills (vol. xii., p. 212), a correspondent writes that they have engaged the attention of Gregory, Barlow, Belidor, and Aldini, as will be seen on turning to the article on Tidal Mills in the "Penny Cyclopædia."

The additions to the Zoological Society's Gardens during the past week include a Punjaub Wild Sheep (*Ovis cycloceros*) from Muscat, presented by Commander Yarforth; a Ruffed Lemur (*Lemur varius*), a Mongoose Lemur (*Lemur mongoz*) from Madagascar, two Rheas (*Rhea americana*), a West Indian Rail (*Aramides cayennensis*) from S. America, a Golden-naped Amazon (*Chrysotis auripalliata*) from Central America, two Yarrell's Curassows (*Crax carunculata*) from S.E. Brazil, two Razor-billed Curassows (*Mitua tuberosa*) from Guiana, deposited; a Short-tailed Muntjac (*Cervulus micrurus*), a Crested Pigeon (*Ocyphaps lophotes*), five Amherst Pheasants (*Thaumalea amherstiæ*), and six Japanese Pheasants (*Phasianus versicolor*), bred in the Gardens.

*THE MORTALITY OF THE LARGE TOWNS OF THE BRITISH ISLANDS IN RELATION TO WEATHER**

THE materials for this inquiry have been obtained from the Weekly Reports of the Registrars'-General for England and Scotland for the ten years, 1865–74. The data discussed embrace returns of deaths from all causes and at all ages, deaths of persons under one year of age, of persons above sixty years of age, and deaths from diarrhœa. The weekly averages have been calculated on the annual rate of mortality per 1,000 of the population.

The results for every one of the large towns show during the winter months an excess above the average mortality. A regards the English towns, that excess is greatest at Norwich, Wolverhampton, and Nottingham, and least at Bradford, Leeds, Salford, and most other towns in the north. In Scotland the winter excess is greatest at Aberdeen, and least at Leith and Greenock. At Dublin, the largest monthly mortality, 22 per cent. above the weekly average, occurs during February and March, being from a month to six weeks later than the time of the maximum of the English and Scottish towns.

In all the English towns, the minimum mortality of the year is in the spring months, the amounts below the averages of each town being greatest at Norwich, Wolverhampton, Birmingham, Leicester, and Nottingham. In Scotland, on the other hand,

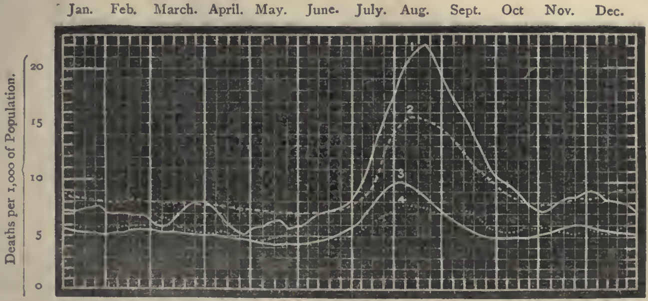


FIG. 1.—Showing the Weekly Deaths among Infants under one year of age on the Annual Mortality per 1,000 of the whole population. For Leicester, Curve 1; Liverpool, 2; London, 3; and Bristol, 4.

autumn is the healthiest season. In Glasgow and Edinburgh the deaths fall about 20 per cent. below the average in the month of September.

It is, however, to the summer death-rate that the greatest nterest attaches, since it is during the hottest weeks of the year that the differences in the rates of mortality of the different British towns stand most prominently out. During the period of high temperature in summer, *every one of the large towns of England shows an excess of deaths above the average*, with the single exception of Bristol, at which place, while there occurs an increased mortality at this season, it only comes near to, but never quite reaches, the average. As regards the time of absolute maximum, it occurs in London in the end of July, but at other places more generally about the beginning and middle of August. Taking any two consecutive weeks which indicate the highest mortality, the excess per cent. above the average is for Wolverhampton, 6; Manchester, 8; Portsmouth, 12; London, 14; Hull, 20; and Leicester, 47. The excess above the average at Leicester being thus eight times greater than that of Wolverhampton.

In Scotland no town exceeds its average during the hottest weeks of the year, but on the contrary the death-rate everywhere is under the average, and in most cases very considerably so. At Aberdeen the rate below the average is 18 per cent. during each of the months, July, August, and September; and at Dublin the annual minimum occurs in July, when the death-rate falls 25 per cent. below the average during the second and third

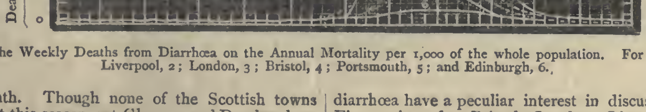

FIG. 2.—Showing the Weekly Deaths from Diarrhœa on the Annual Mortality per 1,000 of the whole population. For Leicester, Curve 1; Liverpool, 2; London, 3; Bristol, 4; Portsmouth, 5; and Edinburgh, 6.

weeks of that month. Though none of the Scottish towns exceed the average at this season, yet Glasgow and Dundee show a decidedly increased mortality, their curves though rising towards never quite reach the average.

In a paper on the mortality of London by Dr. Arthur Mitchell and myself, it has been shown that if the deaths of children under one year of age be deducted from the total mortality, the summer excess disappears from the curve; and it is further showni that, if deaths from diarrhœa be deducted from the whole mortality, the summer excess disappears equally as in the former case. Now, these results hold good for every one of the large towns for which the required data have been published. It follows, therefore, that curves of the death-rate for infants and diarrhœa have a peculiar interest in discussions of this nature. Fig. 1 gives for Bristol, London, Liverpool, and Leicester curves representing the average weekly mortality among children under one year of age, calculated on the annual mortality of 1,000 of the whole population, the averages being dealt with after Mr. Bloxam's method, according to which each average is calculated so as to include that of the week immediately preceding and that of the week immediately following.

Of all the large towns of England, Bristol has the least summer excess of infant mortality, the highest average of any week being only at the rate of eight calculated on an annual mortality of 1,000 of the whole population. In London, the rate rises to ten in the end of July and beginning of August; and in Liverpool it rises to sixteen, a rate which is also reached by the deaths in Leeds, Hull, and Sheffield, and closely approached by a number

* The substance of this paper was read at the general meeting of the Scottish Meteorological Society, held at Edinburgh on July 13, 1875.

of the other English towns. At Leicester, however, it shoots up to twenty-two, and twenty-four on the second and third weeks of August. As regards the whole year, the lowest averages of infant mortality are—Portsmouth, 4·9; London, 5·7; and Bristol, 5·9: and the highest, Leeds, 8·4; Liverpool, 9·1; and Leicester, 9·4. The season of minimum infant mortality is everywhere during the spring months in the sixteen large towns of England. The smallest spring mortality occurs at Portsmouth, the smallest summer mortality at Bristol, the largest summer mortality at Leicester, and the largest mortality during the other nine months of the year at Liverpool.

Fig. 2 shows the distribution of the mortality from diarrhœa through the weeks of the year, in six large towns, the curves being constructed similarly to, and on the same scale as, those of Fig. 1.

The differences in the rates of mortality from diarrhœa indicated by these curves, which are strictly comparable *inter se*, are very great, and a comparison of the two extremes, Leicester and Edinburgh, is startling; the figures showing that for every one who dies from diarrhœa in Edinburgh during the summer months, eight die in Leicester from the same disease in proportion to the population.

From the beginning of November to the summer solstice, the mortality from diarrhœa is everywhere small, being double, however, in Liverpool and Manchester as compared with London and Portsmouth. It will be observed from Fig. 2 that the curves begin to open out and diverge from each other in the end of June. The curve for Edinburgh on no week reaches the annual rate of 2 per 1,000 of the population. The highest for any week are—Bristol, 3·6; Portsmouth, 3·9; London, 5·5; Liverpool, 10·5; and Leicester, 15·8, these two last places again standing higher than any other of the towns.

The following is a list of all the large towns of Great Britain, arranged in the order of the greater or less prevalence of fatal cases of diarrhœa, during July, August, and September, the figures being the average weekly death-rate for the thirteen weeks, calculated on the annual mortality per 1,000 of the population:—*In England:* Leicester, 9·56; Salford, 7·15; Leeds, 7·02; Manchester, 7·00; Liverpool, 6·28; Sheffield, 6·20; Birmingham, 5·78; Hull, 5·56; Nottingham, 5·36; Norwich, 5·02; Newcastle, 4·61; Bradford, 4·42; Wolverhampton, 4·03; Sunderland, 3·89; London, 3·45; Portsmouth, 2·94; and Bristol, 2·38; and *in Scotland:* Dundee, 2·14; Glasgow, 1·90; Greenock, 1·75; Paisley, 1·71; Leith, 1·45; Edinburgh, 1·23; Perth, 1·08; and Aberdeen, 0·96.

From these results it will be seen that the influence of climate is unmistakable. The summer temperature of the Scottish large towns is several degrees lower than that of the English towns, and we see that every one of the Scottish towns has a mortality from diarrhœa lower than the lowest mortality of any one of the English towns. Of all the large towns of Great Britain the lowest death-rate from diarrhœa is that of Aberdeen, which is at the same time characterised by the lowest summer temperature. Further, the diarrhœa mortality of each town is found from year to year to rise proportionally with the increase of temperature, *but the rate of increase differs very greatly in different towns.* This points to other causes than mere weather, or the relative temperature and humidity of the place, as determining the absolute mortality. Thus the summer temperature of Dundee and Perth is nearly the same, and that of Glasgow and Edinburgh is also nearly alike, the excess being rather in favour of Perth and Edinburgh; and yet the diarrhœa mortality of these two towns is respectively less than that of Dundee and Glasgow. It may therefore be assumed that there is something in the topographical, social, or sanitary conditions of Dundee and Glasgow, which intensifies the evil effects of hot weather on the health of the people, so as to swell, for instance, the death-rate from diarrhœa at Dundee to double that of Perth. At Leicester the summer temperature does not exceed that of Bristol; but while the summer death-rate from diarrhœa at Bristol is 2·38, at Leicester it is 9·56; in other words, it may be assumed that there are local peculiarities affecting the population of Leicester, the effect of which is to quadruple the death-rate from diarrhœa in that town as compared with Bristol. It is to these local conditions we must look for an explanation of the great differences in the death-rate of the different towns. The highest average death-rate per annum for the period under discussion is Liverpool 30·6, Glasgow 30·5, Manchester 30·2, Greenock 39·3, and Paisley 29·0; and the lowest is Portsmouth 20·6, London 23·0, and Aberdeen 23·3. Thus, for every two who die at Portsmouth, three die at Liverpool, Glasgow, and Manchester.

These facts suggest large inquiries which call for instant and serious attention. As one of the first steps of the inquiry, it is most desirable to know exactly from a weekly registration of the facts, whether the infant mortality is equally distributed among all infants, however nursed, or whether it may not rather be distributed among them in very unequal proportion, according to the manner in which they are fed. Those, for instance nursed at the breast may be much less liable to succumb to diarrhœa in summer than those fed on cow's milk or those fed on slops. The unusually low temperature of December last very largely increased the death-rate everywhere in the British Islands, particularly from diseases of the respiratory organs and from many diseases connected with the nervous system and the skin. The gross number of deaths registered in the different large towns showed that the excess of deaths thereby caused was very unequally distributed over the country. If there had been a more complete system of registration, for all the large towns, it might have been possible, reasoning from the specific diseases which proved to be unusually fatal at each place, to lay the finger on those local conditions, inimical to health, to which the high rate of mortality in each case was due. During the cold months of the year—December, January, and February—the mortality among females is very considerably in excess of that among males in London; for while during these thirteen weeks the average death-rate among males rises 7·8 per cent. above the weekly average of the year, the death-rate among females rises to 11·2 per cent. above the average. Since the facts of mortality for sex are only registered for all causes and all ages, it is impossible to say from the present system of registration how much of the excess of mortality among females in winter is due to sex, and how much to occupation, or even to fashion.

A comparison of the meteorological with the mortality records shows in an impressive manner the influence of particular types of weather in largely increasing or diminishing the number of deaths from particular complaints. Thus, periods of unusual cold combined with dampness in the end of autumn, cold with drought in spring, cold in winter, or heat in summer, are accompanied with a proportionally increased mortality from scarlet fever, whooping-cough (if these diseases be epidemic at the time), bronchial affections, and bowel complaints respectively. Again, as regards diarrhœa, for example, there appear to be certain critical temperatures, such as 55°, 60°, 63°, and 65°, at which as they are reached, the mortality rises successively to greatly accelerated rates. To work out the problem of the relation of the weather and mortality of our large towns, it is indispensable for the comparison of the different towns with each other, that the system of observation be uniform at all places, particularly as regards the hours and modes of observing the temperature, humidity, and movements of the air, and the rainfall; and it is further indispensable that several meteorological stations be established in each of the large towns.

ALEXANDER BUCHAN

SCIENTIFIC SERIALS

Mental Science Journals, January, April, July.—The January number opens with an article by Samuel Wilks, M.D., "The Study of the Human Mind from a Physiological View." Dr. Wilks finds no more difficulty as regards the relation of the mind and brain than in "the association of other functions with their respective organs." The main purpose of the writer seems to be to show that men are very much of automata. In this he thinks he has followed Dr. Huxley, who however, if he meant anything, meant that men are altogether automata. The illustrations of the automatism of doctors must be alarming to the nervous and ailing. Example: "Up to the present time I have never seen a single case of leucocythæmia of the lympathic glands, or the spleen, or simple idiopathic anæmia, without the patient's having been saturated by iodine, quinine, and iron; but no case is yet recorded of these remedies having done the slightest good."—David Nicholson, M.B., continues his "Morbid Psychology of Criminals," and shows his vigorous common sense in refusing to see that suicide is always an insane act, or that there is any "madness in an idle-minded fellow preferring to live 'like a gentleman' by helping himself directly from moneyed pockets, instead of sweating his life out with a pick

and shovel at fourteen shillings a week."—This number contains an interesting paper on the Hallucinations of Mahomet and others, by W. W. Ireland, M.D.—In the April number we find the Morisonian lectures on Insanity for 1873, this time written entirely by Dr. Clouston; the Morbid Psychology of Criminals continues; an article on the Family Care of the Insane in Scotland, by Prof. Friedrich Jolly, of Strasburg, is valuable, inasmuch as it helps us "to see ourselves as others see us," and pleasing, as this time we may look and be not ashamed. "This visit," says Prof. Jolly, "and the information furnished by these gentlemen, as well as a more careful study of the Scottish Reports and their appendices, convinced me that it is no 'Gheel in the North' with which we have to do, but an organisation which rests on a quite different and much sounder basis."—George Shearer, M.D., communicates notes to show that "Diseases of the general nervous system are by no means infrequent amongst the Chinese, but cases of alienation of mind are comparatively few."—Mr. E. Thompson continues and concludes his paper on the Physiology of General Paralysis of the Insane and of Epilepsy. The worst things in the paper are a few unseemly remarks directed against Dr. Hughlings Jackson.—The July number opens with a Chapter on some Organic Laws of Personal and Ancestral Memory, by J. Laycock, M.D.—The Morisonian lectures on Insanity are continued from the previous number.—David Nicholson M.B., furnishes his excellent articles on the Morbid Psychology of Criminals, which we have always read with much pleasure.—S. Messenger, F.R.C.S., writes under the title, "Moral Responsibility," to show that we all are what we are because, given our parents and our circumstances, we could not have been otherwise. The moral of "this theory of no-moral of responsibility" is very good, "we should be more generally charitable in our judgments, more universal in our forbearance." It is a pity that the men who are continually claiming to be the only scientific men cannot reach such simple conclusions without outraging language and common sense in order to show, by the way, that they are not metaphysicians. Mr. Messenger describes the manufacture of thought as similar to the manufacture of gastric juice—the action of the brain is like "that of the stomach, whose peptic glands secrete the gastric juice from the circulating blood, but need the stimulus of food to excite the process." It would be a great advantage to the scientific men of this stamp if they would try "the means of observation which metaphysicians employ," or any other that might help them to see that intelligence is not a juice.

IN the *Scottish Naturalist* for April and July 1875, the difficult subject of the relationship between the mental development of man and of the lower animals occupies a rather prominent place, in a series of articles by Dr. Lauder Lindsay, on "Illustrations of Animal Reason," and one by the Rev. J. Wardrop, on "Animal Psychosis."—The former writer also contributes a paper on "The Auriferous Quartzites of Scotland," in which he brings forward evidence in support of the view long since published by him of the auriferous character of the whole Lower Silurian area of Scotland; the rocks being identical stratigraphically with those of the gold-fields of the province of Otago, in New Zealand.—There are several other good geological papers, especially one by Mr. R. Walker, "On Clays containing *Ophiolepis gracilis*, &c., near St. Andrew's."—The zoological and botanical papers are mostly descriptive, and we have continuations of the "Lepidoptera of Scotland," by Dr. Buchanan White, and the "Coleoptera of Scotland," by Dr. D. Sharp.

THE numbers of the *Journal of Botany* from March to July contain many articles of interest; and nearly every number is now illustrated by at least one original drawing. Those in the numbers now under notice are the fruit of the Bitter Cola, an undescribed species of Clusiaceæ from Wesetrn Tropical Africa, nearly allied to *Garcinia*, several species or new or rare Hymenomycelous Fungi (coloured), *Deidamia Thompsoniana*, a remarkable species of Passifloraceæ, and *Carex ornithopoda*, a newly discovered British species. Besides a number of abstracts and short notes, the following are the more important original articles in these numbers:—Descriptions of a number of new and unpublished species by Dr. Masters, Dr. Trimen, Mr. J. G. Baker, Dr. Hance, and others. In Cryptogamy, Mr. Worthington Smith describes a number of new species of fungi; the Rev. J. M. Crombie the additions to the British lichen flora since his last notice; and Mr. J. G. Baker several new ferns. One of the best papers in these numbers is by Mr. A. H. Church, with an account of some recent investigations in phyto-chemistry at the laboratory at Cirencester. An analysis of the dried substance of a fungus (*Geoglossum difforme*), and of a lichen (*Collema furvum*), showed the former to contain 19 and the latter as much as 28 per cent. of albuminoids; while the former contains the very large proportion of 13·87, and the latter 6·57 per cent. of ash. Cotton, generally considered to be almost pure cellulose, was analysed with the following result:—

Water	7·56	per cent.
Oil and fat	0·51	,,
Albuminoids	0·50	,,
Gummy matters	0·17	,,
Ash	0·11	,,
Cellulose	91·15	,,
	100·00	

The composition of the pollen of *Cupressus fragrans* was determined as under:—

Carbohydrates and undetermined	85·76	per cent.
Oil and fat	1·87	,,
Albuminoids	8 67	,,
Ash	3·70	,,
	100·00	

Zeitschrift der Oesterreichischen Gesellschaft für Meteorologie, June 15.—This number contains a paper by Herr Hellmann, of Berlin, on the extension of a short series of observations on temperature by means of the long series of a neighbouring station. It was one of Dove's result's that series of mean temperatures of two neighbouring places derived from a different number of years might be reduced so as to extend over equal periods. His hypothesis has proved a fruitful one. The object of Herr Hellmann was to confirm its value, and this he did by taking mean temperatures already obtained by observation for long and equal periods at two neighbouring places; then assuming that, say for the last five years, no observations had been made at one of them, and calculating from those of the other the required means for the whole period. The difference between the real values and those calculated expresses about the amount of error incurred, which is surprisingly small. Thus, out of eighty-four monthly means for seven pairs of similarly situated stations, only four differences exceeded one-tenth of a degree. But when a hill station is compared with a valley station the agreement is not so good, and it appears that with increase of height the climate becomes more uniform; between an inland and a coast station the difference is still greater, but rarely exceeds half a degree. We may conclude that observations made at a place situated on a plain may safely be employed for the extension of a shorter series of observations made at another place at no great distance, similarly situated, and that the error will be greater when stations different in position are compared.

July 1.—This number contains a review of Mr. Symons's publications on British Rainfall, by M. Raulin, of Bordeaux, and, among the "Kleinere Mittheilungen," a paper on the production of centres of cold in winter.

SOCIETIES AND ACADEMIES

LONDON

Royal Horticultural Society, July 7.—General Meeting.—Hon. and Rev. J. T. Boscawen in the chair.—The Rev. M. J. Berkeley briefly alluded to Mr. Worthington Smith's paper before the Scientific Committee.

July 21.—Scientific Committee.—M. T. Masters, M.D., F.R.S., in the chair—Mr. Bennett exhibited a fine specimen of a fasciated cucumber stem bearing two cucumbers.—Mr. W. G. Smith made a further communication on the resting spores of the potato fungus.—A letter was read from Mr. C. E. Broome, including a sketch of *Diplodia*-like bodies met with in the mycelial filaments.—Mr. Renny made a communication on the same subject, and exhibited a species of *Pythium* (*Saprolegnieæ*), which, without care, might be mistaken for the state of *Peronospora* described by Mr. Smith.—A letter was read from Lady Mathison, accompanying specimens of various larvæ which proved very destructive to the otherwise thriving plantation of Falkland Island Tussock grass (*Dactylis cæspitosa*) in the island of Lewis.—Mr. Alfred Bennett called attention to the rapid growth of the flower-stalk of *Vallisneria spiralis*, which he had observed to grow as much as 12 inches in twenty-four hours.—A letter, communicated by Dr. Hooker, P.R.S., was read from Dr. Imray, of

Dominica, accompanied by an excellent series of specimens of the minute moth (*Cemiostoma coffeella*) which injures the leaves of the coffee plant in Dominica.—Dr. Masters exhibited a flower of a hybrid *Tacsonia* in which the anthers were replaced by petals, while from the apex of the tube formed by the filaments, a second corona of blue threads proceeded. Dr. Masters also exhibited a flower of a *Cattleya*, in which there were three equal sepals and four petals all lip-like. From the arrangement of the parts Dr. Masters concluded that there was in this specimen a passage from the whorled to the spiral arrangement.

General Meeting.—Hon. and Rev. J. T. Boscawen in the chair.—The Rev. M. J. Berkeley commented upon the objects exhibited and also upon Mr. W. G. Smith's further observations upon the resting spores of the potato-disease fungus.—Prof. Thiselton Dyer made some observations upon a fine pan of Droseras from the New Forest, exhibited by the Chairman.—Dr. Masters commented on the splendid pitchers of *Nepenthes* sent by Mr. D. Thomson, gardener to the Duke of Buccleugh at Drumlanrig.

Quekett Microscopical Club, July 23.—Annual Meeting.—Dr. Matthews, president, in the chair.—The report showed that the club had completed the tenth year of its existence and that it continued to make most satisfactory progress; the meetings had been well attended, excellent papers had been read and useful work accomplished, whilst the library and cabinet were in good order, and the field excursions had been very successful. The treasurer's statement showed that the year's income from all sources amounted to 291*l.* 13*s.* 11*d.*, and that there was a balance in hand of 73*l.* 9*s.* 9*d.* Votes of thanks to the president and officers were duly passed, as was also a special vote of thanks to the Council of University College for their continued kindness in allowing the meetings to be held in the library of that building.—The annual address was delivered by the President, and upon its conclusion a ballot took place for the election of officers and committee for the ensuing year. Dr. J. Matthews was re-elected President. Messrs. J. Crisp, R. T. Lewis, B T. Lowne, and T. C. White, Vice-Presidents. As Hon. Sec., Mr. Ingpen; as Treasurer, Mr. Gay. Hon. Sec. for Foreign Correspondence, Dr. M. C. Cooke. And to fill the four vacancies on Committee, Messrs. M. H. Johnson, F. Oxley, T. Rogers, and Joseph A. Smith.

Berlin

German Chemical Society, June 28.—A. W. Hofmann, president, in the chair.—Messrs. von Dechen and Wichelhaus have studied the action of nitrobenzole on aniline. They obtain an amorphous violet colouring substance to which they give the formula $(C_6H_4)_3''N_2$; explaining its formation by the equations—

$$1.\quad \underset{\text{Nitrobenzole.}}{C_6H_5(NO_2)} + \underset{\text{Aniline.}}{2C_6H_5NH_2} = H_2O + \underset{\text{Violaniline.}}{(C_6H_5)_3N_3}$$

$$2.\quad (C_6H_5)_3N_3 = NH_3 + \underset{\text{(new substance).}}{(C_6H_4)_3''N_2}$$

Messrs. Oppenheim and Pfaff have continued their researches on oxyuvitinic acid, $C_6H_2\left\{\begin{matrix}OH\\CH_3\\(CO_2H)_2\end{matrix}\right.$. They have prepared the methylic ether and the first anhydride of this acid, which they have found to be produced not only by the action of chloroform but also by that of chloral, of trichloroacetic ether, and of the chloride of carbon $C\,Cl_4$ on the sodium-compound of acetic ether. They have prepared 150 grammes of pure cresol from this acid and by transforming this cresol into cresotinic acid, methylic and ethylic ethers, methyloxybenzoic, ethyloxybenzoic, and oxybenzoic acids, and studying the properties of these bodies they have determined the cresol obtained to be *metacresol*. This leads them to allege the following position to the lateral groups of oxyuvitinic acid—

$$CH_3 : OH : CO_2H : CO_2H = 1 : 3 : 4 : 6.$$

The same chemists have found anisic acid to have the melting-point 184°·2 and methyloxybenzoic acid 106-107°, the melting-points formerly given being 10° too low.—P. Griess has transformed diazocyanobenzol into cyanophenol, by heating its sulphate with water—

$$C_6H_3CN\,N_2 + H_2O = C_6H_4CN\,OH.$$

Hydrochloric acid splits it into ammonia and meta-oxybenzoic acid. The cyananiline necessary for preparing the diazo compound had been prepared by heating uramidobenzoic acid with phosphoric anhydride—

$$C_6H_4\begin{matrix}-NH-CO-NH_2\\-COOH\end{matrix} = C_6H_4\begin{matrix}CN\\NH_2\end{matrix} + CO_2 + H_2O.$$

—A. Ladenburg has repeated Mr. Fittica's experiments without obtaining a trace of his presumed and inexplicable isomers of Nitrobenzoic acid.—O. Witt, by treating diphenylamine with nitrous ether has transformed it into yellow brilliant crystals of diphenylnitrosamine $N\begin{matrix}/C_6H_5\\-NO\\ \backslash C_6H_5\end{matrix}$.—A Pinner has transformed $C_3H_2Cl_2$ into a nitrochloroallylene, which, with tin and hydrochloric acid yields $C_3H_4Cl_3NH_2$ trichloropropylamine. Sodium acts on $C_3H_2Cl_2$ in a peculiar way. It forms with it a solid compound decomposed by water into chloride of sodium and C_3H_2 a gas forming the bromide $C_3H_2Br_2$.—A. W. Hofmann has distilled the compound ammonium $(CH_3)_3NC_2H_3OH$, hoping to obtain vinylic alcohol; he obtained, however, trimethylamine, water, and acetylene.

Paris

Academy of Natural Sciences, July 26.—M. Fremy in the chair. The following papers were read:—Researches on the theory of aberration, and considerations on the influence of the proper motion of the solar system in the phenomenon of aberration, by M. Yvon Villarceau.—On the latitude of Abbadia near Hendaye (Basses Pyrenees), by M. A. D'Abbadie.—On the distribution of magnetism in compound bundles of very thin bars of finite length, by M. J. Jamin.—Note by M. Chevreul on the Compte Rendu of the meeting of July 19.—Complementary notice on the contemporaneous formation of minerals by the thermal springs of Bourbonne-les-Bains (Haute Marne); production of phosgenite, by M. Daubrée.—Researches on the phenomena produced by electric currents of high tension, and their analogy with natural phenomena, by M. G. Planté.—Action of electrolytic oxygen on glycerine, by M. Ad. Renard. The author finds as the result of this action formic and acetic acids and the first glyceric aldehyde.—Study of the pyrites employed in France for the manufacture of sulphuric acid, by MM. A. Girard and H. Morin.—On the toxic properties of the fermentation alcohols, by MM. Dujardin-Beaumetz and Audigé.—On amyloxanthate of potassium (for the destruction of Phylloxera), by MM. Zoeller and Grete.—On the thermal phenomenon accompanying inversion, by M. G. Fleury. The author concludes that the inversion of sugar by acids is an exothermal phenomenon.—Note on a substance serving to adulterate guanos, by M. F. Jean.—New researches on germination, by M. P. P. Dehérain.—Experiments showing that the mammæ removed from young female guinea pigs are not reproduced, by M. J. M. Philipeaux.

THE SCIENCE COMMISSION REPORT ON THE ADVANCEMENT OF SCIENCE

SINCE our last week's issue two Reports of the above Commission have been issued, one of them, the Eighth and Final Report, dealing especially with the Advancement of Science.

We attach so much importance to this branch of the inquiry entrusted to the Commission, that we shall deal with the Eighth Report first; and as the Recommendations which the Commission make and the Considerations which have led up to them have long been anxiously looked for, we shall defer any remarks of our own this week, in order to give the Considerations and Recommendations *in extenso*. The following are the various branches into which the Report is divided :—

1. The Scientific Work carried on by Departments of the Government.
2. The Assistance at present given by the State towards the promotion of Scientific Research.
3. The Assistance which it is desirable the State should give towards that object.
4. The Central Organisation which is best calculated to enable the Government to determine its action in all questions affecting Science.

The general remarks made by the Commission on the evidence adduced on the first three heads are as follows :—

"The great advances in physical science which have been made in this country, and within this century, by such men as Dalton, Davy, and Faraday, without aid from the State; the existence of our numerous learned societies, and the devotion of some few rich individuals to the current work of science, at first sight appear to reduce the limits within which State aid to research is required in this country.

"But whilst we have reason to be proud of the contributions of some great Englishmen to our knowledge of the aws of nature, it must be admitted that at the present day scientific investigation is carried on abroad to an extent and with a completeness of organisation to which this country can offer no parallel. The work done in this country by private individuals, although of great value, is small when compared with that which is needed in the interests of science; and the efforts of the learned societies, not excepting the Royal Society, are directed to the discussion and publication of the scientific facts brought under their notice; these societies do not consider it any part of their corporate functions to undertake or conduct research.

"It will have been seen, from the extracts from the evidence, that amongst the witnesses who have advocated an increase of State assistance are some who have made great sacrifices in time and money in the cause of scientific research.

"But whatever may be the disposition of individuals to conduct researches at their own cost, the advancement of modern science requires investigations and observations extending over areas so large and periods so long that the means and lives of nations are alone commensurate with them.

"Hence the progress of scientific research must in a great degree depend upon the aid of Governments. As a nation we ought to take a share of the current scientific work of the world; much of this work has always been voluntarily undertaken by individuals, and it is not desirable that Government should supersede such efforts; but it is bound to assume that large portion of the national duty which individuals do not attempt to perform, or cannot satisfactorily accomplish.

"The following considerations have been suggested to us by the heads of evidence relating to (1) Laboratories, (2) Observatories, (3) Meteorology, (4) Tidal Observations, and (5) the Payment of scientific workers.

"1. The first condition of scientific investigation is that there should be collections, laboratories, and observatories accessible to qualified persons. The evidence has shown that at present, for certain branches, these do not exist or are incomplete.

"Moreover, there can be no doubt that the Government service should, to a great extent, contain within itself the means of carrying on investigations specially connected with the departments. Even having regard only to the current wants of the State, additional appliances are necessary.

"Three distinct ways have been suggested in which the State might assist in providing the aids to investigation which are required by private individuals. It has been proposed: first, that competent investigators should receive grants in money enabling them to provide themselves with means for conducting their researches; secondly, that laboratories, designed primarily for the service of the State, and those of Universities and other similar institutions receiving aid from the State, should be placed, under proper conditions, at the disposal of such inquirers; thirdly, that laboratories should be erected by the Government specially designed for the use of private investigators, though of course also available for the service of the State. Wherever the first of these methods can be conveniently and economically adopted, we are disposed to consider that it is the simplest and the best; but it must be remembered that for many researches apparatus of a costly but durable character are among the primary requisites; and that to provide these separately for each investigator would involve a large and unnecessary expenditure. It appears to us that the difficulty thus arising might be adequately met by the adoption of the second of the above suggestions. Our attention has, indeed, been called to the inconveniences which might arise from the admission of independent workers into University or State laboratories. But, notwithstanding this difficulty, we think the experiment is one which ought to be tried, and till it has been tried we should hesitate to recommend the erection by the State, for the especial use of private investigators, of laboratories which would certainly be costly, and might possibly be only imperfectly utilised.

"2. Upon a review of the whole of the evidence relating to the subject of Astronomical Physics, we are of opinion that an observatory for that branch of science should be established by the State. In the study of Solar Physics, continuity of the observations is of the greatest importance; and owing to our variable climate, continuous observations of the sun in this country are subject to peculiar difficulties which should be duly considered in the site for such an observatory. The neighbourhood of London is less favourable to physical observations than many other sites which might be found, and for this reason we should prefer that a physical observatory should be placed elsewhere than at Greenwich. On other grounds, also, we think that the Observatory for Astronomical Physics should be an institution entirely distinct from any of the national observatories for Mathematical Astronomy. The subject of Mathematical Astronomy is vast enough to occupy adequately the whole energies of a director, and it is especially important that Astronomical Physics should have the undivided attention of the head of an observatory, because its methods, which are of very recent invention, are as yet incompletely developed, and because, depending, as they do, on a continual comparison of celestial phenomena with the

results of experiments in the laboratory, they are entirely different from those of Mathematical Astronomy.

"Our opinion as to the desirability of such an institution is confirmed by the example of foreign nations; observatories for astronomical physics being already at work in various parts of Italy, and their immediate erection having been determined on at Berlin and at Paris.

"We venture to express the hope that similar institutions may before long be established in various parts of the British Empire. The regularity of the climatic conditions of India, and the possibility of obtaining there favourable stations at considerable heights, render it especially desirable that arrangements should be made for carrying on physical observations of the sun in that country.

"3. With respect to Meteorology we are of opinion that the operations of the Meteorological Office have been attended with great advantage to science and to the country. The subject of Meteorology is a very vast one, and any scheme for its proper cultivation or extension must comprise—(1) Arrangements for observing and registering meteorological facts; (2) Arrangements for the reduction, discussion, and publication of the observations; (3) Researches undertaken for the purpose of discovering the physical causes of the phenomena observed. The resources placed at the disposal of the Committee are inadequate to cover the whole of this wide field; and, having due regard to all the circumstances of the case, we believe that in selecting certain parts of it, as the objects of their special attention, they have been guided by a sound discretion.

"We are also disposed to consider that although, as we have already said, the Meteorological Committee occupies an anomalous position, no other form of organisation could advantageously have been adopted under the actual conditions. We think, however, that if, as we shall hereinafter recommend, a Ministry of Science should be established, the head of the Meteorological Office should be made responsible to the Minister. We fully concur with the opinion expressed by the witnesses that many branches of meteorology can only be effectually promoted by an organisation having the support of Government; and we would draw especial attention to the consideration that if meteorology is to take rank as a branch of terrestrial physics, the observations must be made at stations widely dispersed over all parts of the earth's surface, and those taken by observers of different nations must be so arranged as to be comparable with one another. It is obvious that the intervention of Government would greatly facilitate the attainment of both these objects.

"We are very unwilling that any scientific observations which can adequately be carried on by individuals or associations of individuals, should be undertaken by a department of the Government. So far as the local interests connected with climatic meteorology suffice to ensure due attention being paid to that branch of science, we should prefer to see it left mainly to scientific societies, any assistance the Government might afford being merely subsidiary. That useful results may be obtained by voluntary effort is evident from the work carried on under the direction of Mr. Glaisher, and from the case of the Scottish Meteorological Society, which has succeeded, with very narrow means, in organising a valuable system of observations on the meteorology of Scotland. It is, however, important that any grants for the promotion of meteorological observations in aid of voluntary efforts should be made on some systematic principle; and the attainment of this object would be furthered by making them subject to the control of a minister, who would be cognisant of all the facts relating to the expenditure of the Government upon meteorology.

"We may point out that the returns furnished by the Scottish Meteorological Society and Mr. Glaisher, are adopted by the Registrars General, and are recognised by Committees of Parliament in discussions affecting the public health, the supply of water, and other matters of the same kind. The value of observations undertaken, as in this case, by private individuals or voluntary associations, must vary from time to time, according to the efficiency of the persons principally concerned in their superintendence. We feel, therefore, that the question how far it is proper that such observations should receive official sanction, cannot be decided *a priori*, and must be left to the judgment of the responsible Minister for the time being.

"4. With regard to tidal observations, it will be seen that, in the opinion of the witnesses, these have not hitherto been conducted and reduced systematically. Considering the agencies which the Government can employ for the purpose of making these observations, the importance of providing proper superintendence for them, and of securing their reduction, we think it desirable that they should be carried on under Government control. The expense involved would chiefly consist in the establishment at proper points, and verification, of tide gauges, and in the reduction of the observations; these being entrusted to officers of Government already stationed at the ports and on the various coasts of the Empire.

"5. The witnesses have expressed themselves strongly as to the justice and policy of remuneration to investigators for their time and trouble, and the evidence also shows by implication how great must have been the sacrifices of those who without private fortune have hitherto devoted their great talents and their valuable time to such work without any remuneration whatever.

"It has hitherto been a rule in the granting of Government aid to scientific investigators, subject, so far as we have been able to ascertain, to but very few exceptions, that such aid should be limited to what was necessary to meet the expenditure actually incurred on instruments, materials, and assistance.

"To grants made under these conditions we think that considerable extension might be given.

"It is hardly necessary to assert the principle that when scientific work is undertaken at the request of the Government, the State is not only justified in paying, but is under obligation to pay for what is done on its behalf and for its service. But we desire to express our belief that there are many instances of unremunerative research in which the benefit conferred on the nation by those who have voluntarily engaged in it establishes a claim upon the State for compensation for their time and labour. Without such compensation much important work must remain unperformed, because it must be expected that many of the best men will not be in circumstances enabling them to devote long periods of time to unremunerated labour.

"It is a matter of course that State aid shall only be given to investigators whose capacity and industry have been placed beyond a reasonable doubt."

With regard to head IV., the Commissioners make the following general remarks:—

"The functions of the Government with regard to science may be summed up under the three following heads:—

"1. The treatment of the scientific questions incident to the business of the public departments.

"2. The direction of scientific instruction when given under the superintendence or control of the State.

"3. The consideration of all questions involving State aid towards the advancement of science, and of administrative questions arising out of such aid.

"It would be difficult to enumerate exhaustively all the various topics comprehended under these three heads, and it will be sufficient for the purpose of showing how wide

is the field of action of the State in regard to science, if we point out that under one or other of these heads are included all scientific questions affecting the army, the navy, the public health, the mercantile marine, public works, Government scientific establishments; the elementary instruction in science under the department of education in primary schools, in the science classes connected with the Science and Art Department, and in secondary schools so far as they are subject to Government control; the aid which is now given, or which it is desirable should be given, to universities and other bodies not directly connected with the State, for the middle and higher scientific instruction, and the control which the State either does or should exercise over them in virtue of such aid or otherwise; the appointments to all scientific offices in the gift of the Crown; grants to museums and their control by the State; aid to scientific expeditions of every kind; the establishment and direction of State laboratories and observatories; grants in aid of such laboratories not under State direction, and in aid of scientific research; and generally the allotment and control of public funds for similar purposes.

"The majority of the witnesses who have given evidence in relation to this branch of the inquiry, express dissatisfaction with the manner in which questions under the preceding heads are now determined, and either recommend the appointment of a special minister of science or of a minister of science and education.

"In most cases the witnesses recommend that such a minister should, in regard to science, be advised by a council. Others, however, are of opinion that the functions of such a council might be exercised by an administrative staff of the usual kind."

After adducing a mass of evidence with regard to this subject, the establishment of a Ministry and Council of Science, the Commission thus discusses it:—

"We have given careful consideration to this part of the Inquiry entrusted to us; and, in the course of our deliberations we have been led to attach much importance to the facts stated in the first part of our report, which show that the scientific work of the Government is at present carried on by many different departments.

"There is nothing to prevent analogous, if not actually identical, investigations being made in each of these, or to secure to one department an adequate knowledge of the results obtained, and the circumstances under which they were obtained, by another.

"Investigations admitted to be desirable, nay, practical questions, the solution of which is of the greatest importance to the public administration, are stated by the witnesses to be set aside because there is no recognised machinery for dealing with them; while, in other cases, investigations are conducted in such a manner as to involve a needless outlay of time and money, because they were originally planned without consultation with competent men of science.

"Passing to the question of the advancement of science, we have arrived at the conclusion that much has to be done which will require continuous efforts on the part of the administration unless we are content to fall behind other nations in the encouragement which we give to pure science, and, as a consequence, to incur the danger of losing our pre-eminence in regard to its applications.

"These considerations, together with others which have come before us in the course of our inquiry, have impressed upon us the conviction that the creation of a special Ministry dealing with science and with education is a necessity of the public service.

"This Ministry would be occupied (1) with all questions relating to scientific and general education, so far as these come under the notice of government; (2) with all questions incidental to the application of national funds for the advancement of science; and (3) with all scientific problems in the solution of which the other departments may desire external scientific advice or information. It would also be desirable that the department should receive information as to scientific investigation proposed by other branches of the Government, and record their progress and results.

"It is not within our province to express an opinion as to whether the subject of art should be included among the functions of this department; but we are satisfied that the Minister's attention should not be distracted by any immediate responsibility for affairs which have no connection with science, education, or art.

"We have considered whether the official staff of such a Ministry, however carefully selected, could be expected to deal satisfactorily with all the varied and complicated questions which would come before the department. We have given full weight to the objections which have been raised against the creation of a special council of science, and to the arguments in favour of referring scientific questions to learned societies, or to special committees appointed for the purpose, or to private individuals; but nevertheless we have arrived at the conclusion that an additional organisation is required through which the Minister of Science may obtain advice on questions involving scientific considerations, whether arising in his own department or referred to him by other departments of the Government.

"Such questions have from time to time been referred to the Council of the Royal Society, in which the best scientific knowledge of the time is fairly represented. The Committee chosen by that Council for the administration of the government grant of 1,000*l.* per annum in aid of scientific investigations has performed its work to the satisfaction of the Government, of men of science, and of the public. But if much more is to be done for the advancement of science than at present, and if the Departments in conducting their investigations are to have the benefit of the scientific advice which appears now to be frequently wanting, the Council of the Royal Society, chosen as it is for other purposes, could scarcely be expected to take upon itself functions which, it is true, are not different in kind, but which would involve increased responsibility and the expenditure of additional time and trouble. Moreover, amongst the questions on which the departments would require scientific advice, there would no doubt be many requiring a knowledge of the peculiar exigencies of the public service, which would be more readily understood and solved if some persons in direct relation with the departments formed a part of the body to be consulted. It is obviously of great importance that the council should be so constituted as to possess the confidence of the scientific world, and we believe that this confidence would be extended to a council composed of men of science selected by the Council of the Royal Society, together with representatives of other important scientific societies in the United Kingdom, and a certain number of persons nominated by the Government. We also believe that such a body would deserve and receive the confidence of the Government, and that it would be well qualified to administer grants for the promotion of pure science.

"The general opinion we have expressed as to the proper remuneration of scientific work would be applicable to the members of this Council, but the degree and manner in which the principle should be applied in this instance must be so largely dependent on circumstances that we cannot make any specific recommendation on the subject.

"It would be impossible that the Council should in all cases undertake the direct solution, by itself or even by sub-committees, of the problems submitted to it. In many instances, especially when experimental investigations are required, its duty would be accurately to define the problem to be solved, and to advise the Minister as

to the proper persons to be charged with the investigation.

"We are of opinion that the Council should not have the power of initiating investigations; it should, however, not be precluded, in exceptional cases, from offering to the Minister such suggestions as it may have occasion to make in the public interest.

"We believe that reference to such a council would be found to be so useful and convenient that it would become the usual course in cases of difficulty, but we would not diminish the responsibility or fetter the discretion of any Minister by making such reference obligatory, or by preventing a reference to committees or to individuals chosen by him, whenever that course might appear to him to be more desirable.

Finally the Report concludes with the following "Conclusions and Recommendations":—

"I. The assistance given by the State for the promotion of scientific research is inadequate, and it does not appear that the concession or refusal of assistance takes place upon sufficiently well-defined principles.

"II. More complete means are urgently required for scientific investigations in connection with certain Government departments; and physical as well as other Laboratories and apparatus for such investigations ought to be provided.

"III. Important classes of phenomena relating to Physical Meteorology, and to Terrestrial and Astronomical Physics, require observations of such a character that they cannot be advantageously carried on otherwise than under the direction of the Government.

"Institutions for the study of such phenomena should be maintained by the Government; and, in particular, an observatory should be founded specially devoted to Astronomical Physics, and an organisation should be established for the more complete observation of tidal phenomena and for the reduction of the observations.

"IV. We have stated in a previous Report that the national collections of Natural History are accessible to private investigators, and that it is desirable that they should be made still more useful for purposes of research than they are at present. We would now express the opinion that corresponding aid ought to be afforded to persons engaged in important physical and chemical investigations; and that whenever practicable such persons should be allowed access, under proper limitations, to such laboratories as may be established or aided by the State.

"V. It has been the practice to restrict grants of money made to private investigators for purposes of research to the expenditure actually incurred by them. We think that such grants might be considerably increased. We are also of opinion that the restriction to which we have referred, however desirable as a general rule, should not be maintained in all cases, but that, under certain circumstances and with proper safeguards, investigators should be remunerated for their time and labour.

"VI. The grant of 1,000*l*., administered by the Royal Society, has contributed greatly to the promotion of research, and the amount of this grant may with advantage be considerably increased.

"In the case of researches which involve, and are of sufficient importance to deserve, exceptional expenditure, direct grants in addition to the annual grant made to the Royal Society, should be made in aid of the investigations.

"VII. The proper allocation of funds for research; the establishment and extension of laboratories and observatories; and, generally, the advancement of science and the promotion of scientific instruction as an essential part of public education, would be most effectually dealt with by a ministry of science and education. And we consider the creation of such a ministry to be of primary importance.

"VIII. The various departments of the Government have from time to time referred scientific questions to the Council of the Royal Society for its advice; and we believe that the work of a minister of science, even if aided by a well-organised scientific staff, and also the work of the other departments, would be materially assisted if they were able to obtain, in all cases of exceptional importance or difficulty, the advice of a council representing the scientific knowledge of the nation.

"This council should represent the chief scientific bodies in the United Kingdom. With this view its composition need not differ very greatly from that of the present Government Grant Committee of the Royal Society. It might consist of men of science selected by the Council of the Royal Society, together with representatives of other important scientific societies, and a certain number of persons nominated by the Government. We think that the functions at present exercised by the Government Grant Committee might be advantageously transferred to the proposed Council."

HINRICHS' "PRINCIPLES OF CHEMISTRY"

The Principles of Chemistry and Molecular Mechanics. By Dr. Gustavus Hinrichs, Professor of Physical Science in the State University of Iowa. (Davenport, Iowa, U.S.: Day, Egbert, and Fidlar, 1874.)

THIS work constitutes the second volume of a treatise on "The Principles of the Physical Sciences," and its main object is to present theoretical chemistry in its most modern aspect and to discuss its laws from a dynamical point of view. It is divided into two portions: "Molecular Statics," and "Molecular Dynamics." The former commences with an account of chemical atoms, it being premised that the conception of a chemical atom is the basis of the modern chemical theory. Although the author tells us that the chemical atom is a reality, while the philosophic atom is only a possibility, we have a little difficulty in accepting his definition of a chemical atom as "a very minute, relatively indivisible particle of matter." For it is surely unwise to retain a term so precise in its etymological significance if we admit its divisibility. We are told that "an atom of lead sulphide" can be divided into an atom of lead and an atom of sulphur; and further (p. 19), that "the molecule of gaseous compounds consists of one atom of the compound." But a molecule is defined as a "group of atoms" elsewhere, so that it would appear that a molecule is sometimes an atom, and an atom is sometimes a molecule, and such confusion of ideas must be most detrimental to the acquirement of exact knowledge by the student.

It is useless for us to protest against variations in the mode of writing formulæ, for such protestations have been made any time during the last ten years in vain; but we are quite justified in saying that such changes harass the student to an extent to which the authors of them can scarcely be aware. Why should NaCl be written $NaCl^{ide}$, and $KaNO_3$, KaN^{ate}, and so with all sulphates, oxalates, nitrates, and a host of other salts? And why, when the almost universal custom is to write sulphates as MSO_4, and nitrates as MNO_3, does our author write MO_4S and MO_3N?

We are glad to notice the introduction of the recent surmises as to the absolute weight of atoms, although at present we believe that such ideas cannot be of much

real use to the student. We are told that a milligram of hydrogen contains about 400,000000,000000,000000 atoms of hydrogen, and a milligram of gold 2,000000,000000,000000 atoms, while the atomic weight of gold is given as 196; if this is admitted, the milligram of gold will contain some 40816,000000,000000 atoms in excess of the number given above, and the omission of this will in itself show the extreme generality of such statements. A curious deduction as to the *form* of atoms is drawn from the fact that many minerals are observed, when reduced to powder, to preserve their normal crystalline form; hence, says our author, "we conclude the compound atom possesses form closely related to the cleavage form."

The law of Dulong and Petit is very concisely stated, and its importance in modern chemistry is well illustrated. It is crudely formulated thus:—if a represents the atomic weight and s the specific heat, the product $a\,s$ will be the specific heat S of a gram-atom of the substance, and $S = a\,s$ nearly equal to 6·3.

Or again, if the specific heat S of an element be known, an approximate determination of the atomic weight can be found as follows:—

$$a = \text{nearly } \frac{6 \cdot 3}{s}$$

Thus the specific heat of lead = 0·031, consequently $\frac{6 \cdot 3}{\cdot 031} = 200$, the exact atomic weight of lead being 207. The service afforded by the application of this law to the determination of the *right* atomic weight of an element is also shown in this case of lead, for from the analysis of oxide of lead the atomic weight of lead might be 207, or 103.5, or 69, or 414, or 621, for although we find that sixteen parts by weight of oxygen are united with 207 of lead, we have no direct chemical proof that the 207 represents one atom; but the law of Dulong and Petit now steps in and shows us that the right atomic weight is 207, because it alone satisfies the conditions of that law. And so for other elements the vapour density of whose compounds cannot be determined. The section on Atomicity or valence would be much improved by the introduction of a complete list of the elements with their atomicities, and a discussion of doubtful atomicities.

In the seventh section the author passes at once from what were once called inorganic compounds to the discussion of organic substitutions as shown in the great methyl series of compounds. Such comprehensive statements as, "the binary marsh gas, also called *methane*, CH_4, is the basis of all organic compounds," are of great use to the student, and in this instance the statement at once justifies the passage from mineral chemistry to so-called organic chemistry without one word of introduction or comment. We do not think that the attempted graphical representation of chemical constitution in the eighth section can be productive of anything but confusion to the student. The crosses and dots and three-limbed signs have themselves to be remembered, and cannot give any precise idea of the constitution of a complex compound. A somewhat detailed account of the constitution and syntheses of various serial compounds concludes that portion of the work devoted to Molecular Statics.

The second part commences with an account of the motions of molecules, and it is asserted that since molecules are not spherical, their impact against each other will not alone produce motion of translation, but also motion of rotation, and this is partially illustrated by the motion of a boomerang. The following definitions are stated on the authority of the author:—

1. "The molecules of a body in the gaseous condition have a motion of translation, and also a motion of rotation around their natural axis of maximum moment of inertia."

2. "The molecules of a body when in the solid state have only a vibratory motion about a position of equilibrium."

3. "The molecules of a body when in the liquid state have a vibratory motion, as in the solid state, and also a motion of rotation around their natural axis of minimum moment of inertia."

Among the concluding sections of the book is a very interesting and suggestive account of *caloration*, that is the amount of heat produced or absorbed in any chemical process. The treatment (p. 153), from a caloration point of view, of the reactions of hydrogen, chlorine, iodine, and silver, is worthy of careful study. A few pages at the end ot the book treat of Systematic Chemistry and Applied Chemistry.

Dr. Hinrich's book must be used in connection with his former works, "Elements of Chemistry" and "Elements of Physics," to which frequent references are made. It is mainly intended as a guide to the student, and must be used with the assistance of a teacher. To the advanced student it will be found to be of great use, and most eminently suggestive; but it will be almost useless to any reader who has not before acquired the main principles of chemical science, together with a large storehouse of chemical facts. The work is somewhat disfigured by numerous misprints—*dissociotion* (p. 21), *amidcs* (p. 73), *reductian* (p. 109), *enery* (p. 113), &c., and we think the two plates at the end are extremely confusing; but these minor matters are easily remedied in a second edition, and need not detract greatly from the value of a really useful and comprehensive work.

G. F. RODWELL

THE ZOOLOGY OF THE "EREBUS" AND "TERROR."

The Zoology of the Voyage of H.M.S. "Erebus" and "Terror," under the command of Captain Sir James Clark Ross, R.N., F.R.S., during the years 1839 *to* 1843. By authority of the Lords Commissioners of the Admiralty. Edited by John Richardson, M.D., F.R.S., &c., and John Edward Gray, Esq., Ph.D. F.R.S., &c.

No. XIX.—*Insects* (conclusion). By Arthur Gardiner Butler, F.L.S., F.Z.S., &c. 1874.

No. XX.—*Crustacea.* By Edward J. Miers. 1874.

No. XXI.—*Mollusca.* By Edgar A. Smith, F.Z.S., &c.

THE non-completion of the "Zoology of the Voyage of the *Erebus* and *Terror*" has long been a public scandal. The celebrated voyage of these ships,

commonly known as the "Antarctic Expedition," took place in 1839, and the four following years. Dr. Hooker, under the title of "Assistant Surgeon" to the *Erebus*, was the Naturalist of the Expedition, and assisted by Messrs. M'Cormack and Robertson, the medical officers of the vessels, made an extensive collection of specimens in every department of zoology and botany. The botanical specimens were sent to Kew; the zoological to the British Museum. Dr. Hooker undertook the working out and publication of the former, and Dr. Gray of the latter. At the recommendation of the Admiralty the Government granted the sum of 2,000*l*. for the illustration of the work, half of which was assigned to the botanical and half to the zoological portion. Dr. Hooker's labours resulted in the two large quarto volumes which form the well-known "Botany of the Antarctic Expedition," and remain to the present day the standard authority upon the plants of the southern hemisphere. Very different were the results achieved by the thousand pounds bestowed upon the zoological portion of the work. After the publication of eighteen numbers, the various sections assigned to the different naturalists were left, one and all, incomplete, and have thus remained until the present day. Whether this untoward result was occasioned by the fault of the editor or of the publisher, or by misunderstandings between the two, has never been divulged to the public, nor does it now much concern us to inquire. Whichever may have been the case, the result was equally discreditable to the parties concerned. It is with pleasure, however, we see that the scandal exists no longer. An enterprising publisher has bought up the "remainder" of the plates of the unfinished work, and made arrangements for its completion. Whether it was justifiable on the part of the vendor to sell what had been produced by public money may be open to some doubt, but the purchaser, Mr. Janssen, is at all events entitled to the credit of having done all he could to bring this long neglected work to a satisfactory conclusion. The six numbers of the "Zoology of the *Erebus* and *Terror*" now before us, conclude the different sections, and enable the subscribers after twenty years of patient expectation to send their copies to the binders. On turning over the pages of the lately issued numbers, we find many admirably executed plates among them, and much valuable contribution to Zoological science. Dr. Günther's synopsis of the Australian Lizards is of special interest, and will, we are sure, prove most acceptable to the working naturalists of the Australian Colonies. As regards some of the illustrations of the birds, we may remark that the colouring is not very well executed—notice especially the figures of the King and Emperor Penguins. This is the more the pity, as the figures themselves are the productions of Mr. Wolf's artistic pencil.

OUR BOOK SHELF

Flora of Eastbourne. Being an Introduction to the Flowering Plants, Ferns, &c., of the Cuckmere District, East Sussex, with a Map, by F. C. S. Roper, F.L.S., &c., President of the Eastbourne Natural History Society. 8vo, pp. 165. (London, Van Voorst.)

THIS is an admirable little book of its kind, the greatest care and conscientiousness having evidently been exercised in its compilation. The plan adopted by the author was to include only such species as he had actually gathered himself, or of which he had seen authentic specimens, hence a considerable number of species which we know, from personal observation, to grow within the limits of the Cuckmere district are omitted, or only given in an appendix. However, Mr. Roper will doubtless soon publish a supplement, and the basis upon which he has started is far preferable to the indiscriminate admission of everything from sources of uncertain value. Another cause for the absence of certain species is the quite recent extension of the field of operations to coincide with the Cuckmere drainage district of Mr. Hemsley's projected flora of the whole county. This forms an irregular triangle, having its apex on the ridge of the weald at Cross-in-hand, and its base running along the coast from the Signal House, east of Seaford, to St. Leonards. Its area is about 150 square miles, and it comprises a great variety of soils and situations, but there is very little boggy land, consequently a paucity of bog plants. Mr. Roper's list numbers 700 species, which further explorations will probably augment by about one hundred. It is surprising that such plants as *Papaver dubium*, *Arenaria trinervis*, *Rubus discolor*, *Campanula rotundifolia*, *Ophrys muscifera*, *Juncus maritimus*, *Aira flexuosa*, *Bromus giganteus*, &c., should have escaped observation; but such is the case, and they are not included in the *Flora*. Among the more interesting plants of this part of Sussex, and not found elsewhere in the county, we may mention *Phyteuma spicatum*, *Pyrola minor*, *Bupleurum aristatum*, *Seseli Libanotis*, *Sibthorpia europæa*, and *Bartsia viscosa*. The *Pyrola* was recently discovered in Sussex for the first time by Mr. Roper, so the botanist should never despair of finding something new. The *Flora of Eastbourne* has appeared just at the right time for visitors to Eastbourne this season, who will find it a valuable guide, and all the more welcome, perhaps, because there is a chance of adding to the number of species it includes. We should add that, like most local floras of recent publication, it simply treats of the distribution of the plants, but the book before us differs from most others in its copious references to other works, which will be useful to amateurs who may have occasion to consult descriptions or plates.

We may here mention that we have received a circular from the Lewes and East Sussex Natural History Society respecting a projected Fauna and Flora of East Sussex, which will be forwarded to any person interested in the work on application to the Secretary, Mr. J. H. A. Jenner, Lewes.

Repertorium der Naturwissenschaften. Monatliche Uebersicht der neuesten Arbeiten auf dem Gebiete der Naturwissenschaften. Herausgegeben von der Redaction des *Naturforscher*. (January to June 1875, Nos. 1 to 6, Berlin.)

THIS is a useful supplementary publication to *Der Naturforscher*. It consists of sixteen columns (the columns are numbered and not the pages) in quarto form. The number for May is made up of twenty-four columns, and gives the titles of more than 600 papers, which are published in upwards of eighty separate works. The periodicals thus indexed are the *Monatsberichte* (Berlin), *Comptes Rendus* (Paris), *Botanische Zeitung* (Leipzig), *Flora* (Regensburg), *Hedwigia* (Dresden), *Proceedings of the Royal Society* (London), *American Journal of Sciences and Arts* (New Haven), *Geographical Magazine* (London), *Messenger of Mathematics*, *Astronomische Nachrichten* (Kiel), &c. Though there are several publications we miss, both English and foreign, it will be seen that a good beginning is here made, and that there is a prospect in time of students being fairly informed of what is being done in science in this country and elsewhere in a compact publication issued at a reasonable rate.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*]

Properties of Selenium

IN a letter headed "Anomalous behaviour of Selenium," which appeared in NATURE (vol. xii., p. 187), Mr. Gordon states that "it has lately been observed that the electrical resistance of selenium is greater in light than in the dark." I am anxious to learn where an account of this remarkable observation is to be found.

Mr. Gordon afterwards announces the discovery that a bar of granular selenium belonging to the Cavendish Laboratory exhibits a decrease of resistance under the influence of light. This phenomenon was well-known outside the Cavendish Laboratory more than two years ago. Mr. Gordon also states that the very high resistance of a certain medal of selenium did not sensibly alter under the influence of light; and concludes that "the physical form of the metal" seems to have some influence on its electrical properties. From his description of the medal it would appear that it is made of vitreous selenium. I am therefore surprised that its resistance was so low. A conducting form of selenium having the appearance of black-lead is certainly a novelty.

It is perhaps not generally known that the electrical properties of selenium are very variable. In a paper by Mr. Henry Draper and myself which appeared in the "Proceedings of the Royal Irish Academy" (vol. i. ser. ii. (Sci.) p. 529), we have shown that there is a granular variety of the element which is, at ordinary temperatures, apparently as good a non-conductor as the vitreous variety. Unlike the latter, however, it cannot be rendered electrical by friction. Another granular modification of the element was found to conduct electricity comparatively well in darkness, and scarcely any better under the influence of light; while there is an intermediate state of the element which appears to possess a molecular structure so susceptible of change, that light is capable of converting it temporarily into the form which conducts comparatively well. Some bars which we prepared of this sensitive variety exhibited an increased conductivity of 100 per cent. under the influence of sun-light. In appearance there is not the slightest difference between this and the non-conducting granular variety, both exhibiting a gray granular fracture resembling that of the metal cobalt. In the course of our experiments Mr. Draper and I prepared a large number of bars and plates of various shapes and sizes, but we have not observed any unusual connection between the shape of the bars or plates and their resistance. There is a great difficulty in making observations with reference to this point, as we are as yet unable to produce two or more bars of the sensitive variety possessing the same electrical properties. Thin plates are generally more sensitive to light than cylindrical bars, but we have occasionally prepared bars as sensitive in proportion as a plate measuring 75 × 15 mm., and only 0·5 mm. in thickness.

I have not as yet been able to learn the contents of Prof. Adams's recent paper on this subject, but Mr. Gordon says that he has shown that the phenomenon is a purely optical one. I may state that Mr. Draper and I have long since shown that, so far as the effect of heat on electrical resistance is concerned, some forms of granular selenium conform to the metallic type. This was demonstrated by placing a plate of selenium inside a spiral of platinum, at a distance of about 4 mm. from the wire. The usual decrease of resistance took place when the plate was exposed to light; but on heating the surrounding platinum wire by passing a current of electricity through it, the resistance of the selenium increased considerably. The effect of light is therefore partially counterbalanced by the effect of the heat which usually accompanies it. This partly explains the increase of resistance that is known to follow prolonged exposure to light. A portion of this increase being doubtless due to the slight elevation of temperature that must result from the passage of the current through the selenium. The opposite action of light and heat is very remarkable, especially as the longest light undulations are those that cause the greatest decrease of resistance. It is remarkable, also, that a thin film of non-conducting vitreous selenium transmits these red rays, while an equally thin film of granular selenium is perfectly opaque to them.

RICHARD J. MOSS

Mr. Darwin and Prof. Dana on the Influence of Volcanic Action in preventing the growth of Corals

IN his critique on the new edition of Mr. Darwin's work on Coral Reefs (NATURE, vol. x., pp. 408-410), Prof. Dana adduces four examples of islands in which he thinks comparatively recent volcanic action has prevented the formation of extensive coral reefs. One of these is Savaii, the largest island of Samoa.

Some time ago I read Prof. Dana's "Corals and Coral Islands," while on a tour on Savaii, and on the margin of page 302 I noted this very point now brought forward by the author in his paper in NATURE, intending, at some future time, to show that his view respecting this island is based upon imperfect knowledge, and is altogether incorrect.

I do not intend to enter here into all the details respecting Prof. Dana's incorrect statements, but will confine myself to the one point on which his views and those of Mr. Darwin are at variance. In his work (p. 302) Prof. Dana says: "Savaii abounds in extinct craters and lava streams, and much resembles Hawaii in character; it bears proof in every part of being the last seat of the volcanic fires of the Samoan Group. *Its reefs are consequently few and small.*" In NATURE (vol. x. p. 409), he says: "Savaii has coral reefs on its *western* (eastern) and northern shores, while elsewhere without them. *I failed to find evidence in the case of either of these volcanic regions that they are situated within areas of elevation* rather than subsidence. *Only ten miles* west (this should be *east*) of Savaii lies the large island of Upolu, having very extensive reefs—on some parts of the north side three-fourths of a mile wide; and it has not seemed safe to conclude that while Upolu thus bears evidence of no movement or of but little subsidence, Savaii was one of elevation; or *that the north and west* (*east*) *sides of Savaii have differed in change of level from the rest of the island.*"

In the above passage Prof. Dana has reversed the relative positions of Savaii and Upolu. Savaii is *west* of Upolu, and its reefs are on the *eastern end next to Upolu*, and extend for some distance on its north-eastern side. Its south, west, and north-west sides are free from coral reefs *except in bays*, where they are very narrow.

Now what Prof. Dana did not consider it "safe to conclude," viz., that part of Savaii had "differed in change of level from the rest of the island," is nevertheless a *fact*. And more than that, those parts of the island which present unmistakable evidence of upheaval *are destitute of a coral reef on their shores*, except the narrow fringes above mentioned.

The elevated portions of the island commence at the south-eastern point, in a line with three small islands which stand in the straits between Upolu and Savaii, and which doubtless indicate the line of fissure. I have traced the upheaval for many miles along the southern coast. In some places there are *old water-worn cliffs* from twenty to thirty feet above the cliffs which at present form the coast line, and which are themselves from twenty to thirty feet above high-water mark. These old cliffs are usually within two or three hundred yards of the present coast line, but are sometimes more distant. I have not at present traced this upheaval around the entire western end of Savaii, but I have observed the point at which it commences on the northern side, as well as at the south-eastern extremity.

How this fact tells on the point on which Prof. Dana's view differs from Mr. Darwin's, I may leave to those who are familiar with the subject to decide. My own conviction is, that instead of furnishing proof of the correctness of Prof. Dana's view, Savaii supplies a remarkable example of the correctness of that of Mr. Darwin, that, *ceteris paribus*, the extent of coral reefs is chiefly determined by the depth of water on the coast.

I have visited and examined a good many intertropical islands of the Pacific belonging to the three orders: 1. Volcanic islands with fringing coral reefs, such as Samoa, the New Hebrides, &c. 2. Atolls, such as the Low Archipelago, Ellice, Gilbert Islands, &c. 3. Upraised coral islands, such as Niuē or Savage Island, part of the Friendly, the Loyalty Islands, &c. I have studied their structure with Mr. Darwin's "Coral Reefs" as my text-book; and the further I have gone the more firmly have I been convinced of the correctness of his theory.

Prof. Dana is, without doubt, correct in his opinion that submarine or littoral volcanic action would destroy living corals which came within its influence; and it might for a time, even after the volcano became quiescent, prevent the spread of corals within the area affected by it. But the fact that in some of the areas where extensive reefs are not found, narrow coral fringes exist in bays (as at Savaii), where the slope of the shore is less

steep, is positive proof that the non-existence of extensive reefs cannot in such places be owing to any deleterious influences arising from volcanic action, but must be on account of the depth of water on the coast. S. J. WHITMEE

Upolu, Samoa

Mirage on Snowdon

ON Monday, July 12, I, with a party, ascended Snowdon. The atmosphere was clear until we had reached within half a mile of the summit, when a light cloud rising stealthily from amongst the southern peaks enveloped it. Drifting towards us, when very near, the cloud dropped over the eastern shoulder of the mountain just where it dips towards Capel Curig. As we stood watching, great was our surprise and delight as we beheld painted upon it, not the *arc-en-ciel* with which we are familiar, but a complete and brilliant prismatic circle, apparently about thirty feet in diameter, in the very centre of which we ourselves were depicted, the image being somewhat enlarged but clearly defined; as we arranged the party in groups, or bowed to each other, every form and movement was faithfully reproduced in the picture. It was now about 8 o'clock, with the sun nearly in a line with us. Our guide, who had made some hundreds of ascents, had never witnessed such a sight before. H. J. WETENHALL

Fordfield, Cambridge

OUR ASTRONOMICAL COLUMN

KEPLER'S NOVA, 1604.—We learn from Prof. Winnecke that, in consequence of the remarks upon this star which appeared in NATURE, vol. xi. p. 249, he has lately examined the neighbourhood, and, in addition to the star of 11·12th magnitude there mentioned—the position of which for 1855·0 he finds to be R.A. 17h. 22m. 4·6s., N.P.D. 111° 23·6′—he found one of 12th magnitude in R.A. 17h. 21m. 49·3s., N.P.D. 111° 19·3′. This star agrees almost precisely in place with the 10th magnitude marked upon No. 52 of Chacornac's charts, though not at present of that brightness; but we are able to state that in August 1871 and June 1872 nothing was visible in this position in a telescope which would show stars to 13·14 magnitude in Winnecke's scale. It will be desirable to watch this small star closely, as it is quite possible it might be identical with Kepler's famous star, the observed place of which is not so accurately known as in the case of the similar object observed by Tycho Brahe in 1572. Prof. Winnecke, however, suggests that, as the star marked by Chacornac is just upon the margin of his map, where some distortion exists, it might possibly be identical with No. 16,872 of Oeltzen's Argelander, a star estimated 8·9 in the Bonn Zones; still the place of the 12th magnitude agrees much more closely with that of Chacornac's 10th, read off from his chart as nearly as the circumstances permit. It may be well to compare the fainter star found by Prof. Winnecke, from time to time with the 11·12th close at hand, and easily identified if the instrument be set for Argelander's star, which may be considered a bright 9th magnitude.

THE BINARY STAR 4 AQUARII.—If good measures of this star are practicable during the present season, an idea of the form of the orbit may perhaps be obtained. Dawes's series of epochs will be of material service in this respect; without them, doubt might have been occasioned by the two discordant epochs of Mädler, which may have been owing to distorted images at low altitude. The object is certainly one of considerable difficulty, and really trustworthy measures are perhaps only to be expected from practised observers in command of instruments of excellent definition. In Barclay's second catalogue it is described as just elongated in the direction 144°, with power 450 on the 10-inch refractor at Leyton, at the epoch 1865·74; this angle shows direct progress, very much in accordance with Dawes's measures. Possibly the companion may now be found nearly due south of the primary.

THE NEBULÆ.—Prof. Schönfeld has published in Part II. of "Astronomische Beobachtungen zu Mannheim"—Carlsruhe, 1875—a continuation of the valuable series of observations commenced by him in 1860, for accurate determination of the positions of a selected list of nebulæ. In this second part we have the places of 336 of these objects, obtained by direct reference to stars, which, as in the case of those employed in fixing the positions of the nebulæ included in the first part (Mannheim, 1862), have been meridionally determined at Bonn by the late Prof. Argelander; the mean places are found in Vol. vi. of the Bonn Observations. Schönfeld's epoch is as before, 1865·0, for which year the precessions are computed with Bessel's constants, still preferred by many of the German astronomers. The differences from Schultz's Preliminary Catalogue are shown, and are generally small. As one result of more recent observations, it is remarked by Schönfeld that a sensible proper motion of the great nebula in Andromedæ, which appeared to be indicated by a comparison of Flamsteed's observations with those of D'Agelet and Lalande, is not confirmed.

Prof. Adams, in his last address as President of the Royal Astronomical Society, remarks upon the great value attaching to Schönfeld's micrometrical observations of the nebulæ, of which we have here the continuation.

ENCKE'S COMET.—Mr. J. Tebbutt of Windsor, New South Wales, reports his discovery of a comet, which he supposed to be Encke's, on the morning of May 7th, in the constellation Cetus. It is, we believe, the second occasion upon which this able amateur astronomer has detected this comet, before the arrival of an ephemeris from Europe, and no doubt in the present case his independent discovery, which he communicated telegraphically to the Government astronomers at Sydney and Melbourne, will lead to a number of observations for position at the Australian observatories, which might have been otherwise lost. The search for comets without the aid of an ephemeris is hardly an occupation which can be expected in a public observatory, where time is valuable for routine work—hence an argument for the early and general publication of ephemerides—and an inducement for some amateurs, especially in southern latitudes where a great necessity for systematic sweeping of the sky in search of comets appears still to exist, to so employ their leisure time. One at least of the lost comets of short period, is far more likely to be recovered in the southern hemisphere, than in these latitudes.

THE ARGENTINE OBSERVATORY.—Dr. Gould has just circulated in two small pamphlets, in English, the annual Report for 1874 of proceedings at the Observatory of Cordoba, and at the Meteorological Office, which has also been organised by this distinguished astronomer. With regard to astronomical work, the observations for the "Uranometry" are completed, as already mentioned in this column. The charts will be thirteen in number, including the whole of the southern heavens as well as the first ten degrees north of the equator, and about 8,500 stars will be represented upon them, of which about nine-tenths have southern declination. A catalogue will accompany the Atlas, as with the works of Argelander, Heis, and Behrmann. The zone-work was in a very forward state, 82,537 stars having been observed, and with the exception of an insignificant number of zones for which it might be necessary to wait till a later period of the year, Dr. Gould expected to complete this laborious undertaking by the end of last month. The third of the principal sub-divisions of work at Cordoba, the formation of what is called "the smaller Catalogue" is also well advanced: the catalogue is intended to consist of nearly 5,000 of the brighter stars of the southern heavens, each one observed not less than four times; in the year 1874, 12,500 observations of 3,600 different stars were made, the greater number during Dr. Gould's visit to his native city, a sufficient proof that he has been

zealously supported in the extensive plans of observation arranged by him, by the other officers of the establishment. The great comet of 1874 was followed with the large refractor of the Argentine Observatory (which, Dr. Gould informs us, is an 11-inch by Fitz, of New York) until the 18th of October, the comet having been first seen there, in the morning twilight on July 27; at the last observation it was within about 12° of the South Pole. [Our last remarks on this comet should have been headed Comet, 1874 (III.)].

THE LATE W. J. HENWOOD, F.R.S.

THIS distinguished mining geologist, who died at Penzance last week, in his seventy-first year, was originally a clerk in the employment of Messrs. Fox, of Falmouth, to whose counsel he was considerably indebted in his early scientific work. By very great industry and careful observation he acquired an unsurpassed knowledge of the mineral deposits of Cornwall and Devon, and after fulfilling a succession of important mining appointments, he became Assay Master of tin to the Duchy of Cornwall. This post being abolished, Mr. Henwood's great experience was utilised in reporting upon and developing a number of mining districts in South America, Canada, &c.; and after the cessation of his travels, he lived at Penzance in comparative retirement. His great works are the fifth and eighth volumes of the "Transactions of the Royal Geological Society of Cornwall," devoted respectively to the metalliferous deposits of Cornwall and Devon, and to those of the foreign countries he had visited. But his scientific writings, besides these, were very numerous; a list of them occupies seven columns in the "Bibliotheca Cornubiensis."

As a scientific man Mr. Henwood was characterised by indefatigable labour, great caution, love of accuracy, and moderation of expression. In his publications he scarcely ever mentions a fact of any kind which had not come under his own experience, without giving the authority for it. Thus many of his writings are marvels of copious reference. He persisted in doing everything with this extraordinary amount of labour and care up to the last, notwithstanding that he suffered for many years from a very painful heart-disease. His scientific work ceased only with his death. So long as he could sustain even an hour's intellectual effort during the day, that was devoted to the arrangement of his stores of facts and observations. I believe that scarcely one of his cherished objects in this respect remains unfulfilled.

Mr. Henwood's address to the Royal Institution of Cornwall in 1871, extending, with references, to sixty-five pages, affords ample evidence of the value of his observations and of his scientific ability. It includes the most admirable and complete compendious account of the mode of occurrence of metalliferous deposits in Cornwall which has yet appeared, and is characterised by that absence of theoretical assumption which specially marked him as an observer. The orderly arrangement of accurately-observed facts was his object; theorising he had little affection for; suspended judgment on unproved theories was his consistent attitude.

In personal character Mr. Henwood won the high regard of all who knew him intimately. His acquaintance with men and manners was so great and varied, his memory so retentive, and his conversational style so simple and lucid, that to talk with him was one of the most delightful and instructive of intellectual recreations. His estimate of his own labours and merits was unaffectedly modest, although he would resist, if possible, any unfair representation of his work.

In the spring of the present year the Murchison Medal of the Geological Society was awarded to Mr. Henwood. An extract from a letter written by him to a friend on this subject may fitly close this notice; "Mr. Evans's far too flattering estimate of my poor labours was most kindly intended. Although the distinction cannot but afford me pleasure, this is as nothing compared with the kind, and even affectionate, congratulations of yourself and my other friends. All these I carefully preserve, as they will show what I have done far better (though in an undeservedly favourable light) than the mere official record."

G. T. BETTANY

THE INTERNATIONAL CONGRESS AND EXHIBITION OF GEOGRAPHY

THE Geographical Exhibition continues to have increasing success, although the price of admission has been raised, except for schools, for which the original price, a penny a head, has been kept, and the galleries are crowded with children under the guidance of their teachers. It is said that all the soldiers of the garrison of Paris will be marched through the galleries under the guidance of their officers, when the Congress is over. The Exhibition will be prolonged to the end of the month.

Several improvements have been made in the English section since our last notice. Examples of the several maps published by the Ordnance Survey have been exhibited from an inch to ten feet per mile. Although completed only at a late period, the exhibition of the Geological Survey of Great Britain has been very successful; an immense number of maps have been exhibited, and are said to be the finest in the whole exhibition building. We might refer to a number of other exhibits honourable to English enterprise, but we must confess that Russia has carried the day, not on account of her private enterprise, but in consequence of the strenuous action of the Government. It is very likely that St. Petersburg will be chosen by common consent for the seat of the next geographical exhibition.

M. Glœsener, member of the Royal Academy of Sciences of Belgium, exhibits a chronograph available for registering the flight of projectiles as well as for recording astronomical observations for the determination of longitude. The cylinder can be put into rotation at the rate of four turns in a second or one turn in thirty seconds, according to the order of phenomena. It requires only the power of Daniell cells and ordinary magnet needles, without any electrical spark. It is very cheap, compact, and easy to set in operation.

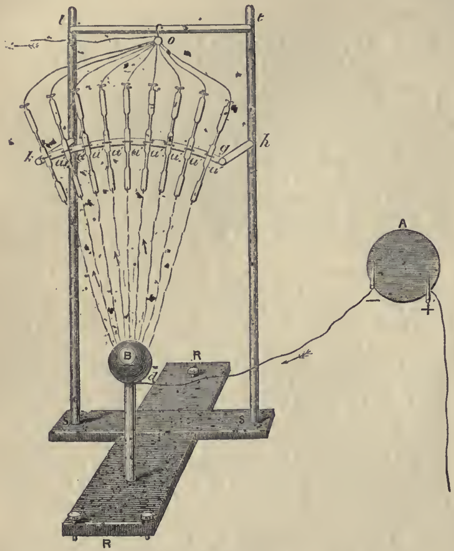
The Rysselberghe self-registering meteorograph has been admitted, as we have already noticed, to supersede any similar instrument in existence. Copper plates engraved automatically can be used in printing, having turned into relief by the processes already described.

M. Lynström, of the University of Helsingfors, has sent to the Geographical Exhibition an interesting instrument invented by him to demonstrate that auroræ are produced by electrical currents passing through the atmosphere in the polar regions. The apparatus is put daily into operation by M. Mohn, the director of the Meteorological service of Sweden, and it was constructed at the expense of Mr. Oscar Dickson, the Gottenburg merchant, who has fitted out the Swedish Polar Expedition under Prof. Nordenskiöld. Our illustration will give an idea of the apparatus.

A is an electrical machine, the negative pole being connected wtih a copper sphere and the positive with the earth.

S S′ are of ebonite as well as R R *d d*, so that B is quite isolated as the earth in the space. B is surrounded by the atmosphere. *d′ d′ d′ d′ d′ d′* are a series of Geissler tubes with copper ends above and below. All the upper ends are connected with a wire which goes to the earth, consequently a current runs in the direction of the arrows through the air, and the Geissler tubes become luminous when the electrical machine is set into operation.

These Geissler tubes represent the upper part of the atmosphere which becomes luminous when the aurora borealis is observed in the northern hemisphere. The phenomena produced by the Lynström apparatus are quite consistent with the theory advocated by Swedish observers that electrical currents emanating from the earth and penetrating into the upper regions produce auroræ in both hemispheres. The experiment differs from the



apparatus of M. De la Rive, who placed his current *in vacuo*, and did not show the property of ordinary atmospheric air of allowing to pass unobserved at the pressure of 760 mm. a stream of electricity which illuminates a rarified atmosphere. The experiment is most attractive, and hundreds of persons witness it every day.

The arrangements for the general daily meetings of the Congress are very good. Every morning the seven sections meet at nine o'clock and discuss the subjects placed on the *ordre du jour*. At three o'clock all the members meet in the Salle des Etats, under the presidency of one or other of the presidents of the various geographical societies of Europe. No discussion takes place at these general meetings, but the presidents of sections report on the discussions which have taken place at the morning sitting. Consequently, all who attend the evening meeting obtain a summary of the transactions of the day. Visitors are admitted to the general meetings only. Sometimes several sections meet together in the morning to deliberate on subjects of common interest, and general deliberations will be proposed at the end of the session.

A subject very much discussed has been the adoption of a first meridian. Struve proposed Greenwich. One of the most interesting questions has been on the substitution of the centesimal for the sexagesimal division of the quadrant, or of the entire sphere. It was decided by twenty-three to seven in favour of the centesimal division of the quadrant, reserving the larger question of its extension to the entire sphere till the matter is brought before the general meeting. The present system found no advocate. M. Bousquet de la Grie's proposal for dividing the compass into 360 points, to be reckoned from left to right, has also been approved.

The question of ascending currents in the atmosphere has been seriously discussed, M. Faye maintaining that only descending waterspouts have been observed. M. Faye's theories, however, have found very little support. The general opinion, as supported by Mohn and others, being that no descending current can be observed without an ascending one, so that there is a circular rotation of the atmosphere in altitude, and the upper strata are in constant communication with inferior strata of the atmosphere.

A commission has been appointed on the question of a great Transiberian railway. The Russian colonel Bogdanovitch spoke in favour of a line by Ekaterineburg and Tiumen, which has the advantage of putting Europe into communication with the large rivers of Southern Siberia. He said that the Russian government had decided upon the construction of a section 1,000 miles long.

Lectures were delivered by MM. Gerard Rohlfs, Nachtigall, and Schweinfurth, on the exploration of Central Africa, and these intrepid explorers answered a number of questions in reference to their travels.

On Sunday about 300 members, amongst them a number of ladies, visited Compiègne to see the museum of Cambodian antiquities, collected by M. Delaporte, a lieutenant in the French national service, and exhibited in the ex-imperial palace inhabited by Napoleon III. M. Delaporte published in 1873, at Hachette's, a large work in two folio volumes, with an immense number of illustrations, and a graphic atlas in chromolithography. The King of Cambodia, having been admitted to a French protectorate, sent a number of antiquities to Compiègne, where M. Delaporte has organised the museum which was visited on Sunday. M. Delaporte himself was in attendance to explain the manner in which all those astonishing relics of an unknown part had been brought to light. These monuments have undergone a systematic destruction, it is supposed, in the fifth century B.C., and are mostly concealed in the centre of immense forests which have grown since that time, and situated in infested districts which are mostly inhabited by tigers and poisonous snakes. It was M. Jules Simon who had the honour to grant the mission whose results have been so fruitful, and the zeal elicited by explorers was so great that the credit of 10,000 francs granted was almost sufficient to collect a quantity of stones which fill the basement of the Palace.

Of the juries appointed by the Geographical Congress five have given their awards, while the remaining two have not yet come to any decision. Letters of distinction, the highest reward the Congress can bestow, have been conferred upon England—namely, in Group 1 upon the Topographical and Trigonometrical Office of India and the Ordnance Survey Office of Southampton; in Group 2 upon the Hydrographic Office; in Group 3 upon the Meteorological Office, the office of Geological Survey of Great Britain, and the Royal Geographical Society of London; in Group 4 upon the Palestine Exploration Fund for maps and plans and photographic reliefs. Letters of distinction have also been conferred in the United States upon: Group 2 the Navy Department; Group 3 the United States Signal Service, and upon Mr. William Martin for a description of the island of Hawai. Numerous first-class medals have, moreover, been conferred upon Englishmen and Americans.

THE MANATEE AT THE ZOOLOGICAL GARDENS

OF those mammalian animals which, instead of making their customary abode the land, reside in water either fresh or salt, the Seals and Porpoises are best known by sight to the public at large. These two just named animals are representatives of two great zoological groups, the Pinnipedia and the Cetacea, the relationships

between which are not at all intimate; in other words, notwithstanding the similarity in their habits, they must have been derived independently from different, probably terrestrial, mammalian ancestors, which themselves were not intimately related. The Pinnipedia include the Seals, Sea-Lions, and Walruses, animals closely allied to the Bears, Dogs, and Cats. The Cetacea include the Whales, Dolphins, and Porpoises, which are so much modified that their correct affinities are still matters of doubt.

There is, however, still another aquatic mammalian group or order which at the present time includes among its members only two well-marked forms or genera; these being the Dugong and the Manatee. The order is that of the Sirenia, and its members differ in their organisation considerably from both the Seals and the Whales, more nearly approaching the latter, and appearing to be most nearly allied to the Ungulate Herbivora.

The Manatees—of which there are two well-defined species, one found in and at the mouths of the rivers discharging themselves on the eastern coast of intertropical America, and the other on the opposite side of the Atlantic Ocean, on the shores of Western and Southern Africa—are large-sized somewhat seal-like herbivorous animals, sometimes reaching 17 feet in length, differing from the Seals and resembling the Whales in not having any indications of hinder extremities, at the same time that the caudal portion of the body is expanded into a horizontally-flattened tail. In them the contour of the face is peculiar, the whiskered snout being much flattened, like a pointed cone with a considerable portion of the end cut off transversely. The large nostrils are situated within a short distance of one another, at the upper portion of the truncate edge; they are closed by valves during the time that the animal is submerged. The eyes are peculiarly small and inconspicuous. The external ears are wanting. The mouth is small, without front teeth, and is placed low down, the gape being close to the anterior end of the animal. The neck, from its extreme shortness, can scarcely be said to exist as such.

Neglecting the tail, the body, which is very sparsely covered with hair, has the shape of a much elongate barrel, slightly flattened above and below. The skin is very like that of the Hippopotamus. Far forward, just behind the head, the two fore-limbs project laterally from below. The elbow is conspicuous, though placed not far from the side, and the fore-arm together with the hand, form a flat oval flapper devoid of any indications of fingers, except that at the extreme edge rudimentary nails are developed. These arms are used by the animal as claspers, which can be flexed over the chest; employed as locomotor organs at the bottom of the water, or made to assist in the prehension of food. In the female the mammæ are pectoral, and the consequent general configuration has probably led to the fabulous descriptions of the existence of "mermaids."

In shape the tail is unlike that of any other animal, being spatulate. It most resembles that of the Beaver, but is a direct continuation backwards of the body, and is covered with an unmodified skin. As in the Whales and Beavers, the vertebral column forms a bony axis of support for the flattened muscular and fibrous expansion covered with thick cuticle, which forms the propelling mechanism.

The skeleton is of an extremely dense texture and very massive; the skull and ribs more resembling ivory than bone. In the number of the vertebrae which form the neck there is also a peculiarity, not shared even by its ally, the Dugong. In all mammalia there are seven cervical vertebrae, the same in the Giraffe as in the Elephant, in the Kangaroo as in Man. In the Manatee there are, however, only six, as in one other mammal only, namely, Hoffmann's Sloth. The ribs, as well as being very dense, are broader than is usually the case. As in the Whales there are no bony traces of hind limbs, a rudimentary pelvis being alone found.

As far as the soft parts are concerned, it may be mentioned that the apex of the heart is deeply cleft, more so than in the Elephant and the Seals. This is the case also in the Dugong. The arteries in many parts break up into innumerable minute branches before they become distributed, to form the so-called *retia mirabilia*. The lungs run a considerable distance along the back of the animal, nearly reaching the root of the tail, instead of being entirely included in the thoracic region.

The half-grown female Manatee which has just reached the Zoological Society's Gardens, is the first living specimen which has been seen in this country. It came from the coast of Demerara, and was three weeks on the journey, during which time it was in a big swinging tank constructed to hold it. Two previous unsuccessful attempts were made in 1866 to forward living specimens to Regent's Park; in one case the animal did not die till within two days of its reaching Southampton. The valuable memoir by Dr. Murie in the eighth volume of the Society's *Transactions* was based on the dissection of these two specimens, which were preserved immediately they died in a condition fit for minute investigation.

The living animal appears to be in a good state of health, its movements are much less active than those of the Seals, and as food it takes vegetable marrow and lettuce in preference to anything else.

A third member of the order Sirenia was the *Rhytina*, a toothless animal, sometimes reaching 24 feet in length, discovered by Steller during Behring's expedition in 1741 on the shores of the island which bears his name. The slaughter of these creatures for their flesh was so recklessly conducted that they had all disappeared in 1789, and have never been seen since. There are three skeletons of this extinct species (*Rhytina stelleri*) in existence, all in Russia.

THE WÖHLER FESTIVAL

THE 31st of July was a festive day for Chemical Germany, and for the numerous admirers of the celebrated senior of German chemistry, Prof. Wöhler of Göttingen; not only as the seventy-fifth anniversary of his birth, but also as the supposed fiftieth anniversary of his entering upon his professional duties. In 1825 Dr. Wöhler became teacher of chemistry to the Berlin "Gewerbeschule;" in 1831 he exchanged this position for a similar one in Cassel, and from 1836 up to the present day he has been forming generations of chemists who flocked to Göttingen attracted by his fame. We need not remind our readers of the numerous discoveries of this great and genial man, of which the artificial formation of urea, the production of aluminium, his researches on cyanic and cyanuric acids, on boron and silicon, his joint researches with Liebig on uric acid and benzoyl-compounds, and many others, are known to all chemists, and have opened new roads to science.

From eight o'clock in the morning until noon of the] above-mentioned day, one deputation relieved another to express their thanks and congratulations. The Faculty of Science of Tubingen sent a diploma of Doctor of Science, so that similar to the triple crown of the Head of the Roman Church, three doctor's degrees, that of Medicine, of Philosophy, and of Science are now worn by the Head of German Chemistry. The German Chemical Society at Berlin was represented by three members of iits council, two of this deputation being pupils of Dr. Wöhler. They presented an appropriate address in a handsome cover of malachite, an allusion to the services rendered by the great chemist to the allied science of mineralogy. In the evening many of the undergraduates of the University (now eleven hundred in number) expressed their admiration in the time-honoured shape of a torch procession.

The following day found Prof. Wöhler unbent by the honorary burden of the 31st of July, and some privileged friends and pupils had the pleasure of seeing him working at the analysis of a new mineral with the same zeal he would have shown fifty years ago. This formed the most pleasant part of the Wöhler Festival, being a hopeful sign of the vigour and power left to this great man. The readers of NATURE (vol. xii. p. 179) were able, only a few weeks ago, by the perusal of extracts from charming recollections of Prof. Wöhler's youth, to witness a similar proof. In fact, his youth has accompanied him into his old age, A. OPPENHEIM

THE GIGANTIC LAND TORTOISES OF THE MASCARENE AND GALAPAGOS ISLANDS*

III.

I WILL now indicate the characteristics of the different races which I have been able to recognise in the materials to which I have had access.

It has been mentioned above that the principal mark of distinction is in the form of the skull: some species having a depressed skull with the surface flat above, whilst in others it is much higher and convex above. Hand-in-hand with this difference in the skull goes another in the pelvis; the flat-headed Tortoises having a broad, horizontally dilated bridge between the obturator foramina, whilst in the round-headed form the bridge is vertically compressed. Such a distinction might have been expected between the Galapagos Tortoises on the one hand, and the Mascarene races on the other; but what justly excites our surprise is that the Galapagos Tortoises and the extinct forms of the Mascarenes belong to the same (the flat-headed) type and that, therefore, a much greater affinity exists between them, than between the extinct and living races of the Mascarenes.

I.—FLAT-HEADED TYPE

A. The *Galapagos Tortoises* may be recognised by the invariable absence of a nuchal plate, by the convergence of the posterior margins of the two gular plates which never form a straight line, by the black colour of the shell, by a large scute of the inner side of the elbow, by the double alveolar ridge of their jaws. Among the carapaces which I have examined I can distinguish five forms; of the first four severally two are more nearly related to each other than to the other pair, the fifth being intermediate between these two pairs. The degree of distinctness and affinity which obtains in the carapaces is expressed clearly and in exactly the same manner in the skulls, as will be seen from the following characteristics:—

1. In the first species (*Testudo elephantopus* of Harlan) the shell is broad and depressed, with the upper anterior profile sub-horizontal in the male, and with corrugated but not deeply sculptured plates. Sternum truncated behind. The snout is very short. Skull with an immensely developed and raised occipital crest, with a sharp outer pterygoid edge, and a deep recess in front of the occipital condyle. The skeleton of a fully adult male example and one of an immature female are in the Oxford Museum and the collection of the Royal College of Surgeons. Young individuals are by no means scarce in collections. Either this species or the next appears to have inhabited James' Island.

2. *Testudo nigrita* has likewise a broad shell which, however, is considerably higher than in the former species; the anterior profile in the male is declivous, and the plates are deeply sculptured. Sternum with a triangular excision behind. The snout is longer and the occipital crest low; but the outer pterygoid edge is equally sharp, and the recess in front of the occipital condyle equally deep as in *T. elephantopus*. The principal specimens examined by myself of this species, are one 41 inches long, in the British Museum; the type of the species (described and named by Dumeril and Borbron) in the collection of the Royal College of Surgeons; and the large skull in the British Museum, figured by Dr. Gray under the name of *Testudo planiceps*.

3. Porter's account of the race inhabiting Charles Island is sufficiently characteristic to enable us to recognise it in an adult specimen, the shell of which is elongate, compressed into the form of a Spanish saddle, and of a dull colour without any polish. The sterum is truncated behind. Skull with the outer pterygoid edge flattened, with the tympanic cavity much produced backwards, and without recess in front of the occipital condyle. The only adult example wdich I have examined is 33 inches long, and belongs to the Museum of Science and Arts, Edinburgh. It was lent to me by the Director, Mr. T. C. Archer, who most kindly allowed the skull and limb-bones to be extracted, which could be effected without the least injury to the outward appearance of the specimen. This species I have named *Testudo ephippium*.

4. The smallest of the Galapagos Tortoises is one for which I have proposed the name *Testudo microphyes*, the carapace of a fully adult male being only 22½ inches long. We may presume that this specimen, for an examination of which I am indebted to the Museum Committee of the Royal Institution of Liverpool, is a representative of the race from Hood's Island, Porter having expressly stated that the tortoises of that island are small, and similar to those of Charles Island. Indeed, the shell is elongate as in *T. ephippium*, but the anterior profile is declivous. The skull has the characteristics of a young skull of one of its more gigantic congeners; the outer pterygoid edge is flat, and there is no recess in front of the occipital condyle, as in the species from Charles Island.

5. In the last species (*Testudo vicina*) the skull is depressed as in the first, with the upper exterior profile sub-horizontal in the male, and with the lateral anterior margins reverted so as to approach the peculiar shape of *T. ephippium*. The concentric sculpture of the plates is distinct. Sternum of quite a peculiar shape, much constricted and produced in front, and expanded and excised behind. The skull is extremely similar to that of *T. ephippium*. Unfortunately nothing is known of the history of the adult male example which formerly was in the possession of Prof. Huxley and ceded by him to the collection of the British Museum.

B. The *Mauritian Tortoises*.—It would be a matter of considerable interest to ascertain whether the tortoises of Mauritius lacked the nuchal plate, like the Galapagos races to which in other respects they are so closely related. The only carapace which I have seen is deprived of the epidermoid scutes, and, besides, so much injured in the nuchal region that it is impossible to determine the absence or presence of a nuchal plate. But the Mauritian tortoises were characterised by a peculiarity hitherto unknown among recent land tortoises, viz., by a treble serrated dental ridge along the lower jaw.

The examination of a considerable number of bones, part of which were obtained during the search for Dodo-bones, and are now in the British Museum, whilst for others from the district of Flacq I am indebted to M. Bouton, has convinced me of a multiplicity of species in this island. The majority of the bones were found near Mahe'bourg, in a ravine of no great depth or steepness, which apparently once conveyed to the sea the drainings of a considerable extent of circumjacent land, but which has been stopped to seaward most likely for ages by an accumulation of land. The outlet from this ravine having

* The substance of this article is contained in a paper read by the auther before the Royal Society in June, 1847, and will appear in the forthcoming volume of the "Philosophical Transactions," and to which I must refer for the scientific portion and other details. Some facts which have come to my knowledge subsequently to the reading of this paper, are added. Continued from p. 261.

been thus stopped, a bog was formed called "La Mare aux Songes," with an alluvial deposit varying in depth from three to twelve feet. The tortoise bones occur at a depth of three or four feet, imbedded in a black vegetable mould; lighter coloured specimens are from the vicinity of the springs. (Zool. Trans., vi. p. 51). Among these bones I have distinguished four species, the more important characteristics of which may be particularised as follows:—

1. *Testudo triserrata.*—Proximal half of the scapula trihedral, with the anterior side convex; acromium trihedral, straight. Coracoid anchylosed to scapula at an early stage of growth. Humerus moderately slender, with the shaft flattened, and a deep hollow between the head and tuberosities. Shaft of the ulna narrow, much twisted. Ossa ilei short and broad; transverse and vertical diameters of pelvis subequal; front part of pubic bones abruptly bent downwards. Femur stout, with much dilated condyles; a deep and broad cavity between the head and trochanters.

2. *Testudo inepta.*—Proximal half of the scapula trihedral, with the anterior side concave; acromium compressed, with the end curved. Coracoid never anchylosed to the scapula. Humerus moderately slender, with the upper half of the shaft trihedral, and without hollow behind the head. Shaft of the ulna broad, not much twisted. Ossa ilei narrow and long; vertical diameter of pelvis much exceeding in length the horizontal; front part of pubic bones gently declivous. Femur stout, with much dilated condyles, and with a deep and narrow cavity between the head and trochanters.

3. *Testudo leptocnemis*, sparsely represented, with a scapulary similar to that of *T. triserrata;* ossa ilei of moderate length and width, femur slender, with moderately dilated condyles, and with a deep and broad cavity between the head and trochanters.

4. *Testudo boutonii*, known from scapulary and humerus only. The former bone is strongly compressed; acromium with the end curved. Coracoid not anchyclosed to scapula. Humerus very stout, with the shaft trihedral in its whole length, and without hollow behind the head.

C. The *Rodriguez Tortoise.*—The remains from Rodriguez which I have hitherto examined, and for which I am indebted to M. Bouton and to the trustees of the Glasgow Museum, consist of fragments of the cranium, perfect cervical vertebræ, pelvis, and the larger leg-bones. They indicate one of the best marked species of the entire group, with a double alveolar ridge, and with the neck and limbs of greater length and slenderness than in any other species. The neural arch of the sixth nuchal vertebra is perforated by a large ovate foramen on each side close to the anterior apophyses. These perforations were closed by membrane in the living animal, and evidently caused by the pressure of the apophyses of the preceding vertebra, the animals having had the habit of bringing the neck in a vertical position, so that these two vertebræ were standing nearly at a right angle. Some of the bones are exceedingly large, larger than any of those from the Mauritius, and must have belonged to individuals of the size of our large living male from Aldabra.

II.—Round-headed Type: *T. indica.*

To this type belong all the specimens with a nuchal plate which have been deposited in British collections within the last forty years, or which elsewhere have been described or figured; and more especially the Tortoises from Aldabra. Whether all these specimens have come from this small group is impossible to say, as we know very little or nothing of their history. Although I have succeeded in bringing together a considerable number of specimens, from which it would appear that also in this much smaller division several races could be distinguished, I think it best to defer, for the present, the detailed publication of the results of my examination which ere long may be supplemented or modified by important accessions.

In conclusion we may ask whether the facts which I have endeavoured to place before the readers of NATURE are more readily explained with the aid of the doctrine of a common or manifold origin of animal forms.

The naturalists who, with Darwin, maintain a common origin for allied species, however distant in their habitats, will account for the occurrence of the tortoises in the Galapagos and Mascarenes in the same way as, for instance, for the distribution of the Tapirs, viz., by the hypothesis of changes of the surface of the globe. Taking into consideration other parts of the Faunæ, they would have to assume, in this case, a former continuity of land (probably varying in extent and interrupted at various periods) between the Mascarenes and Africa, between Africa and South America, and finally between South America and the Galapagos. Indeed, the terrestrial and freshwater faunæ of Tropical America and Africa offer so many points of intimate relationship, as to support very strongly such a theory. The Tortoises, then, would be assumed to have been spread over the whole of this large area, without being able to survive long the arrival of man or large carnivorous mammals. The former, especially before he had provided himself with missile weapons, would have eagerly sought for them, as they were the easiest of his captures yielding a most plentiful supply of food; consequently they were exterminated on the continents, only some remnants being saved by having retired into places which by submergence became separated from the mainland before their enemies followed them. With this hypothesis we would be obliged to contend for this animal type an age extending over enormous periods of time, of which the period required for the loss of power of flight in the Dodo or Solitaire is but a fraction.

To my mind the advocacy of an independent origin of the same animal type, however highly organised, in different localities, seems equally justified. It has been urged that closely similar structures of the animal organism have been developed without genetic relationship; so, also, the same complex organic compound, as sugar, is produced normally by the plant and abnormally by the human organism. Without overstepping too far the limits of probability, we may assume that some Land-Tortoises were carried by stream and current from the American Continent to the Galapagos, and that others from Madagascar or Africa, found in a similar manner a new home in the Mascarene Islands. These tortoises may originally have differed from each other, like the *Testudo tabulata*, *radiata*, *sulcata* of our days, possibly not exceeding these species in size, but being placed under the same external physical conditions evidently most favourable for their further development, they assumed in course of time the same gigantic proportions and other peculiarities, the modifications in their structure which we observe now being partly genetic, partly adaptive.

Thus this curious phenomenon in the geographical distribution of animals can be explained by either of those two theories, and does not appear to me to strengthen the position of one more than that of the other. The multiplicity of the races which I have pointed out above I need not further discuss. As regards the Galapagos, this fact is quite in accordance with what has been long recognised in the distribution of the birds of the same archipelago, and the co-existence of several races in Mauritius is perfectly analogous to the variety of species of Dinornis in New Zealand.

ALBERT GÜNTHER

NOTES

Prof. Schönfeld, of Mannheim, has been appointed successor to the late Prof. Argelander as Director of the Observatory at Bonn, and will enter upon his duties on Sept. 1. Dr.

Valentiner, chief of the German Astronomical Expedition to Cheefoo, and first assistant at the Leiden Observatory, will succeed Schönfeld at Mannheim.

THE biennial general meeting of the essentially International Astronomical Society will be held at Leiden from the 13th to the 16th inst.

THE Professorship of Natural History at the Newcastle College of Physical Science, vacated by the removal of Dr. Alleyne Nicholson to St. Andrews, has been filled by the appointment of Mr. George S. Brady, of Sunderland. The chair has hitherto been held in conjunction with the Lectureship on Physiology in the Durham University College of Medicine, in Newcastle, a union which it has been found expedient to abolish. The appointment we now record will be regarded with satisfaction by every one who is desirous of seeing the value of the labours of our working naturalists duly recognised in the localities where they have carried on their work.

THE Natural History Society of Newcastle, one of the best in the kingdom, appears to be going through a crisis. At a recent meeting, several of the honorary curators sent in their resignations, including names so well known as H. B. Brady, G. S. Brady, H. B. Bowman, Lebour, and Freire-Marreco, together with both the secretaries. We understand that an informal meeting has been held by a number of those interested in the systematic teaching of natural history, to take steps for obtaining specimens to form an independent typical collection for the use of the professors of the College in their lectures. This is as it should be. Collecting for mere collecting's sake is no part of science; as an adjunct to systematic teaching it is invaluable. A great centre like Newcastle should possess such a collection formed for such a purpose; and the effort is worthy of support and assistance from all friends of science teaching.

AT the distribution of prizes to the Taunton College School by the High Sheriff of Somerset on July 29th, the headmaster, Mr. Tuckwell, commented severely on the exclusion of science from the competition of the Huish Scholarship, to which we drew attention in these columns some weeks ago. The High Sheriff said that he was one of the Trustees who had prepared the scheme; that, looking to the Founder's expressed desire to forward the study of theology, they had wished so to shape the examination as to carry out his views; but that the Trustees were not a bigoted body, nor unduly wedded to their first opinion; that Mr. Tuckwell's criticisms deserved attention; and that he promised on behalf of the Trustees to reconsider the arrangements before another year. In thanking the High Sheriff for the liberal tone in which he had met the questions raised, Mr. Tuckwell protested against the belief that a divine worthy of the name could be trained in the present day by any system of education which should exclude a deep knowledge of science.

M. MOUCHEZ, the new member of the Academy of Sciences, has just organised a Practical School of Astronomy at Montsouris. Refractors, equatorial as well as meridian, and horizontal telescopes will be placed at the disposition of any competent person wishing to be instructed in astronomy. An astronomer from the National Observatory will instruct the pupils without fee; the Minister of Marine has ordered that two marine officers should always be in attendance for this purpose. The course of instruction will embrace celestial photography and spectrum analysis. No qualification of nationality will be required for admittance, only general competency.

M. WURTZ, Professor in the Faculty of Medicine of Paris, has been appointed Professor in the Faculty of Sciences.

THE French Association for the Advancement of Science commences its sittings at Nantes this day week.

M. LE VERRIER has presented to the Prefect of the Seine a plan for connecting, by means of a telegraphic network, all the public clocks of Paris with the principal clock of the Observatory.

THE British Medical Association brought its Edinburgh meeting, which has been a very successful one, to a close last Friday. Brighton has been selected as the place of meeting for next year, with Sir J. Cordy Burrows as President-elect.

IT turns out that in the recent attack on the Palestine Exploring party, there were nine wounded, including Lieutenants Conder and Kitchener. Measures have been taken to secure the arrest and punishment of the assailants.

IT appears from a letter in Friday's *Times* that that most interesting relic of antiquity, "Cæsar's Camp" at Wimbledon "is being deliberately levelled to the ground, effaced and destroyed by its owner, Mr. Drax, the member for Wareham." It is difficult to believe in an act of such deliberate vandalism. Mr. Drax is stated to have asked such an exorbitant price for the land that negotiations were rendered impossible; had Sir John Lubbock's "Ancient Monuments Bill" been passed this session, this evidently doomed and unreplaceable monument of antiquity could easily have been saved, and the owner would have received a fair price for his land.

M. WILFRID DE FONVIELLE made a successful night ascent on August 1, for the purpose of observing meteorites. From 10 P.M. to 4 A.M., forty-two meteorites were observed between Rheims and Fontainebleau. Some of these emanated from Cassiopeia, others from Perseus, and as many as nine took a vertical direction, descending from the part of the heavens which was concealed by the balloon. None of these were very noteworthy, and it is probable that none would have been observed at the surface of the earth. Eight persons were in the car, and another trip was to be made last Sunday from Paris.

THE International Geographical Exhibition is not the only one of the kind now open in Paris; as our readers no doubt know another has been established by M. Nicolle at the Palais des Champs Elysées for Fluviatile and Maritime Industries, and is attracting an immense number of visitors. It will continue up to the month of November, when another will be opened for Electrical Industries. The English Section in the Fluviatile and Maritime Exhibition is very successful. The Board of Trade has sent specimens of the apparatus in use for salvage and for warnings at British seaports; the contributions by private individuals also give a fair idea of British Maritime Industries.

ON Saturday last a deputation from the Royal Colonial Institute waited upon Lord Carnarvon to urge upon Government the propriety of establishing a Colonial Museum in London. The Government, it seems, have been entertaining the idea of establishing such an institution, and Lord Carnarvon spoke hopefully of the possibility of accomplishing the praiseworthy object; he thinks it would be well to place it contiguous to the India Museum.

A CORRESPONDENT of the *Illustrated London News* of Aug. 1, writes, July 25, from Pen-y-Gardden, Denbighshire, describing a shower of hay similar to that referred to in last week's NATURE, p. 279, as having occurred at Monkstown. It passed over the town of Wrexham, five miles distant from Pen-y-Gardden, and in a direction contrary to that of the wind in the lower atmosphere.

MR. MAGNÚSSON, writing to yesterday's *Times*, reports the continued outbreak of volcanic eruptions in various parts of Iceland, and makes an earnest appeal to the British public for help to those, and they are many, who have been rendered quite destitute—landless and homeless—by the calamity. No people are

more deserving of help than the Icelanders, and moreover, they have the claim upon us of close kindred.

WE have received the "Fourth Report of the Meteorological, Magnetic, and other Observatories of the Dominion of Canada for 1874," pp. 316. The Report gives full details of the tri-daily observations made at the various meteorological stations, the monthly means and extremes, and, as regards temperature and rainfall, a comparison of the results of 1874 with the averages of previous years. The most important fact perhaps noted in the Report is the gradual extension of the system over British North America.

FROM a letter from the Canada correspondent of *The Scotsman*, dated 23rd July, 1875, we learn that the summer in Canada has been unusually cold. The nights have been quite chilly so as to necessitate extra covering; and during the whole summer the temperature has only once reached 90°; on the evening of the 18th July it fell to 43°. Capt. Richardson, of the *Nova Scotian*, which had just arrived, reports having passed a large number of icebergs on the coast, and having sailed through floating ice for twenty-four hours. Reports from the extreme north state that the ice had given way to a greater extent than for many years, in which case the Arctic Expedition will probably reach a higher latitude before the summer closes than was expected.

IN the *Bulletin Hebdomadaire* of the Scientific Association of France it is stated, after a careful review of the loss sustained by the different districts, that the total loss caused by the late inundations in the South of France exceeds the enormous sum of eighty millions of francs, and that 550 persons perished.

THE June number (just issued) of the *Bulletin* of the French Geographical Society contains an interesting chart of the world, by M. Malte-Brun, intended to exhibit at a glance the proportion of the known and unknown regions. Countries known in their details are wholly covered with red, and those of which we have a good general knowledge, with red having a slight dash of white. White, with specks of red, indicates countries imperfectly known, while those entirely unknown are left in white. Of course the various shades of red run into each other, but countries unknown and imperfectly known considerably exceed in extent the two other classes, so that there is little danger of exploring and surveying parties wanting work for many years to come. The greater part of Asia and America comes under the two last categories, as also nearly the whole of Africa and Australia; indeed, notwithstanding all that has recently been done in the way of geographical discovery, the white at least balances the red in Malte-Brun's chart.

THE same number of the *Bulletin* contains a valuable illustrated paper, by M. L. Chambeyron, giving some details concerning the physical geography of New Caledonia.

THE *Geographical Magazine* states that the committee of the statistical section of the Russian Geographical Society appointed to report on a proposition made by MM. Sobolyef and Jansson, to publish a gazetteer of Central Asia, has reported favourably on the subject. They recommend that particular attention be paid to historical geography and ethnology, as statistical data are subject to frequent alterations. The territory to be embraced by the work is bounded on the north by the watersheds of the Ural and Irtysh; on the west coast by the Caspian; on the south by the Elburz, the Hindu Kush, and the Karakorum Range; and in the east by Mongolia. The authorities for every statement made, are to be carefully referred to for future reference, and great care is to be taken with respect to the spelling. A final programme will be laid down by a joint committee of the three sections of the Russian Geographical Society.

THE New York *Tribune* of July 10 contains a long article, with many illustrations, on Prof. Hall's magnificent collection of fossils, which, at a cost of $65,000 has been secured for the American Museum of Natural History, at the Central Park, New York.

THE Watford Natural History Society has already taken an established place in the first rank of our local societies and field-clubs. It has not been many months in existence, but already have we received the first number of its neatly printed *Transactions*, containing the following papers:—"The Cretaceous Rocks of England," by J. L. Lobley, F.G.S.; "Notes on the Flora of the Watford District," by Arthur Cottam; and "Notes on the proposed Re-issue of the Flora of Hertfordshire, with Supplementary Remarks on the Botany of the Watford District," by R. A. Pryor, F.L.S.

IN connection with the Sheffield Ladies Educational Association, Mr. Barrington Ward, F.L.S., has recently concluded a successful and well attended series of elementary lectures on Botany. The results of the examinations on the lectures appear to have been highly satisfactory, and to judge from the specimen examination paper sent us, the questions were well calculated to test the real knowledge of the students.

IN Part I. No. 1, for 1875, of the *Journal* of the Asiatic Society of Bengal will be found a very valuable illustrated paper by Major G. E. Fryer, "On the Khyeng People of the Sandoway District, Arakan." Details are given of the habits of the people, with a brief grammar and copious vocabulary of their language.

MR. G. K. GILBERT's preliminary Geological Report contained in Lieut. Wheeler's Report of the work done by his expedition in 1872 in Nevada, Utah, and Arizona, gives a few interesting data bearing on the former glaciation of N. America. About White's Peak, in the Schell Range, Nevada, are the terminal moraines of five or six glaciers that descended to 8,000 feet altitude in lat. 39° 15′. At about the same altitude, and in lat. 39°, are moraines and an alpine lake upon the flanks of Wheeler's Peak, of the Snake Range, Nevada. Old Baldy Peak (N. lat. 38° 18′), near Beaver, Utah, overlooks two terminal moraines, one of which contains a lakelet at an altitude of about 9,000 feet. No traces were seen of a general glaciation, such as the Northern States experienced, and the cumulative negative evidence is of such weight that Mr. Gilbert is of opinion that the glaciers of the region referred to were confined to the higher mountain-ridges.

THE same observer shows that the level of what is now Great Salt Lake must at one time have been much higher and its area much greater than it is at present. Former levels are marked by a series of conspicuous shore-lines carried on the adjacent mountain slopes to a height of more than 900 feet. When the waters rose to the uppermost beach they must have covered an area of about 18,000 square miles, eleven times that of the present lake, and a trifle less than that of Lake Huron; the average depth was 450 feet, and the volume of water nearly 400 times greater than now. The lake was diversified by numerous rocky islands and promontories, and its water was fresh. The flooding of the Great Salt Lake valley, Mr. Gilbert believes, marked a temporary climatal change, and was contemporary with the general glaciation of the northern portion of N. America, and with the formation of the numerous local glaciers of western mountain systems; he considers it a phenomenon of the Glacial Epoch. While the general climatal change that caused or accompanied that epoch (depression of temperature, carrying with it decrease of evaporation, if not increase of precipitation) may be adduced as the cause of the inundation of Utah, Mr. Gilbert sees no reason to suppose that the relative humidities of

the various positions of the N. American continent were greatly changed; and this consideration will aid in accounting, he thinks, for the curious fact that the ice in the eastern seaboard stretched unbroken past the fortieth parallel, while under the same latitude in the Cordilleras no glaciers formed below 9,000 feet.

THE third part of the second series of the magnificent work of Mr. William H. Edwards upon the Butterflies of North America has been published by Messrs. Hurd and Houghton, of Cambridge, Massachusetts, and embraces five plates, executed by Miss Mary Peart. The plates represent species of *Papilio*, *Argynnis*, *Apatura*, *Chionobas*, and *Lycæna*; all of them being rare and, for the most part, unfigured species, and also many but recently described.

WE have received the *Journal* of the Anthropological Society for April and July, containing in full the papers which have appeared in abstract in our reports of the meetings of the Society. Many of the papers are of great value, and the illustrations, especially those of the Andamanese, are very interesting.

IT is rumoured that, on the retirement of Sir Henry James from the directorship of the Ordnance Survey, a post which he has filled during a lengthened period with so much distinction, he will be succeeded by Col. A. Ross Clarke. We congratulate the Government on this selection, just at once to a most meritorious officer and to Science and the State. Col. Clarke's eminence as a mathematician and a geodesist are too highly appreciated wherever those sciences are cultivated, both at home and abroad, to need any comment from us.

THE additions to the Zoological Society's Gardens during the past week include a Manatee (*Manatus americanus*) from Demerara, a Ground Hornbill (*Bucorvus abyssinicus*), a White-thighed Colobus (*Colobus bicolor*) from West Africa, a Rose-crested Cockatoo (*Cacatua moluccensis*) from Moluccas, deposited; two Jaguars (*Felis onça*) from America, a Squirrel Monkey (*Saimaris sciurea*) from Brazil, purchased; four Amherst Pheasants (*Thaumalea amherstiæ*), a Siamese Pheasant (*Euplocamus prœlatus*), and two Vinaceous Doves (*Turtur vinaceus*) bred in the Gardens.

PHYSICAL PROPERTIES OF MATTER IN THE LIQUID AND GASEOUS STATES*

THE investigation to which this note refers has occupied me, with little intermission, since my former communication in 1869 to the Society, "On the Continuity of the Liquid and Gaseous States of Matter." It was undertaken chiefly to ascertain the modifications which the three great laws discovered respectively by Boyle, Gay-Lussac, and Dalton undergo when matter in the gaseous state is placed under physical conditions differing greatly from any hitherto within the reach of observation. It embraces a large number of experiments of precision, performed at different temperatures and at pressures ranging from twelve to nearly three hundred atmospheres. The apparatus employed is, in all its essential parts, similar to that described in the paper referred to; and so perfectly did it act that the readings of the cathetometer, at the highest pressures and temperatures employed, were made with the same ease and accuracy as if the object of the experiment had been merely to determine the tension of aqueous vapour in a barometer-tube. In using it the chief improvement I have made is in the method of ascertaining the original volumes of the gases before compression, which can now be know with much less labour and greater accuracy than by the method I formerly described. The lower ends of the glass tubes containing the gases dip into small mercurial reservoirs formed of thin glass tubes, which rest on ledges within the apparatus. This arrangement has prevented many failures in screwing up the apparatus, and has given more precision to the measurements. A great improvement has also been made in the method of preparing the leather-washers used in the packing for the fine screws, by means of which the pressure is obtained. It consists in saturating the leather with grease by heating it *in vacuo* under melted lard. In this way the air enclosed within the pores of the leather is removed without the use of water, and a packing is obtained so perfect that it appears, as far as my experience goes, never to fail, provided it is used in a vessel filled with water. It is remarkable, however, that the same packing, when an apparatus specially constructed for the purpose of forged iron was filled with mercury, always yielded, even at a pressure of forty atmospheres, in the course of a few days.

It is with regret that I am still obliged to give the pressures in atmospheres, as indicated by an air- or hydrogen manometer, without attempting for the present to apply the corrections required to reduce them to true pressures. The only satisfactory method of obtaining these corrections would be to compare the indications of the manometer with those of a column of mercury of the requisite length; and this method, as is known, was employed by Arago and Dulong, and afterwards in his classical researches by Regnault, for pressures reaching nearly to thirty atmospheres. For this moderate pressure a column of mercury about 23 metres, or 75 feet, in length had to be employed. For pressures corresponding to 500 atmospheres, at which I have no difficulty in working with my apparatus, a mercurial column of the enormous height of 380 metres, or 1,250 feet, would be required. Although the mechanical difficulties in the construction of a long tube for this purpose are perhaps not insuperable, it could only be mounted in front of some rare mountain escarpment, where it would be practically impossible to conduct a long series of delicate experiments. About three years ago I had the honour of submitting to the Council of the Society a proposal for constructing an apparatus which would have enabled any pressure to be measured by the successive additions of the pressure of a column of mercury of a fixed length; and working drawings of the apparatus were prepared by Mr. J. Cumine, whose services I am glad to have again this opportunity of acknowledging. An unexpected difficulty, however, arose in consequence of the packing of the screws (as I have already stated) not holding when the leather was in contact with mercury instead of water, and the apparatus was not constructed. For two years the problem appeared, if not theoretically, to be practically impossible of solution; but I am glad now to be able to announce to the Society that another method, simpler in principle and free from the objections to which I have referred, has lately suggested itself to me, by means of which it will, I fully expect, be possible to determine the rate of compressibility of hydrogen or other gas by direct reference to the weight of a liquid column, or rather of a number of liquid columns, up to pressures of 500 or even 1,000 atmospheres. For the present it must be understood that, in stating the following results, the pressures in atmospheres are deduced from the apparent compressibility, in some cases of air, in others of hydrogen gas, contained in capillary glass tubes.

In this notice I will only refer to the results of experiments upon carbonic acid gas when alone or when mixed with nitrogen. It is with carbonic acid, indeed, that I have hitherto chiefly worked, as it is singularly well adapted for experiment; and the properties it exhibits will doubtless, in their main features, be found to represent those of other gaseous bodies at corresponding temperatures below and above their critical points.

Liquefaction of Carbonic Acid Gas.—The following results have been obtained from a number of very careful experiments, and give, it is believed, the pressures, as measured by an air-manometer, at which carbonic acid liquefies for the temperatures stated:—

Temperatures in Centigrade degrees.	Pressure in atmospheres.
0	35·04
5·45	40·44
11·45	47·04
16·92	53·77
22·22	61·13
25·39	65·78
28·30	70·39

I have been gratified to find that the two results (for 13°·09 and 21°·46) recorded in my former paper are in close agreement with these later experiments. On the other hand, the pressures I have found are lower than those given by Regnault as the result of his elaborate investigation (*Mémoires de l'Academie des Sciences*, vol. xxvi. p. 618). The method employed by that distinguished physicist was not, however, fitted to give accurately

* "Preliminary Notice of further Researches on the Physical Properties of Matter in the Liquid and Gaseous States under varied conditions of Pressure and Temperature." Paper read before the Royal Society by Dr. Andrews, F.R.S., Vice-President of Queen's College, Belfast.

the pressures at which carbonic acid gas liquefies. It gave, indeed, the pressures exercised by the liquid when contained in large quantity in a Thilorier's reservoir; but these pressures are always considerably in excess of the true pressures in consequence of the unavoidable presence of a small quantity of compressed air, although the greatest precautions may have been taken in filling the apparatus. Even $\frac{1}{500}$ part of air will exercise a serious disturbing influence when the reservoir contains a notable quantity of liquid.

Law of Boyle.—The large deviations in the case of carbonic acid at high pressures from this law appeared distinctly from several of the results given in my former paper. I have now finished a long series of experiments on its compressibility at the respective temperatures of 6°·7, 63°·7, and 100° Centigrade. The two latter temperatures were obtained by passing the vapours of pyroxylic spirit (methyl alcohol) and of water into the rectangular case with plate-glass sides, in which the tube containing the carbonic acid is placed. The temperature of the vapour of the pyroxylic spirit was observed by an accurate thermometer, whose indications were corrected for the unequal expansion of the mercury; while that of the vapour of water was deduced from the pressure as given by the height of the barometer and a water-gauge attached to the apparatus. At the lower temperature (6°·7) the range of pressure which could be applied was limited by the occurrence of liquefaction; but at the higher temperatures, which were considerably above the critical point of carbonic acid, there was no limit of this kind, and the pressures were carried as far as 223 atmospheres. I have only given a few of the results; but they will be sufficient to show the general effects of the pressure. In the following Tables p designates the pressure in atmospheres as given by the air-manometer, t' the temperature of the carbonic acid, ϵ the ratio of the volume of the carbonic acid under one atmosphere and at the temperature t' to its volume under the pressure p' and at the same temperature, and θ the volume to which one volume of carbonic acid gas measured at 0° and 760 millimetres is reduced at the pressure p and temperature t':—

Carbonic Acid at 6°·7.

p. at.	t'. °	ϵ.	θ.
13·22	6·90	$\frac{1}{14\cdot36}$	0·07143
20·10	6·79	$\frac{1}{23\cdot01}$	0·04456
24·81	6·73	$\frac{1}{29\cdot60}$	0·03462
31·06	6·62	$\frac{1}{39\cdot57}$	0·02589
40·11	6·59	$\frac{1}{58\cdot40}$	0·01754

Carbonic Acid at 63°·7.

p. at.	t'. °	ϵ.	θ.
16·96	63·97	$\frac{1}{17\cdot85}$	0·06931
54·33	63·57	$\frac{1}{66\cdot06}$	0·01871
106·88	63·75	$\frac{1}{185\cdot9}$	0·00665
145·54	63·70	$\frac{1}{327\cdot3}$	0·00378
222·92	63·82	$\frac{1}{446\cdot9}$	0·00277

Carbonic Acid at 100°.

p. at.	t'. °	ϵ.	θ.
16·80	100·38	$\frac{1}{17\cdot33}$	0·07914
53·81	100·33	$\frac{1}{60\cdot22}$	0·02278
105·69	100·37	$\frac{1}{137\cdot1}$	0·01001
145·44	99·46	$\frac{1}{218\cdot9}$	0·00625
223·57	99·44	$\frac{1}{380\cdot9}$	0·00359

These results fully confirm the conclusions which I formerly deduced from the behaviour of carbonic acid at 48°, viz. that while the curve representing its volume under different pressures approximates more nearly to that of a perfect gas as the temperature is higher, the contraction is nevertheless greater than it would be if the law of Boyle held good, at least for any temperature at which experiments have yet been made. From the foregoing experiments it appears that at 63°·7 carbonic acid gas, under a pressure of 223 atmospheres, is reduced to $\frac{1}{447}$ of its volume under one atmosphere, or to less than one half the volume it ought to occupy if it were a perfect gas and contracted in conformity with Boyle's law. Even at 100° the contraction under the same pressure amounts to $\frac{1}{381}$ part of the whole. From these observations we may infer by analogy that the critical points of the greater number of the gases not hitherto liquefied are probably far below the lowest temperatures hitherto attained, and that they are not likely to be seen, either as liquids or solids, till much lower temperatures even than those produced by liquid nitrous oxide are reached.

(*To be continued.*)

NEW METHOD OF OBTAINING ISOTHERMALS ON THE SOLAR DISC*

On June 5, 1875, I devised a method for obtaining the isothermals on the solar disc. As this process may create an entirely new branch of solar physics, I deem it proper that I should give a short account of it in order to establish my claim as its discoverer.

In the American Journal, July 1872, I first showed how one can, with great precision, trace the progress and determine the boundary of a wave of conducted heat in crystals, by coating sections of these bodies with Meusel's double iodide of copper and mercury, and observing the blackening of the iodide where the wave of conducted heat reaches 70° C. If we cause the image of the sun to fall upon the smoked surface of thin paper, while the other side of the paper is coated with a film of the iodide, we may work on the solar disc as we formerly did on the crystal sections.

The method of proceeding is as follows: beginning with an aperture of object-glass which does not give sufficient heat in any part of the solar image to blacken the iodide, I gradually increase the aperture until I have obtained that area of blackened iodide which is the smallest that can be produced with a well-defined contour. This surface of blackened iodide I call the *area* of blackened temperature. On exposing more aperture of object-glass, the surface of blackened iodide extends and a new area is formed bounded by a well-defined isothermal line. On again increasing the aperture another increase of blackened surface is produced with another isothermal contour; and on continuing this process I have obtained maps of the isothermals of the solar image. By exposing for about twenty minutes the surface of iodide to the action of the heat inclosed in an isothermal, I have obtained thermographs of the above areas; which are sufficiently permanent to allow one to trace accurately their isothermal contours. There are other substances, however, which are more suitable than the iodide for the production of permanent thermographs.

The contours of the successively blackened areas on the iodide are *isothermals*, whose successive thermometric values are inversely as the successively increasing areas of aperture of object glass which respectively produced them.

As far as the few observations have any weight, the following appear to be the discoveries already made of this new method. (1) There exists on the solar image an area of sensibly uniform temperature and of maximum intensity. (2) This area of maximum temperature is of variable size. (3) This area of maximum temperature has a motion on the solar image. (4) The area of maximum temperature is surrounded by well-defined isothermals marking successive gradations of temperature. (5) The general motions of translation and of rotation of these isothermals appear to follow the motions of the area of maximum temperature which they inclose; but both central area and isothermals have independent motions of their own.

On projecting the enlarged image of a sun-spot on the blackened surface and then bringing a hot-water box, coated with lamp-black, near the other side of the paper, one may

* The discovery of a method of obtaining Thermographs of the Isothermal Lines of the Solar Disc, by Alfred M. Mayer in Silliman's *American Journal* for July.

develop the image of the spot in *red* on a dark ground. A similar method probably may serve to develop the athermic lines in the ultra-red region of the solar and other spectra.

OUR BOTANICAL COLUMN

FERULA ALLIACEA.—The late Mr. D. Hanbury was a valuable and frequent contributor to the Kew Museums, and the very last contribution made, or rather bequeathed by him, has a scientific as well as a melancholy interest. The specimen in question was a fine umbel, bearing ripe fruits of *Ferula alliacea*, Boiss., the label to which we believe was written at his dictation just before his death. Seeds of this plant were also received at Kew from him some time before the receipt of this specimen, and these have germinated, and, though healthy, are as yet naturally very small plants. In the "Pharmacographia" Mr. Hanbury refers to this plant as exhaling a strong odour of Asafœtida, but says it is not known as the source of any commercial product. In contradistinction of this, however, Mr. W. Dymock, Professor of Materia Medica at Bombay, writing on the Asafœtidas of the Bombay market in a recent number of the *Pharmaceutical Journal*, says that this plant produces one of the distinct kinds known in the above drug market under the name of "Abushaheree Hing," and is brought from the Persian Gulf ports, principally from Abushaher and Bunder Abbas, and is produced in Khorassan and Kirman. The specimens received at Kew from Mr. Hanbury appear to have been first received by him from the author of the paper in question, for he refers to having sent such specimens; therefore, if the specimens are authentic, there is no reason to doubt the truth of the statement made by Mr. Dymock, that the drug which appears in the Bombay Customs Returns as Hing or Asafœtida, is produced by this plant. It arrives in Bombay either in skins sewn up so as to form a flat oblong package, or in wooden boxes. Its appearance varies according to age, being soft, and about the thickness of treacle when quite fresh, and of a dull olive brown colour and a pure garlic odour. It becomes hard and translucent and of a yellowish brown colour after being kept some time. Slices of the root are found mixed with the resin in about equal proportion. In 1872–73 as many as 3,367 cwt. of this drug were imported into Bombay from the Persian Gulf. The information given in the paper from which we have quoted the above particulars seems to be of a trustworthy nature, and will prove a valuable addition to what we already know of the Asafœtidas.

DIVERSE EFFECTS OF THE SAME TEMPERATURE ON THE SAME SPECIES IN DIFFERENT LATITUDES.—In the *Comptes Rendus des Séances de l'Académie des Sciences*, June 1875, Mr. A. de Candolle gives the results of some experiments instituted by himself last winter to determine the degree of influence of heat on the vegetation of the same species under otherwise diverse conditions. The sudden burst into life and the rapid development of the vegetation of northern regions is proverbial; the advent of mild weather seems to bring at once into activity the accumulated vital energies, and growth is exceedingly rapid. In the south the same temperature would have far less visible effect on the same species. De Candolle has attempted by direct experiment to ascertain to what extent this influence is exercised. For this purpose he procured specimens of several common deciduous trees from Montpellier, and submitted them to the same temperature as, and with, specimens of the same species collected at Geneva. In the ordinary course of things the same species came into leaf from three weeks to a month earlier at Montpellier than at Geneva, but the specimens from the south, by the side of the northern specimens, did not unfold their leaves so early as the latter by about three weeks. The White Poplar Hornbeam and Tulip Tree were the principal trees employed. Catalpa, a very late leafing subject, exhibited less diversity in this respect. This phenomenon is equally striking in cereals and other cultivated plants. The learned author attributes these differences in effect mainly to the fact that vegetation, or external growth, never entirely ceases in the south, whereas in the north there is a long period during which internal changes and modifications of substances alone is carried on.

SCIENTIFIC SERIALS

The American Journal of Science and Art, July.—The original articles are:—On the United States Weather Map, by E. Loomis, which we have already noticed.—On a magnetic proof plane, by H. A. Rowland. The apparatus required is a small coil of wire $\frac{1}{4}$ to $\frac{1}{8}$ inch in diameter and containing 10 to 50 and a Thomson galvanometer. Having attached the small coil (or magnetic proof plane, as Mr. Rowland calls it) to the galvanometer, it has to be laid on the required spot and then suddenly pulled away and carried to a distance, and the momentary deflection of the galvanometer will be proportional to that component of the lines of force at that point which is perpendicular to the plane of the coil. By a coil of this kind it is possible to determine the intensity of the magnetic field at any point, and thus be able to make a complete map of it. Illustrations of the method are given.—On pseudomorphs of chlorite after Garnet at the Spurr Mountain Iron Mine, Lake Superior, by Raphael Pumpelly, with a coloured plate of a section magnified $\frac{22}{1}$.—A brief note on the application of the horizontal pendulum, by Harcourt Amory.—Explosive properties of methyl nitrate, by Carey Lea. This communication describes a new method and the requisite apparatus for preparing it, so that danger is reduced to a minimum.—On zonochlorite and chlorastrolite, by G. W. Hawes.—On glycogen and glycocoil in the muscular tissue of *Pecten irradians*. The glycogen has the formula of the sugars of that of the starch group plus a molecule of water. The amount of glycocoil occurring in the tissue is small. Analyses are given.—On Dr. Koch and the Missouri mastodon, by Edmund Andrews. The object of the article is to show that Dr. Koch's testimony contributes nothing reliable on the question of the occurrence of human remains in conjunction with the mastodon.—On the rate of growth of corals, by Prof. Joseph Le Conte. Examining a grove of madrepores he noticed that all the prongs grew to the same level, which at the time were very near the surface; and that all of them were dead at the tips for about three inches. The varying level of the ocean at the place is known from the Coast Survey Report, and as it seems that during the high water the madrepores *grow* up, the living points of the madrepores grow up till the descending water-level exposes and kills them down to a certain level; with the rise of the mean level again new points start upwards. The annual growth, calculated from the known rise and fall of water level, is from $3\frac{1}{2}$ to 4 inches per annum.—Results of dredging expeditions off the New England Coast in 1874, by A. E. Verrill. Lists of species are given.—Examination of gases from the meteorite of Feb. 12, 1875, by A. W. Wright.—Discovery of two new asteroids, 144 and 145, by C. H. Peters. The diameter of 144 is as the 10th, and 145 as 11·5.—The discovery of a method of obtaining thermographs of the isothermal lines of the solar disc, by Alfred M. Mayer. We reprint the paper this week.

Jahrbücher für wissenschaftliche Botanik. Herausgegeben von Dr. N. Pringsheim. Band x. Heft. I. (Leipzig, 1875).—In the first part of the tenth volume of Pringsheim's well-known *Jahrbuch* we have three papers all of very considerable importance. The first is a translation of Count Francesco Castracane's paper on the Diatomaceæ of the Carboniferous period. Ashes of coal from Liverpool yielded, on microscopic examination, several species of Diatomaceæ. The chief forms identified by Count Castracane all belong to fresh-water genera and species, viz.:—

Fragilaria Harrisonii. Sm.
Epithemia gibba. Ehrbg.
Sphenella glacialis, Kz.
Gomphonema capitatum, Ehrbg.
Nitzschia curvula, Kz.
Cymbella Scotica, Sm.
Synedra vitrea, Kz.
Diatoma vulgare, Bory.

In addition to these there existed a Grammatophora, a small Coscinodiscus, and probably an Amphipleura (*danica?*). These three marine forms were only observed on one occasion, and their presence must have indicated some accidental inroad of sea-water among the vegetation from which the piece of coal was formed. All the fresh-water forms which occurred in the coal are not to be distinguished from the living forms of the same species, a fact of great interest and importance, as it indicates the remarkable permanence of these forms in time; and it is probably an unique instance of the occurrence of species which have remained unmodified through all the lapse of ages which separates the present epoch from the coal period. Count Castracane examined other varieties of coal besides that obtained from near Liverpool, viz., coal from the mines at St. Etienne, another from Newcastle, and a third specimen

of the Scotch "Cannel coal." In all these *fresh-water* diatoms were found to be more or less numerous. The three specimens yielded different species of Diatomaceæ, but no new forms were detected. The coal for examination was finely pulverised, then placed in a piece of combustion tubing and heated to redness, a gentle stream of oxygen being passed over the substance. The temperature must not be raised too high, in order not to fuse the siliceous skeletons of the Diatomaceæ. The residue is to be treated with nitric acid and chlorate of potash, and heated, then washed carefully with distilled water, and mounted in the usual way. The examination of other varieties of coal would no doubt yield results of the highest interest and importance.—The second paper, "Beiträge zur Theorie der Pflanzenzelle," is by Dr. J. Tschistiakoff, and is devoted to the development of the pollen of *Epilobium angustifolium*. The chief point in the paper is the description of the pro-nucleus, which is also to be met with, according to Tschistiakoff, in the spores of Cryptogams. In the mother-cells of the pollen-grains the protoplasm becomes differentiated into certain zones or regions, one called the pro-nucleus, which contains the nucleolus. The pro-nucleus becomes more differentiated during the growth of the cell, and may divide or disappear. When new pro-nuclei are formed, one ultimately becomes developed into the true nucleus of the cell. The paper is illustrated by five plates.—The last paper is upon the development of the Prothallium of the Cyatheacæ, by Dr. Hermann Bauke. The species chiefly examined were: *Cyathea medullaris, Alsophila australis*, and *Hemitelia spectabilis*. The paper treats of—1. The germination of the spore and the development of the Prothallium; 2. The development of the Antheridia; 3. Development of the Archegonia and Fertilisation; 4. Male Prothallia and proliferation of Prothallia; and 5. Anomalies. The general results of the paper show that in most points the development of the Prothallium of the Cyatheacæ agrees with that of the Polypodiaceæ. A special peculiarity is the occurrence of one rarely of two, stalk-like cells to the Antheridium. The subject is exhaustively treated, and it is illustrated by five plates.

Reichert und Du Bois-Reymond's Archiv für Anatomie, Physiologie, &c., 1875. No. 1, May.—On the Pronation and Supination of the forearm, by Hermann Welcker, Halle. The author believes that the motions of pronation and supination should be regarded not merely as movements of rotation, but also as hinge-movements about an axis passing through the middle of the head of the radius and the styloid process of the ulna. For the term "extreme supination" he would substitute dorsal flexion of the radius; for "pronation," volar flexion of the radius. The actions and positions of the muscles concerned are carefully analysed, and diagrams are given illustrating and supporting the view taken.—Another paper by the same author discusses the effect of the ileo-tibial tract of the fascia lata.—In a paper on the partial excitation of nerves, Hermann Munk gives a *résumé* of his previous papers on the various effects produced on the fibres of nerves according to their situation with respect to the electrodes used, and attributes the contradictory results attained by Rollett and Bour, who believe in a difference of functional irritability in different nerve-fibres, to their having used induction-currents, while he had used constant currents in his experiments.—Dr. Dönhoff points out that calves born early in the year have a longer and thicker coat of hair than those born later in the season; and that this occurs indifferently whether the mother is kept in the stall all the year round, or only passes the winter in the stall.—Dr. Wenzel Gruber, of St. Petersburg, describes a case of the occurrence of the lateral tuberosity of the fifth metatarsal bone as a distinct epiphysis, and two cases of epiphyses on the tubercle of the trapezium.—Dr. von Ihering, in a paper on the temporal ridges of the human skull, supports Hyrtl's description of two temporal ridges, of which one or other is usually better developed. He comes to the conclusion that the upper ridge is related to the temporal fascia, and the lower to the limit of the temporal muscle, and that the temporal ridges in man correspond accurately with those of the anthropomorphic apes. He figures skulls of a Paumotu Islander and of a Hungarian in the Göttingen Museum, as instances of remarkably prominent temporal ridges.—Dr. Albert Adamkiewicz, of Königsberg, contributes a remarkable paper on the analogies to Dulong and Petit's Law of Specific Atomic Heat in Animal Temperature. He conducted an elaborate series of experiments to determine the influence of the surrounding temperature and the size of the body on the specific temperature of the animal, and to discover the physical explanation of the results attained by physiological experiments on temperature. The paper extends over nearly seventy pages, and it is impossible here to do more than indicate the subject of inquiry.

No. 2, July.—This number, in addition to the conclusion of the last-named paper, contains another by Dr. Adamkiewicz on the conductivity of muscle for heat. The conclusion drawn from experiment is that on a scale representing the conductivity of copper as 1000, water as 1·4, and that of air as 0·05, the conductivity of muscle is represented by 0·6.—J. Steiner, of Halle, gives the results of experiments with curare on fishes, newts, molluscs, starfishes, holothurians, and medusæ. He finds that in fishes there is paralysis of the central organ of voluntary motion, of the respiratory centre, and of motor nerves, and that the times at which the effects appear are in the order named. The period at which paralysis of motor nerves sets in, is much later than in higher vertebrates. In the electrical rays the power of the electrical nerves remains much longer than that of motor nerves. In crabs the phenomena are similar to those in fishes, but they appear still later. In molluscs, starfishes, and holothurians, there is only a paralysis of the central organ of voluntary motion. Curare appears to have no effect on medusæ.—Fanny Berlinerblau describes a case of direct transition from arteries to veins in the human subject.—E. Tiegel gives an account of the physiological effect of a capillary electrical current.—Dr. W. Gruber has four papers—(1) on the occurrence of a second zygomatic bone in man; (2) on the piso-hamatus muscle; (3) on an anomalous extensor digitorum communis in the hand, and a similar anomaly in the extensor digitorum longus in the foot; and (6) on the flexor pollicis longus.—W. Krause figures a human embryo at about the fourth week, with a pear-shaped allantois.—E. Meyer gives an account of comparative investigations in the mammalia on the cause of the pale or red appearance of striated muscles, and concludes that the shade of colour varies with the work done by them.—Prof. Aeby, of Berne, has a paper on the sesamoid bones of the human hand.

THE *Geographical Magazine*, August.—In connection with Lieut. Cameron's explorations, Mr. C. R. Markham takes occasion to give an interesting *résumé* of the history of the discovery of the course of the Congo, and strongly advocates that relief should be sent out to Cameron.—An interesting sketch follows of the journey of Chekanovski and Müller to the Siberian river Olena (Olenek), in 1873–74; this is illustrated by a sketch-map.—The number also contains a large sketch-map of the countries between Kashmir and Panjkirah, including Chilas, Kandia, and other districts of Dardistan, compiled by Mr. Ravenstein from the most trustworthy recent sources.—"Sign-posts on Ocean's Highway.—The Physical Education of Dust.—Mountains," is the title of an article by Mr. H. P. Malet.

SOCIETIES AND ACADEMIES

VIENNA

Imperial Academy of Sciences, April 1.—On cold mixtures, with special reference to those consisting of snow and sulphuric acid, by Prof. Pfaundler.—On palæogeological geography, by Dr. A. Boué.—On the carboniferous lime fauna of the Barents Isles (in the N.W. of Novaya Zemlya), by Dr. F. Toula; this interesting paper contains a list of no less than one hundred different species found in that remote locality.

April 15.—The following papers were read:—On anomalous dispersion, by Prof. E. Mach.—On a new direct proof for the rotation of the earth, by F. v. Sedlmayer Seefeld.—On the generating of nitrogen from the albuminoid matter undergoing assimilation in the body, by Prof. J. Seegen and Dr. Nowak.—On an apparatus for the determination of the mechanical equivalent of heat, by H. J. Puluj.—On the orbit of Planet (III.) Ate, by Director von Littrow and Dr. Holetschek.—On the variability of diurnal temperatures, by Dr. J. Hann.—On the function of lime with germ-plants of *Phaseolus multiflorus*, by Prof. J. Boehm.—Several papers of minor interest.

BERLIN

German Chemical Society, July 12.—A. W. Hofmann in the chair.—A. Borodin, in treating an amarine salt with nitrite of potassium, has obtained a nitrosoamarine. He concludes amarine to be an imidobase.—A. Michaëlis and F. Graeff have discovered a new mode of formation of phosphenylic chloride, by treating diphenylmercury with terchloride of phosphorus:

$$PCl_3 + Hg(C_6H_5)_2 = PCl_2C_6H_5 + HgClC_6H_5.$$

J. V. Janowsky published new analyses of the mineral Cronsted-

tite.—A. Kundt and E. Warburg have investigated the specific heat of the vapour of mercury. Their reason for doing so was the exception shown by most vapours with regard to the kinetic molecular theory of Clausius. If c signifies the specific heat of a gas of constant volume, and c' the specific heat of the same gas at constant pressure: then $\frac{c'}{c}$ according to that theory should be $= 1 \cdot 67$, while most gases have been found to possess the coefficient $= 1 \cdot 405$. Mercury-vapour affords a particular interest, because its molecule is monatomic compared with those diatomic volumes of most other gases. It was found to coincide with the law of Clausius $\frac{c'}{c}$ having been found $1 \cdot 67$.—A. Schüller and V. Wartha described a new ice-calorimeter, a modification of Bunsen's instrument which offers the facility of applying ice which is not entirely pure.—F. Beilstein, as also A. Claus, described derivations of dichlorobenzoic acid.—R. Gnehm described derivatives of diphenyl-amine.—V. Meyer and Lecco have treated iodide of tetramethyl-ammonium with iodide cf ethyl, and also iodide of tetracthylammonium with iodide of methyl, without observing in either case an exchange of ethyle against methyl.—W. Klobukowsky and E. Nölting have made researches respecting the constitution of rufigallic acid, which lead them to adopt the formula formerly described by M. Jaffé.—Ph. Zöller and E. A. Grete have added some new observations on xanthogenic salts as a remedy against Phylloxera. Amylic xanthogenate appears to be as efficacious as the corresponding ethylxanthogenate. Amylxanthogenate of potassium can be prepared in Vienna at the price of 3*l.* a hundredweight.—C. Liebermann has submitted emodine, the substance accompanying chrysophanic acid in the root of rhubarb, to new researches. He considers it as methylpurpurine—

$$C_{14}H_7 \left\{ \begin{array}{l} CH_3 \\ (OH)_3 \\ \left.\begin{array}{l} O \\ O \end{array}\right\} \end{array} \right.$$

By oxydation it yields anthrachinone-carbonic acid—

$$C_{14}H_7(CO_2H)(OH)_3(O_2)''.$$

Heated with powdered zinc, emodine yields anthracene.—C. Liebermann and E. Fischer have transformed purpurine into amidoalizarine—

$$C_{14}H_6 \left\{ \begin{array}{l} OH \\ (OH)_2 \\ O_2 \end{array} \right. + NH_3 = H_2O + C_{14}H_6 \left\{ \begin{array}{l} NH_2 \\ (OH)_2 \\ O_2 \end{array} \right.$$

This body, by the action of nitrous acid, gives an isomerid of alizarine, viz., purpuroxanthine.—A. Pinner fcund chloracrylic acid to be transformed by water into malonic acid.—H. Gabriel has studied the body called ammelide by Gerhardt, and has found the formula $(C_3N_3)NH(OH)_2$ predicted by this chemist.—P. Meyer has prepared a number of derivatives of glycocoll, containing phenyl or tolyl and chlorine, obtained by the action of aniline and toluidine on the chloride of chloracetic acid. He likewise has studied the action of those bases on the ether of chloracetic acid.—C. L. Jackson has found in the residues of aniline obtained from a German manufactory a base homologous with xenylamine, viz., $C_{13}H_{13}N = C_{13}H_{11}NH_2$. The radical being most likely, tolylphenyl.

Paris

Academy of Sciences, Aug. 2.—M. Frémy in the chair.—The following papers were read:—On the magnets formed of compressed powders, by M. J. Jamin.—Memoir by M. N. Joly, entitled: A gap in the teratological series filled up by the discovery of the genus "Ileadelphia."—On neutral substrata, by M. Weddell. This paper relates to another one read by M. Contejean at the meeting of July 19, with reference to botanical geography.—A critical examination of the basis upon which the calculus generally used to estimate the stability of bridges with metal supports and straight prismatical beams, is based; with propositions for the adoption of a new basis, by M. Lefort.—On the integration of an equation with partial differentials of the second order, by M. N. Nicolaides.—On the recurrent sensibility of the peripherical nerves of the hand, by M. A. Richet.—Researches on the nodules of oligoclase in the lava of the last eruption of Santorin, by M. F. Fouqué.—On the method of buying beetroot by the density of their juice, by M. Durin.—On microzymata and their functions in the different ages of one and the same being, by M. J. Bechamp.—A new process for the determination of free oxygen in urine, by M. D. Freire.—Observations by M. Blanchet, on the project of creating a sea in the interior of Africa.—A memoir by M. P. Maille, on cyclones. On the variations in the brilliancy of Jupiter's fourth satellite, with deductions regarding its physical constitution and its movement of rotation, by M. Flammarion. The author states the following results of his observations: The IV. satellite of Jupiter undergoes considerable variations in its brilliancy and appears to us as a star between the 6th and the 10th magnitudes. As its phases as seen from the earth are hardly perceptible, we conclude that its physical constitution is absolutely different from that of the moon. There is a probability (but no certainty) in favour of the hypothesis that it revolves like the moon, presenting always the same face to the planet. In that case, its brightest hemisphere would be that which it turns towards the sun when on the superior western quarter of its orbit, and its darkest hemisphere the one it turns towards the sun when it stands in the lower eastern quarter of its course. This hypothesis does not account for all the variations observed, and this little world seems to undergo atmospherical revolutions which cause its reflecting surface to vary at any point of its orbit. It appears sometimes nebulous and dim. Its reflecting power is as a rule inferior to that of the three other satellites of Jupiter.—On molecular combinations by M. C. Friedel.—On the complete separation of arsenic from animal matter and on its determination in the different tissues, by M. Arm. Gautier.—On the determination of glucose in wine, by M. A. Bechamp.—On the breaking off of the teats of guinea-pigs, by M. de Sinety.

THE SCIENCE COMMISSION REPORT ON THE ADVANCEMENT OF SCIENCE

IN our last issue we published the substance of the Eighth and final Report of the Royal Commission on Science, presided over by the Duke of Devonshire, which includes the measures deemed by that body necessary for the advancement of science in England.

We now propose to lay before our readers a summary of the evidence on the above branch of the investigation undertaken by the Commission. It must be borne in mind that the evidence given on this topic fills a Blue Book of more than 400 closely printed pages, and the extracts from it with which the Commissioners fortify the Report now under notice fill some forty pages. These extracts have been selected with obvious impartiality. The further compression which it must undergo in order to fit it for our columns must necessarily weaken the force of the testimony borne by a cloud of able witnesses. All we can hope to do, within our limits, is to give an idea of some of the salient points established, and of the general tendency of the whole.

Adhering to the subdivision, adopted by the Commission, under four principal heads, we proceed to

I.—*The Scientific Work carried on by Departments of the Government.*

The following enumeration of State Scientific Institutions now existing, together with that of the various Departments responsible for them, is given on the authority of the Royal Commission :—

Topographical Survey [Treasury (Office of Works)].
Hydrographical Survey [Admiralty].
Geological Survey [Privy Council].
Astronomical Observations :—
Greenwich and the Cape of Good Hope [Admiralty].
Edinburgh [Treasury (Office of Works)].
Meteorological Observations :—
Greenwich [Admiralty].
Edinburgh [Treasury (Office of Works)].
The Meteorological Office.
[The Meteorological Office is not administered by any Public Department, but is directed by a Committee, which, although appointed by the Royal Society, is independent of that body.]
Botany.—Royal Gardens, Kew; Botanic Garden, Edinburgh; Botanic Gardens, Dublin [Treasury (Office of Works)].
The Chemical Department of the War Office.
The Standards Department of the Board of Trade.

Analogous work is carried on in some of the colonies and foreign possessions by departments of their respective Governments.

In one case, that of the Royal Observatory, Greenwich, the work is examined into and reported on to the Admiralty by a Board of Visitors composed of men of science.

This extraordinary list is substantially that with which Col. Strange opened his evidence as the foundation on which the present demands for reform must be based. It establishes conclusively three most important points. (1) That the State does, and therefore should, actively aid scientific research. (2) That it does so partially, many essential branches being without aid. (3) That a divided administration such as this list of six or seven departments concerned with science indicates, cannot possibly secure harmony, systematic efficiency, or the extension which, as knowledge and the wants of the nation advance, may be requisite.

The Commissioners then add the following statement, showing the annual charges borne by imperial funds, at the present time, to defray the expenses of such of these various investigations as appear separately in the Estimates for the year 1874-75 :—

Topographical Survey (excluding military pay of men employed)	£132,000
Hydrographical Survey	121,055
Geological Survey	22,920
Astronomy	9,703
Meteorology	12,082
Botany, including the maintenance of Botanical Gardens as places of public recreation	21,470
Standards Department of the Board of Trade	2,063

In addition to these recurring charges, sums are voted from time to time for various expeditions and for experiments incidental to the services of the various departments, such as the investigations concerning the causes and processes of disease carried on under the direction of the Lords of the Privy Council, and the various experimental researches carried on for the army and navy.

Even if no questions of completeness or extension were raised, the fact of an expenditure, reaching probably about half a million annually, without any pretence of a system to regulate it, is one in itself deserving very serious consideration.

As to the insufficiency of our present administrative arrangements, we have valuable evidence from several Government officials and gentlemen engaged in national works.

Sir Henry Rawlinson, a member of the Indian Council, states that in that Council they perpetually have references before them which they are unable to deal with. He adds :—

". . . We have, for instance, Sir William Baker upon the Council, and General Strachey and Colonel Strange, both attached to the office; yet, notwithstanding their valuable aid, there are many subjects referred to us with which we are quite incompetent to deal."

He then refers to the following subjects among others: —The Manufacture of Iron and Steel in India; the Efflorescence of Soda on Irrigated Land; the Fermentation of Beer, "which may involve a loss of 200,000*l.* or 300,000*l.* a year to the British Government;" the question of Drought arising from the Destruction of Forests; the Construction of Harbours and of other Hydraulic Works; the Founding of Brass Guns; Tidal Observations; the Publication of Works on the Flora and Fauna of India; Geological and Trigonometrical Surveys; Sea Dredging; and Observatories.

He points out that many of these questions are practical and economical, but that still there is a scientific element in almost all of them, and he adds :—

"References on all these subjects are constantly coming home, and we have no means of answering them in our own body, while it is very unsatisfactory to be obliged to

send out for gratuitous information. We do sometimes, it is true, apply to individuals and sometimes to societies, but in very many cases, I am afraid, the questions are shelved, because there is no competent and authoritative body to refer to."

Capt. Douglas Galton, of the Office of Works and Public Buildings, thinks that, as a rule—

". . . Our statesmen do not appreciate properly the value of scientific advice or scientific inquiry, and that they are very much fonder of experiments made upon a large scale with no defined system, than they are of experiments which have been brought out as the result of a carefully studied previous inquiry. I think that an enormous amount of money was wasted in the case of the inquiry into armour plates, both for ships and forts. In that case the Government appointed a partly scientific committee, but it was mixed up with other persons who were not scientific; and instead of commencing a series of experiments upon a small and clearly defined scale, from which they could have drawn conclusions for making their larger experiments, they began by firing at any plates that were offered to them which had no relation one to another, either in their relations to the guns or to the form of backing, or in any other way, and consequently it was difficult to draw useful calculations from them."

Mr. Froude, who was a prominent member of the late Committee on Naval Designs, and who is now devoting his whole time without remuneration to the investigation of the proper forms of ships of war, states that if, at an earlier time, a laboratory had existed, and proper experiments had been made, enormous sums would have been saved which have been expended in the actual construction of ships, or, as he terms it, in "experiments on the scale of twelve inches to a foot;" and that definite results would have been arrived at with less loss of time.

It will be seen from the evidence of General Strachey that he also disapproves of the mode in which Government is at present advised on questions of science, especially on the ground of the absence of scientific training in the political and official classes of this country.

Sir Wm. Thomson has given the following evidence:—

". . . With a vast amount of mechanical work which is necessarily undertaken by the Government, and which is continually in hand, questions involving scientific difficulties of a novel character frequently occur; questions requiring accurate knowledge of scientific truth hitherto undeveloped are occurring every day. In both respects the Government is at present insufficiently advised, and the result is undoubtedly that mechanical works are sometimes not done as well as they might be done, that great mistakes are sometimes made; and again, a very serious and perhaps even a more serious evil of the present system, in which there is not sufficient scientific advice for the Government, is the undertaking of works which ought never to be undertaken."

"Are you able to point out any instances which you have in your mind of mistakes which you think have occurred from the want of good advice on the part of the Government?—One great mistake undoubtedly was the construction of the *Captain*, and I believe that a permanent scientific council advising the Government would have made it impossible to commit such a mistake. They would, in the very beginning, have relieved the Government from all that pressure of ignorant public opinion which the Government could not possibly, in the present state of things, withstand."

The present system of Special Committees is objected to by Sir William Thomson, and by other competent witnesses.

Sir William Thomson thinks "that a single body would be better than a number of small committees for advising the Government on the great variety of questions which from time to time would be likely to arise."

Admiral Richards, late hydrographer of the Admiralty, is of opinion that—

"The members of such committees must be selected more or less to fulfil certain political conditions, and that, as a rule, they would come new to the subject that they were going to consider, and I do not believe that the Commission which sat on the Naval Designs the other day was a very successful one. I do not know that any great advantages have arisen or are likely to arise from it."

Mr. Froude, in reply to the remark, "You do not consider committees of that kind to be a very satisfactory way of proceeding?" thus states his objection to the present system:—

"I do not think so, because they have to find out the dream and the interpretation both, which is always a difficulty. They have to feel their way to a *locus standi*, which would already be possessed by a Council habitually operating with reference to the subject."

Additional examples of these defects are given, not only by these witnesses, but also by others, whom we shall quote when dealing with the proposed remedies.

Evidence was taken by the Commission as to the insufficiency of the present appliances for investigation.

The attention of the Commission was especially directed to the want of laboratories for the use of the officials charged with scientific investigations urgently required for the economical management of the public departments.

Mr. Anderson, the superintendent of machinery at Woolwich, who has been responsible for the expenditure of "very nearly 3,000,000*l*. of public money," points out that there are no means at the disposal of State servants to enable them to investigate questions on which large expenditure depends. With special regard to his own department he states:—

"There is a very great deal which I should like to see taken in hand systematically. . . . There is much that we are in the dark about; we are groping in the dark in almost everything at present."

". . . . Although we know a very great deal with regard to iron, cast, wrought, and in the condition of steel, there is yet very much which we do not know, and I am persuaded that if we could with certainty treat ordinary cast iron in the way that we sometimes do, nearly by chance, we would do away with three-fourths, or a very large proportion of the wrought iron which is now used in this country, and we should use cast iron."

He next refers to another question of great importance to almost all the public departments:—

". . . There is another very important subject which I might mention to the Commission. Some twenty years ago we were using ten or twelve pounds of coal per horse-power per hour, and the majority of engines still require six pounds, but by the improvements that have taken place we are now down to two pounds. There is a little engine at work now in the London district which is working at $1\frac{3}{4}$ pounds. There is a great gulf yet between getting steam-engines that will work at $1\frac{3}{4}$ pounds per horse-power per hour, and the point where we are now; I mean getting that done practically: but I believe that if the right man, or two men, were told off to thoroughly investigate this subject, and not to stop working until they had brought it to a practical shape, we could in ten years from this time get down to one pound

per horse-power per hour. I see that there are very many leakages or loss in steam-engines in the very best way that we make them at present. The knowledge that was gained by Joule's experiments a few years ago seems to me to have been of immense value. Those experiments that he carried out for himself were the sort of thing which I think the Government should have done for the sake of the country. He did more to make engineers thoroughly dissatisfied with their present knowledge with regard to what they can do with steam than anything which had been done before. I believe that what Mr. Joule did will do more for this country than even what James Watt did. The part that James Watt took was very great, and the world gives him full credit for it, but the world is scarcely willing to give credit to Joule for what he will do; but he has made all engineers dissatisfied. They know that the best steam-engine is not doing one-sixth of the work which it ought to do and can do. That is a sad state of matters to be in when we know that we are so far wrong, but yet no one will go to the trouble of going to the end of the question so as to improve the steam-engine as it might be done; in fact, it will cost a great deal of trouble and a great deal of expense, I have no doubt."

With regard to the question whether it is "desirable that the Government should establish any laboratories for carrying on those investigations," he thus stated his opinion:—

"I should like to see a grand laboratory fitted with everything that would go towards the investigation of such matters, and at the same time a testing apparatus for getting at the physical facts as well. To get up the proper plant would be very expensive, but still I should like the nation to have it, so that any public department could go to this same laboratory and ask them for assistance to investigate any doubtful point."

Mr. Anderson's evidence finds a parallel in that given by Mr. E. J. Reed, M.P., late Chief Constructor of the Navy. He says:—

"I think that there are many branches of science remaining undeveloped at present, the development of which would be of great advantage to the country. I base that opinion partly upon the experience which I acquired at the Admiralty, in which I continually found that great and important questions were undeveloped for the want of organisation and of the means of developing them."

". . . A second illustration which I should like to give is this: the present condition of the marine steam-engine and boiler is very unsatisfactory. It is unsatisfactory to such an extent that I believe if the manufacture of iron and steel were improved with reference to its use in the construction of engines and boilers, and if improved material were applied by improved methods, a saving of one-half of the present weight would be attained; and when I say one-half, I know that I am speaking greatly within the limits which some persons who have thought very much about this question would be prepared to express. Of course, if that be so, if we are carrying about in our mercantile and other steamships twice the weight which is essential for the production of the power, that is so much taken off either from the further power and speed which might be obtained, or from the freightage and commercial value of the vessel.

"I may mention that in the manufacture of shafts, for instance, of the marine engine and of stern posts, and other large forgings for ships, the method of production is comparatively rude, and it very much needs development. . . . So much has the subject been neglected, that at this moment I have the responsibility of seeing some very large forgings indeed made for certain ships, and the most effectual manner in which I can give effect to my responsibility is that of selecting the very best working smith that I can find, and putting him into the manufactory where those things are being made, for him to do the best that his experience enables him to do, in order to see them properly constructed. I believe that if a regular independent scientific investigation were applied to a manufacture of that nature, enormous advantage would at once result."

The Standards Department of the Board of Trade is another department requiring advice in varied scientific subjects. The Warden of the Standards (Mr. Chisholm) states that there is no scientific authority to which he is entitled to appeal.

Sir William Thomson, in reference to the subject of standards, says:

"The conservancy of weights and measures is a subject involving questions of the most extreme scientific nicety. Faraday made statements showing how completely unknown at present are the properties of matter upon which we depend for a permanent standard of length. One of the very first objects that should be undertaken in connection with the conservancy of the standards of weight and length is secular experiments, on the dimensions of metals and solids of other classes under various conditions of stress, temperature, and atmosphere. Those would involve scientific experiments of an extremely difficult character, and also operations extending from year to year. There ought to be just now a set of experimental specimens of solids laid up which should be examined every year, or every ten years, or every fifty years, or every hundred years, the times when observations are to be made from age to age being regulated by the experience of the previous observations. This would not be a very difficult or expensive thing to institute in such a way as eventually to obtain good results, but it would be an operation of a secular character, which could only be carried out by the Government."

Dr. Frankland thus refers to the various requirements of Government involving chemical investigations:—

". . . The State requires many important investigations to be carried on. Such investigations are being continually conducted in buildings often very ill-adapted for the purpose, and which are fitted up for the purpose at a great cost. The laboratory of the Rivers Commission, for instance, which we have occupied for four years, was constructed in a house in Victoria Street; a rent of 200*l.* a year is paid for it, and it is literally nothing more than a moderate sized room, and two smaller ones, very ill-adapted for the purpose. Consequently, this laboratory is not so efficient as a building erected for the express purpose of conducting such investigations would be."

We pass now to

II.—*The Assistance given by the State towards the Promotion of Scientific Research.*

It may be convenient to consider the assistance given by the State towards scientific research as being either permanent or occasional.

Our museums of natural history are examples of the first. These afford to the students of those branches of science aid analogous to that afforded to students of literature and art by our national libraries and galleries.

No similar facilities are provided for the student of the physical sciences—such collections of instruments as exist being wholly inadequate both as to character and completeness. Moreover, as the Commissioners remark, "a mere collection of instruments, however complete, without working laboratories, is of little use to the student

of the experimental sciences, and as there are no public laboratories available for the researches of private investigators, it may be said that in many branches of experimental science the State affords no permanent material aid to such investigators."

Assistance of a permanent description is also afforded to learned societies, by providing them with apartments free of rent, or with annual grants of money in lieu of such accommodation: the sum of 500*l.* granted annually to the Royal Geographical Society under certain conditions is an instance of such a grant.

We may regard as a permanent aid to science the grant of 1,000*l.* for researches carried on by private individuals, which is annually voted by Parliament, and administered by a Committee of the Royal Society.

The first proposal for such a grant was contained in a letter (dated October 24th, 1849) from Earl Russell then (Lord John Russell) to the then President of the Royal Society (the Earl of Rosse), and was to the following effect:—

"As there are from time to time scientific discoveries and researches which cost money and assistance the students of science can often but ill afford, I am induced to consult your lordship, as President of the Royal Society, on the following suggestion:—

"I propose that at the close of the year the President and Council should point out to the First Lord of the Treasury a limited number of persons to whom the grant of a reward, or of a sum to defray the cost of experiments, might be of essential service. The whole sum which I could recommend the Crown to grant in the present year is 1,000*l.*, nor can I be certain that my successor would follow the same course; but I should wish to learn whether, in your lordship's opinion and that of your colleagues, the cause of science would be promoted by such grants."

Lord Rosse, in reply to the proposal made by Lord J. Russell, expressed his personal opinion that the judicious employment of grants in the way proposed "would very materially promote the advancement of science;" and of the two alternatives, namely, expending the 1,000*l.* in rewards, or appropriating it to the payment of the expenses of experiments, he preferred the latter, indicating his reasons as follows:—

"There are often details to be worked out before it is possible to employ usefully newly discovered principles. In many of the sciences reductions are required before observations can be made use of. Both in science and art, facts technically called constants are the materials of discovery; to determine them accurately is of great importance. Now in all these cases, and in many others, the work to be done is laborious and expensive, and as it adds but little comparatively to the fame of the individual, it especially requires encouragement."

With regard to this "Government grant" Sir Edward Sabine in his evidence says: . . . "I suppose that the 1,000*l.* in one year was designed as an experiment to try the matter in the first instance. I always understood that Lord Russell contemplated that the sum would be augmented if the plan were found to work well."

No change however has been made either in the amount of the grant or in its mode of distribution since its first establishment.

As examples of the second—occasional—kind of aid, expeditions for special researches, outfits of ships, and apparatus and grants of money for such researches, are mentioned. Great as is the value of these contributions, the Commissioners pointedly remark that "they do not appear to be granted or refused on any sufficiently well-defined principle."

The lesson, indeed, which crops up throughout the invaluable investigations of this Commission, is that there is a total want of system in almost all that we do, as a nation, towards advancing scientific research.

(To be continued.)

THE ENCYCLOPÆDIA BRITANNICA

The Encyclopædia Britannica; a Dictionary of Arts, Sciences, and General Literature. Ninth Edition. Vol. II., ANA to ATH. (Edinburgh: Adam and Charles Black, 1875.)

IN reviewing the first volume of this new edition of the "Encyclopædia" (NATURE, vol. xi. p. 343), we were obliged, by want of space, to omit more than the briefest possible remarks upon the general plan of the work. The conspicuous and increasing success of the work is apparently a sufficient answer to those who would find fault with the form of arrangement peculiar to this "Encyclopædia." Among the considerable number of Cyclopædias which have been produced in Great Britain during the last hundred years, this one, almost alone, has been reproduced in a number of successive editions, growing in excellence and reputation, and many people might take this fact to be a sufficient proof that it is well designed to meet a general want. But this success must surely be due in great degree to the eminence of the contributors, to the skill of the editors, or to any circumstance rather than the scheme of the work.

We have always been unable to comprehend the exact *raison d'être* of a cyclopædia which is neither strictly alphabetical nor strictly systematic. The "Britannica" may be compared to a solid body of pudding with plums in the form of excellent treatises disposed here and there. Now we entirely fail to perceive any convenience in this mode of construction. That it is not very suitable for the purpose of simple reference seems to be proved by the need of a full index to the whole of the volumes. Nor, if a person wishes to use one of the articles for careful continuous study in the manner of a text-book, is it convenient to have it embedded in a very heavy quarto volume, one of a large and costly series. Many valuable and highly useful treatises are in fact buried in this "Encyclopædia," and are hardly available for purposes of general reading. That this is so has been confessed by the separate publication of some of the principal treatises in former editions; those, for instance, by Sir John Herschel on "Physical Geography," and on "Meteorology."

Cyclopædias have varied in form from the purely alphabetical ones, best represented now in "Chambers' Cyclopædia," which approximates to the character of a dictionary, to "Lardner's Cyclopædia," in which each subject was treated in a distinct and handy volume. Coleridge tried to combine the two principles in the "Encyclopædia Metropolitana," in which all sciences and branches of knowledge were to be expounded in a series of elaborate treatises, arranged according to logical method, while an alphabetical dictionary of reference

was added as a complement. The treatises contributed to this work by Herschel, Airy, De Morgan, Peacock, Whately, Senior, and others, are some of the most profound works in English scientific literature, and maintain their scientific value after the lapse of forty years or more. It was the weight of these too-valuable treatises which damned the commercial success of the whole scheme.

The "Encyclopædia Britannica" has effected a compromise between the systematic and alphabetic methods in another way, altogether inferior in a logical point of view, but far more successful as actually carried into effect. In this volume we have forty-four important articles, almost every one of which is written by a master of the subject, if not in every case by its most eminent representative. The longest of these except one is that on *Astronomy*, by Mr. R. A. Proctor. It occupies eighty quarto pages, in addition to four large plates of engravings, and might be easily made to fill a good-sized octavo volume of 400 or 500 pages. This article is on the whole a satisfactory compendium of the science, but it is matter of regret that Mr. Proctor cannot avoid exhibitions of bad taste. He has no right to insinuate in the second column of p. 786 that two of the joint authors of an important scientific paper are the *assistants* of the one first named. The accuracy of some of Mr. Proctor's statements as to the history of recent discoveries in solar astronomy would have to be seriously called in question, were it possible in an article of this kind to enter upon a subject involving many details.

One of the most profound and at the same time interesting articles is that of Dr. E. B. Tylor on *Anthropology*, occupying about sixteen pages. As we should expect from the principal founder of the new science, it contains a luminous abstract of the evidence concerning the antiquity, descent, and development of the human race, mainly brought to notice since the last edition of the "Encyclopædia" was published. Taken in connection with Prof. Daniel Wilson's article on *Prehistoric Archæology*, and Prof. St. George Mivart's elaborate account of the *Ape Family*, filling twenty-one pages, we have in this single volume of the work a full supply of information relating to the origin and affinities of the human species. It is curious to compare the views discussed in these articles with those propounded in earlier editions of the "Encyclopædia" under the title "Creation."

Probably the longest article in the volume is that, the joint production of Prof. T. Hayter Lewis and Mr. G. E. Street, upon *Architecture*, which, taken together with a very useful glossary of architectural terms, extends over ninety-four pages. If reprinted in a separate volume it would form a convenient and much-needed text-book of the science. As treated by Mr. Ferguson, the history of architecture forms in fact one of the most instructive branches of the new science of Sociology, and no subject of study is better calculated to produce correct views of the origin and development of civilisation. We are unable to understand why the work of Mr. Ferguson is referred to in the Bibliography of the subject (p. 457) only under the head of Chinese Architecture.

It will be a matter of regret to many that Professor Huxley's article on the *Classification of the Animal Kingdom* is restricted to six pages, but it is surprising how many profound remarks he has managed to compress into this narrow compass. The article, however, is only suited for the reading of experts. The article, again, on the word *Aryan*, by Prof. Max. Müller, is another one of which the brevity must be lamented, unless it be supplemented by other articles on closely allied topics, to which there is no reference.

In spite of the fulness and excellent quality of some of the articles relating to physical or natural science, we entertain some fear that the weakest side of the "Encyclopædia" will lie in this direction. The method of arrangement prevents us from speaking with confidence, because it is impossible to say how far subjects which are weakly treated or altogether omitted in their alphabetical place, will be introduced into later systematic articles. There are indications, however, that Prof. Spencer Baynes is not as ably supported in chemical, mathematical, or general physical subjects as he should be. The brief account of *Antimony*, for instance, is a very perfunctory production, and, if the other elements are to be treated in like manner, we should prefer to find them omitted altogether. If Mr. Baynes can spare barely more than one column for an element of considerable importance, he need not have told us that the paint said in the Holy Scriptures to have been used by Jezebel was made of stibnite containing antimony. Nor need a sentence have been wasted in repeating a tradition to the effect that the metal was called antimony because a preparation of it proved fatal to monks (hence *antimonachos*), a tradition, it is added, which will hardly bear investigation. If so, why give the tradition when there is so much else of importance omitted.

The article on *Assaying*, though not positively bad, is not up to the proper mark, and is not sufficiently precise to be of any technical value. The subject should either have been omitted or more developed, and placed in the hands of Mr. Chandler Roberts, the chemist and assayer of the Royal Mint, who would have been in every way the most fit writer to treat it.

We hope that the column given to *Anthracite* is not a specimen of the way in which so important a subject as Coal is to be dismissed. Yet it contains no reference to Coal, Fuel, or other articles on related topics. Moreover, we are unable to comprehend why, if there is to be a satisfactory systematic article on Coal, as surely there must be, this brief separate account of anthracite should be given. As the article remarks, "No sharply defined line of demarcation can be drawn between anthracite and the bituminous varieties of coal, as the one series merges by imperceptible degrees into the other." If so, why allow the mere name to give rise to a separate article, when the alphabetic system is not observed in other cases?

Every now and then the mixture of systems gives rise to a waste of space by useless repetitions. Thus, under *Asteroids*, we find an article of seventeen lines, ending with a reference to p. 806 in the article on *Astronomy*. Turning to this page, we find a pretty full account of the asteroids, filling four columns, and containing a complete and useful table of the whole of the minor planets, which were 143 in number when the table was drawn up, although two or three new additions have since been

made. It is obvious that a mere reference under the name *Asteroid* would have been sufficient. The editor avoids the introduction of the copious references which are to be found in the "Penny Cyclopædia," "Rees' Cyclopædia," and many other ones, but he does not do this consistently and completely. In other cases subjects of considerable importance are treated with the brevity of a dictionary, and yet no references are added. Take, for instance, the account of the word *Anodyne* given in seven lines, and containing merely the meaning and etymology of the name, and a list of six substances used as anodynes. There is no reference to anæsthetics or any other article where the subject might be fully studied.

Perhaps the worst article allowed to stand in this volume is that under the word *Angle*, which tells us in twenty-seven lines, and by aid of a figure, what an angle is, what a right angle is, how the whole circumference is divided into 360°, and so on, concluding by a reference to geometry and trigonometry. Such a puerile description of the word would not be tolerated in "Chambers' Information for the People" or Cassell's Popular Educational works. There is only a single sentence in this article which could in all probability give new information to any person likely to consult such a work as the "Encyclopædia Britannica."

It is not our duty, of course, to form any judgment upon the larger part of this volume, which treats of literary or artistic subjects. The many articles treating of classical, biographical, geographical, and other information are probably on the whole superior to the parts devoted to physical and mathematical science. The scarcest and perhaps the weakest articles altogether are those on mathematical topics. There are, indeed, in this volume only two articles of any length which can be called mathematical. That on *Annuities* is a fair one, especially as supplemented by other articles to which reference is made. That upon *Arithmetic*, however, is a very dry, perfunctory production, chiefly consisting of a mere compendium of the ordinary rules. We do not recognise the name of the author by his initials, and the name is not made public in the list of principal contributors. It is obvious that the "Encyclopædia Britannica" will not compare in the mathematical department with the "Penny" or the "English" Cyclopædias, which contain a splendid series of articles by De Morgan of permanent interest and value. While, therefore, we can entertain no doubt that, taken as a whole, the "Encyclopædia Britannica," as now republishing, is excellently edited, we think that Prof. Baynes is inclined to sacrifice in some degree the less for the more popular branches of knowledge.

We are driven to this conclusion when we compare the number and length of the articles given to the more severe scientific subjects with those upon more popular topics, such as *Architecture* and *Archæology*. The treatise on *Army*, again, taken in connection with that upon *Arms and Armour*, takes up a very large amount of space. No doubt it is requisite that War, which occupies unfortunately so large a part of the attention of Europe at the present time, should be fairly noticed in an "Encyclopædia" intended for the use of all. It is a matter of opinion and a question of degree and of proportion in which it is hopeless for Prof. Baynes to please all parties. But it may be well to remind Prof. Baynes that the more popular articles are those which will soon lose their value. Such an article as that on *Army* rapidly becomes antiquated by the progress of political and social changes and of mechanical invention, whereas good mathematical essays like those of De Morgan or Peacock retain their value for hundreds of years. Almost the only volume of "Lardner's Cyclopædia" now sought after is that by De Morgan on the Doctrine of Probabilities.

Although the "Encyclopædia Britannica" seems a very costly work to purchase, it must really be considered, in proportion to its contents, very cheap. We find that this second volume contains at least 1,100,000 words, in addition to thirty large and expensive engraved plates. Now, the same quantity of matter purchased in the form of detached treatises would probably cost from two to four times as much. It is true that when we select our own library we generally purchase works which we intend to read more or less completely, whereas the persons who would read an encyclopædia through would be truly exceptional characters, though we have heard it reported that such persons do exist. A cyclopædia is published on the principle which auctioneers seem to adopt in selling books, of mixing up what a purchaser does not want with what he does want; so that he has to buy all the more. Those, however who do want a library selected for them cannot do better than confide in the work of Prof. Baynes and his predecessors.

OUR BOOK SHELF

Annual Record of Science and Industry for 1874. Edited by S. F. Baird. (New York: Harper and Brothers, 1875.)

The Year-book of Facts in Science and the Arts for 1874. Edited by C. W. Vincent, Assistant in the Library of the Royal Institution of Great Britain. (London: Ward, Lock, and Tyler, 1875.)

The American "Annual Record of Science," is a work that each year grows in interest and value. It now consists of two distinctive parts (1), an historical summary of the progress of various branches of science and industry during the past year; and (2), classified groups of paragraphs, giving a succinct report of noteworthy occurrences or special scientific investigations. At the end of the volume is a catalogue of scientific books published during the year, and also a capital index to the whole work. The summary of progress has grown from sixteen pages in 1871, when this Annual first appeared, to 200 pages in the present volume. Each department of science is separately treated, and in the preparation of the different parts the editor has had the co-operation of numerous eminent men of science. Evidently no pains have been spared to make the Record as complete as possible, and so far as we are competent to judge, it is as accurate as it is comprehensive.

In his modest preface to the volume, the editor tells us he has been urged by some to make the abstract of papers more detailed; we think, however, Mr. Baird has exercised a wise discretion in his present arrangement, and at the same time we are glad to learn that he intends publishing a series of annual reports on special branches of science similar to what already exists, to some extent, in Germany. In England we have nothing corresponding either to the general record of science or to the special reports, and the want of such works is increasingly felt. We hope that before long some one of our leading publishers will see their way to issuing a really good digest of the annual progress of natural knowledge in all its various branches.

Why could not the record before us be published in England as well as in America? This seems a very feasible plan, and would doubtless add to the usefulness of the work, inasmuch as English collaborateurs might be added.

Very different from the American annual is the English year-book, yet it is, we believe, the only "year-book of science" of which we can boast. Outside it resembles a shilling railway novel; inside it is a pleasant gossipping account of odds and ends of science picked up at the Royal Institution. An altogether disproportionate amount of space is devoted to extracts from the papers and addresses of Prof. Tyndall, and the woodcuts on the title-page are taken from the same source. We are glad, however, that the "Year-book of Facts" still remains, notwithstanding the death of its former indefatigable compiler. Mr. Vincent tells us he undertook at short notice to continue the work of the late Mr. Timbs. To compile a year-book under such circumstances can be no light duty, and hence we must be lenient to its shortcomings. So far as the book goes, Mr. Vincent has done his work well, and gives a bill of fare that no doubt will be relished by the *dilettante* scientific public. But it should be clearly understood that the volume is merely a *scrap-book* of popular science, and not in any sense an annual register, such as we hope may soon be issued.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*]

Systems of Consanguinity

In Sir John Lubbock's *vindication* of his original charge that I seem to have two theories of the facts in my work on Consanguinity (NATURE, vol. xii. p. 124), he fails to show that the classificatory system was interpreted by me as "arbitrary, artificial, and intentional." This is one of the theories, and in fact the principal one, which he ascribes to me, and which I repudiate. The other theory, that which I did advocate, is presented both in his address before the Anthropological Institute and in this vindication (stated partially and imperfectly), as something that I "admit." "Mr. Morgan admits that systems of relationship have undergone a gradual development, following that of the social system." (Address, p. 4, NATURE, vol. xii. p. 125.)

It would require too free a use of your columns to explain at length how, by quotations severed from their connections, and by a use of their phraseology not in accordance with my design, a defence of an unwarranted statement has been put together.

I beg leave to re-state the propositions in my work on Consanguinity, which contain the substance of the views I have advocated, and to which I stand committed; and to request those who may be interested in the subject to read the last chapter in the light of these statements.

In that chapter, entitled "General Results," the facts are discussed under seven propositions, in substance the following:—

Proposition I. That the systems of consanguinity given in the tables may be resolved into two, which are radically distinct, one of which is called *descriptive* and the other *classificatory*. The first is that of the Aryan, Semitic and Uralian families, and the second that of the Malayan, Turanian, and Ganowánian families.

Proposition II. That these systems are to be ranked as domestic institutions.

Proposition III. (in full). "Can the origin of the descriptive system be accounted for and explained, from the nature of descents and upon the principle of natural suggestion, on the assumption of the antecedent existence of marriage between single pairs?" (Con. p. 472.)

The affirmative of this proposition is maintained. "It is the institution of marriage between single pairs which teaches the descriptive system; whilst this form of marriage has been taught by nature through the slow growth of the experience of the ages." (Con. p. 469.)

Proposition IV. (in full). "Can the origin of the classificatory system be accounted for and explained, from the nature of descents, upon the assumption of the existence of a series of customs and institutions antecedent to a state of marriage between single pairs, of which the Hawaiian custom is one?" (Ib. p. 474.)

The affirmative of this proposition is likewise maintained. Under it the solution of the origin of the Malayan system is given, and also of the Turanian, together with the customs and institutions, fifteen in number, arranged in a sequence, which stand connected with the birth and growth of these systems. Assuming, for example, the intermarriage of brothers and sisters in a group, every relationship in the Malayan system is found to be that which would actually exist; wherefore, the system itself proves the antecedent existence of this form of marriage. The same line of argument and of inference is then applied to the Turanian system. In Propositions III. and IV. I speak of both forms as *natural* in contradistinction to *artificial*, although they are radically different. They are natural in the sense that they are in accordance with descents as they actually existed when each system respectively was formed. This is the main proposition in that chapter, occupying in its discussion nineteen of its forty-three pages. It presents the theory of the author; it is the only place where the origin of the classificatory system is discussed.

Proposition V. This proposition maintains the unity of origin of such tribes of the American aborigines as are found to possess an identical system of consanguinity.

Proposition VI. (in full). "Where two or more families, constituted independently on the basis of such a system of relationship, are found in disconnected areas or upon different continents, can their genealogical connection be legitimately inferred from their joint possession of the same system?" (Ib. p. 498.)

After showing that the people of South India who speak the Tamil, Telugu, and Canarese dialects have a system of consanguinity identical with that of the Seneca-Iroquois of New York, in upwards of 200 relationships, the question is raised, "How shall this identity be explained?" It was my discussion of this question that confounded my distinguished adversary, which he misunderstood at first, and is not sure that he "quite comprehends even now." How his difficulty could have arisen I confess puzzles me. Under Proposition III. the origin of the descriptive system had been discussed, and under Proposition IV. that of the classificatory; but under this (VI.) the question was whether any evidence of the Asiatic origin of the Ganowánian family could be found in this identity of systems. The four hypotheses quoted by him (vol. xii. p. 124) are produced and discussed here. "Spontaneous growth" was referred to and of course rejected as an adequate explanation of this identity of systems.

Proposition VII. relates to inferences that may be drawn from partial identity of systems.

These several propositions show very plainly, I submit, that these systems are not explained in that volume as "arbitrary, artificial, and intentional," and equally plainly that they are explained as growths or results of certain customs and institutions.

Turning now to Sir John Lubbock's vindication, his first principal quotation is taken from the discussion of my first proposition, where "natural and spontaneous" is used in opposition to resulting growths from customs and institutions, the cause being unknown in the first case, and known in the second. His second quotation is from the discussion of my sixth proposition, where "spontaneous growth" is used, and in the same sense.

The discussion of the mass of materials accumulated in that volume was confined to forty-three out of five hundred and eighty-three pages. It was a new subject, in which it was necessary to invent, to some extent, a new terminology. I am aware of its great defects, but I deny that two theories of the facts are to be found therein, or that I have explained the classificatory system as "arbitrary, artificial, and intentional," which is the point from which this discussion started.

Rochester, New York, July 20 LEWIS H. MORGAN

Weather on the Atlantic

I HAVE reluctantly come to the conclusion that attempts to forecast the weather on the North Atlantic frequently result in disappointment. A recent passage from New York to this country has enabled me to gather some remarkable data on this subject, so remarkable, indeed, that any one crossing for the first time might reasonably question the action of the barometer. If I had had only one on board, I should certainly have doubted its

accuracy, but having three, the readings of them cannot be questioned by the most sceptical.

We left Sandy Hook on the forenoon of April 10, with a light north-west wind and pleasant weather. Temperature of the air 46, barometer 29·82. From that date to the 16th the ship steamed 2,210 miles, and the mercury, with the exception of a slight fluctuation which never exceeded $\frac{5}{100}$ of an inch, fell steadily until it reached 29·14 on the latter day. Throughout this period the wind veered and backed between N.N.W. and E.N.E., never exceeding in force a whole sail breeze, and frequently light or calm for hours together. The sky was generally overcast until the meridian of 32° W. was passed; light rain fell once, but no snow or sleet. Temperature of the air ranging between 34° and 57°.

Until the ship was to the eastward of Cape Race (passing 300 miles south of it), as no gale blew I expected a heavy fall of snow; but as it did not come, I assumed that the snow-covered ice on the Grand Bank of Newfoundland caused this unusual depression of the mercury. Great was my surprise, therefore, to see it falling lower as the distance increased from the supposed cause of the depression, while the wind gradually died away, the clouds opened out and assumed softer forms, the horizon cleared, and the long northerly swell subsided. The latter is always a sign of fair weather on this troubled sea. If a storm be advancing towards a ship, the swell usually comes before the wind, so quickly is the motion of the water translated.

While on the subject of waves, I may state that I have been investigating the cause of the greater height of the waves raised by a north-west wind above those raised by a south wind. The observations were made while crossing several offshoots of the Gulf Stream, and I found that in every instance the sea was smoother in the warm water than in the cold. If this view be correct, then the waves in tropical seas should be inferior in height to those of the temperate zone. The question is, Are they so?

Snow has an extraordinary effect on the barometer, but its action is most mysterious, as in this case the ship was several hundred miles from any locality where snow could have fallen.

In March 1872 I witnessed a similar instance of great depression in the barometer, with no wind and a clear sky. On reaching the land it was found to be covered with snow. In that instance there was scarcely a cloud visible during the last 400 miles, and not a single flake fell on the ship. I believe the remarks of an old seaman on the weather of the Atlantic are very true, viz., "The longer one sails on it the less one knows about it."

The presence of heavy field-ice in the month of April, so far south as 41° 40′ N., only fifty miles north of the latitude of Naples, has excited considerable astonishment amongst Atlantic navigators, since many steamers were entangled in it as early as the 24th of January.

The Admiralty Chart of 1873 indicates March as the first month of its arrival, and further gives lat. 42° 13′ N. as the extreme southern limit of its existence, whereas it has already been met with twenty-seven miles south of that parallel, forming a dangerous barrier to ships on the great highway to America: and the commanders of those vessels, relying implicitly on the correctness of a survey which should be above suspicion, have seriously injured their vessels, thereby jeopardising many lives and valuable property in a locality where every feature of it should be as well known as the waters of the Serpentine or the Thames above bridge. It is, moreover, notorious that this is not the only defect in the chart of 1873. The northern limit of the Gulf Stream is laid down from 100 to 150 miles south of its true position; and the existence of another important current (the Labrador), which plays no mean part in the economy of the globe, is entirely ignored, although its line of demarcation from the adjacent waters is as well defined as that of its great neighbour.

It is stated by the old residents of Canada that such a severe winter as this has not occurred in the Dominion for forty years. During the months of January and February at Montreal the wind only blew from the south for six hours. Not only was the thermometer low, but the northerly gales were incessant, rendering outdoor exercise almost an impossibility. These storms broke the ice of Newfoundland and Labrador from its moorings before the summer sun could soften it, and hence the reason of its floating down south. Being almost as hard as granite, and with the sea water at 30°, it will not readily decompose.

The recent severe winter must affect the fortunes of the polar expedition for good or for evil. Channels into which ice has drifted will become inaccessible until late in the season, but, on the other hand, the pack-ice will be less inconvenient from its solidity and compactness. It is not probable that many large bergs will reach the Atlantic this season.

Celtic W. W. KIDDLE, R.N.

The late W. J. Henwood, F.R.S.

MR. G. T. BETTANY is no doubt very nearly, if not quite, correct in saying of Mr. Henwood (NATURE, vol. xii. p. 293), "I believe that scarcely one of his cherished objects in this respect [the arrangement of his stores of facts and observations] remains unfulfilled."

In a letter to me, dated July 31, 1875, Mr. Henwood remarked: "I believe all I have done since [I wrote you last] has been to make some preliminary calculations regarding the corrections for temperature of the results of my observations on magnetic intensity, made on the surface and near the bottom of Dolcoath Mine in 1832. I think they hold out promise of something if I have only strength to put them in order." On the fifth day after writing this he died. M. Y.

Zoology of the "Erebus" and "Terror"

Palmam qui meruit ferat. Referring to the article on this subject (NATURE, vol. xii. p. 289), allow us, as the publishers of the botanical portion, to say that the indefatigable labours of Dr. Hooker, aided by the Government grant, resulted in *six* vols. 4to.; not *two*, as stated by the reviewer. This was published in three divisions, viz.: 1. Flora Antarctica, 2 vols.; 2. Flora Novæ Zealandæ, 2 vols.; 3. Flora Tasmaniæ, 2 vols.; the whole comprising nearly 600 coloured plates.

L. REEVE AND CO.

5, Henrietta Street, Covent Garden, Aug. 14

The Rocks at Ilfracombe

COULD any of your readers state in your columns the nature of a curious appearance in the rock near Ilfracombe (North Devon), on the way to Coombe Martin, just where the road begins to descend to the latter place? Here on the right-hand side the bank is considerably excavated, and through the scaly and friable strata, whose cut surface is perpendicular to the road, rock of a harder kind seems to have been pushed, presenting a rounded surface, which gives the appearance of trees laid in the bank and partly uncovered; indeed, I first heard of them as "petrified trees," and from the road they look very much like the trunks of silver birches. Our Ilfracombe driver told me that a great many people came to look at them, some saying they were trees, others that they were not.

There are several of them, and various lengths are visible, from about a yard to twenty feet, I should think.

WILLIAM S. TUKE

OUR ASTRONOMICAL COLUMN

BINARY STARS.—(1) η CASSIOPEÆ.—Dr. Duner, of the Observatory of Lund, Sweden, has calculated elements of this binary from measures 1782-1874; the orbit is as follows:—

Peri-astron passage	1748·413	
Angle between the lines of nodes and apsides	245°·91	Meridian of 1850
Node	50 ·83	Meridian of 1850
Inclination	68 ·46	Meridian of 1850
Angle of excentricity ($=\sin^{-1} e$)	38 ·812	
Mean annual motion	+ 2 ·04112	
Semi-axis major	10″·681	
Period of revolution	176·374 years.	

The comparison with measures used by Dr. Duner in his calculation shows very small residual errors, but the elements here transferred from Leverrier's "Bulletin International" of the 12th inst., though representing the angles of Struve, Dawes, Jacobs, and Dembowski, with small negative errors give the distances measured since 1827, very sensibly in defect of the observations. Thus for Dembowski's measures we have—

1863·26	Error in position	− 0°·72	Error in distance	− 0″·69
1867·16	,, ,,	− 0 ·71	,, ,,	− 0 ·63
1871·05	,, ,,	− 0 ·18	,, ,,	− 0 ·46

For a normal founded upon measures by Jacobs, Dawes, and Dembowski, for 1854·20, the error in position

is, – 2°·4, and in distance, – 0″·74. The elements above are perhaps affected by error of copy, but as they stand they will admit of some improvement.

With Dr. Duner's semi-axis and period, and Mr. Otto Struve's first approximation to the annual parallax, the mass of this system would be upwards of ten times the solar mass.

It will be remarked that the angles in the above orbit are expressed by Dr. Duner in decimals of degrees, and we may take this opportunity of directing attention to a very useful table of five-figure logarithms adapted to decimals of the degree published at Berlin in 1872 by Dr. C. Bremiker, which will be found available not only in double-star computations, but very generally for five-figure work. The figures closely resemble those in De Morgan's well-known tables (which are now apparently out of print), and consequently are exceedingly clear and readable, and the price nominal (one shilling). Several miscellaneous tables and various useful constants are appended. The work will be sent over in paper cover, and in binding this or any other set of tables for frequent use, we would recommend the strong gilding of all the edges as materially facilitating their working. When shall we have a table of *four-figure* logarithms to the same extent as tables for five figures are usually printed? Such a work would be by no means without its value.

(2) γ LEONIS.—Dr. Doberck, of Col. Cooper's Observatory, Markree, has calculated elements for this star, though the arc described is at present less than 30°, under which condition orbits widely different may be obtained. Peri-astron passage, 1741·11; period of revolution, 402·6 years; node, 111° 50′; λ, 194° 22′; γ, 43° 49′; excentricity, 0·7390; semi-axis major, 2″·00.

There are several of the revolving double-stars of which much better orbits than have yet been published might now be found; as, for instance, ω Leonis and λ Ophiuchi. Of the fairly determined orbits, the shortest period appears to be that of 42 Comæ Beren—25·5 years, according to Mr. Otto Struve; and the longest that of Castor, 997 years, according to the very complete investigation of Herr Thiele.

THE MINOR PLANETS.—M. Leverrier, in his "Bulletin International" of the 8th inst., announces the discovery of No. 148 at Paris, by M. Prosper Henry, on the same morning. The planet is of 10·7 mag., and was found a little west of 70 Aquarii.—Circular No. 31 of the "Berliner Jahrbuch" contains new elements of Lachesis (120); the period of revolution at the next opposition in November is 2,028 days. In No. 30 appeared new, though still uncertain, elements of Austria (136); period 1,261 days.

THE AUGUST METEORS.—The extensive systematic plan of observation at the principal meteor epochs which has been for some time organised by the Scientific Association of France, at the instance of M. Leverrier, has again been attended with success, on the occasion of the Perseid shower. At Rouen on August 9, between 11h. and 15h., 200 meteors were noted, of which 180 came from the Perseus-radiant; at Rochefort, on the same night, 258 meteors were observed, nearly the whole conformable; and on the 11th, at the same place, 260, many with the same radiant.—About August 5th, in the neighbourhood of London, an unusual number of meteors, more than one as bright as stars of the first magnitude, diverged from Omicron in Andromeda.

Prof. Oppölzer's *definitive* elements of Comet 1862 (III.), with which the August meteor-stream is associated, are here subjoined:—

Perihelion passage, 1862, August 22·91192 G.M.T.

Longitude of perihelion ...	344° 41′ 32″	M. Eq. 1862·0
,, Ascending node ...	137 27 10	M. Eq. 1862·0
Inclination to ecliptic ...	66 25 48;	
Eccentricity	0·9607588	
Semi-axis major	24·53142	
Period of revolution	121·502 years.	

The point of nearest approach to the earth's orbit at the descending node is passed 19·357 days after perihelion; if in 1862 the comet had arrived at perihelion July 21·557, a little before noon on the 10th of August, it would have been distant from the earth less than twice the distance of the moon. It might not be without interest to determine the effect of so close an approach to our globe, upon the orbit of the comet; but in such an unusual computation it appears almost necessary that earth and moon should be treated as distinct disturbing agents; perhaps the ordinary methods might apply, if the intervals were taken sufficiently short and the elements changed with sufficient frequency.

THE SEPARATION OF THE ARAL AND THE CASPIAN

IN a note on the Hyrcanian Sea (vide NATURE, vol. xii., p. 51), it was stated that the waters of Aral, whose surface is now about 159 feet above sea level, formerly overflowed at their S.W. corner, when the lake possessed a depth of 50 feet more than at present. It is certain that the spur of Ust Urt, which formed a waste weir at the point in question, has been lowered by the action of escaping water; and the level at which the overflow took place, in the first instance, was probably some few feet higher than the figure of 209 which has been given. The greatest height ever reached by the water contained in the basin of Lake Aral may therefore be said with tolerable accuracy to be about 220 feet above the sea.

On the N.W., near the head of the Tchagan stream, where Aral must have overflowed to flood the country round the limits of Ust Urt, the barometrical height of a point situated in latitude 47° 7′ 27″, and longitude (east from Greenwich) 58° 17′ 41″, is 257 feet (*a*). This height approximates sufficiently to that which has been indicated for the overflow at S.W., to suggest that future levelling operations will find a point somewhere in this neighbourhood situated at less than 220 feet above the sea. There is, in addition, in latitude 43° 15′, a cleft in the eastern cliff of Ust Urt, by which, and probably by other similar clefts yet to be discovered, the waters of Lake Aral may have overflowed to the west; and in such a case they would, as they travelled down to the lower level of the Caspian Sea, have submerged many extensive, depressed tracts, which occur on the surface of the intervening country. The separation of the two seas, which has afforded subject for much discussion, seems thus actually to have been due to the cessation of the overflow of the basin upon the higher level. Nor is, perhaps, that separation so entirely complete as has generally been thought, for Lake Aral could possibly be filled and made to overflow again; and under such restored conditions, the physical aspects of the country lying between the two seas would very nearly resemble those which are possessed at the present time by the country on the lower courses of the Amú Darya, and are caused by the annual flooding from that river. In such a drowned condition, the Aralo-Caspian region was naturally included in the water-spread of the Hyrcanian Sea by all the classical historians and geographers who have described it; and though, perhaps, no possible overflow from Lake Aral could now exactly reproduce the physical aspects of 2,000 years ago, such difference as would be observable is susceptible of explanation by considerations to be presently entered upon.

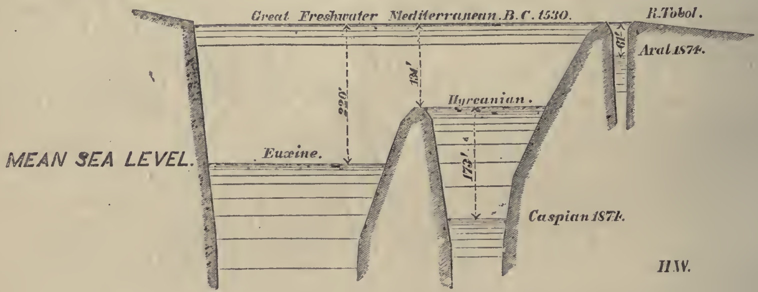
Since the accidental circumstance of more or less water having existed in several depressions upon the surface of the Aralo-Caspian region is the only known variation which has attached to its physical aspects from the earliest historical times, there is a strong presumption that no phenomena of upheaval have occurred, and that over-

(*a*) These figures are taken from the Catalogue of Trigonometrical and Astronomical points in the Russian Empire. Edited by the Director of the Geodesical Department of the Military Topographical Staff.

flow could still take place in a northerly direction also from Lake Aral. Some sixteenth century maps show the river Obi flowing out of the lake of Kitay, which is one of the names of Aral; and by such an overflow may be explained that supposed irruption of Ocean into Asia which the most ancient Greek and Latin authorities have recorded. Nor would the demonstration of the possibility of this overflow in any way affect the reputation either of Herodotus or of Aristotle, who both maintained the isolation of the Hyrcanian from the ocean; for the overflow from Aral might or might not have taken place during a series of years, depending as it did upon the magnitudes of the annual floods of the rivers which supplied it, at the epoch when the winter broke up, on the highlands of Central Asia.

It was estimated in the note on the Hyrcanian Sea that when the Oxus discharged directly westwards, the waterspread of Lake Aral and the lands drowned by its overflow might have added about 70,000 square miles to the area of 140,000 square miles, which is possessed by the Caspian of to-day. If 30,000 square miles be added besides, for the volume which Oxus, Ochus, and Arius probably supplied, the total area of the Hyrcanian Sea would have been about 250,000 square miles, which would have formed a waterspread almost reaching up to the ridge which divides the Caspian from the Black Sea, *i.e.* the level of the largest possible Hyrcanian Sea may have been 89 feet above mean sea-level, in the lowest of the two basins which formed it. The observations of Pallas have, however, placed beyond doubt that the ancient limits of the Caspian were situated at a much higher level than this; and since these limits, which are delineated in a map illustrating his works, did not owe their existence to the overflow from Aral, in conjunction with the volumes of water delivered by the rivers of the Caspian basin, they must have been formed by water flowing out of the Euxine basin. And this latter could not consequently have had at such a time a communication with the Mediterranean Sea.

We know that at the present day a very much larger volume than is required to compensate its surface evaporation is contributed by the various rivers supplying the Black Sea, and passes thence through the Bosphorus into the Sea of Marmora. Before this escape existed, the level of the Euxine would have been higher, and the surplus waters would have overflowed to the east by the channel of the Manytsch into the basin of the Caspian, whose level would, in turn, have been raised. The united waterspread of the two basins would have continued to rise, until the surface evaporation equalled the supply of water



it received; or until it found an escape into a lower level, and this latter circumstance was the one which almost certainly occurred, and in a northern direction.

The part of the ancient shore of the Caspian, which Pallas has delineated, and which is situated at a point called Cholon Komyr, in latitude 45° 30′ 25″, and longitude (east from Greenwich) 44° 51′ 34″, has a height of 221 feet above the sea (*b*). In other words, the great inland sea of fresh water, which extended from the western shores of the Black Sea to the eastern shore of Lake Aral, had its surface precisely on the level at which, it has been stated, there is a strong presumption that Lake Aral could overflow to the north and form a junction with the Frozen Ocean by the drainage lines of the Tobol and of the Obi. Under all the circumstances it is scarcely hazardous to say that this presumption becomes all but a certainty; and that the height of the low ridge, which divides the drainage on the north of Lake Aral, will eventually be found to be 220 feet or less, at its lowest point, above sea-level.

The actual original separation of the Aral and the Caspian may thus be referred to the rupture of the Bosphorus, and to that consequent rush of waters from the Euxine into the Mediterranean, which is known as the Deluge of Deucalion. The immediate result of this cataclysm would have been a fall in the level of the Caspian from 220 to 89 feet above the sea; and though actually isolated from Lake Aral, it would have appeared connected with it by marshes, alimented by the overflow of the latter basin. Though the Caspian level still continued to fall, from surface evaporation, the aqueous character of the intervening bed of the drained-off waters would thus have been preserved for a long time, and such a condition will explain the probable difference in physical aspect which would distinguish the long since desiccated Aralo-Caspian region if it were subjected once more to an overflow of Lake Aral. The cessation of this overflow would have, in the first instance, hastened the drying up of the higher levels of the intervening country, and accentuated to the Orientals upon the shores of the higher sea that isolation of the two basins which the Europeans upon those of the lower were not, and in fact could not be, acquainted with until very long afterwards.

HERBERT WOOD

(*b*) See note (*a*).

GUN-COTTON WATER-SHELLS

IN the published accounts of Field Artillery Experiments which are just now being carried on at Okehampton, in Devonshire, considerable prominence has been given to the formidable nature of the so-called water shells, with which practice has been carried on against rows of targets, in the form of "dummy" soldiers, representing columns of infantry, shrapnel shells and common shells, filled with gunpowder, having been fired in comparison with them.

The term *water-shell* denotes not a shell of special form or construction, but simply a new system of bursting

shells of ordinary construction, elaborated by Prof. Abel nearly three years ago, by which the breaking up of cast iron shells into a large number of fragments and their dispersion with considerable violence is accomplished by filling the shell with water instead of with an explosive agent.

In a memoir communicated by Mr. Abel to the Royal Society in 1873,* it was pointed out that detonation was transmitted from a mass of dry compressed gun-cotton to distinct masses of the material saturated with water and separated from each other and from the detonating (or "initiative") charge by small spaces filled with water, the whole being enclosed in a case of stout wrought iron; and Mr. Abel stated that the suddenness and completeness with which detonation was transmitted through small water-spaces had suggested to him the possibility of applying water as a vehicle for the breaking up of cast iron shells into numerous and comparatively uniform fragments, through the agency of force suddenly developed in the perfectly closed shell, completely filled with water, by the detonation of a small quantity of gun-cotton or other similarly violent explosive substance, immersed in the water. Mr. Abel considered that if such a result were obtained, a shell or hollow projectile of the most simple construction could be made readily to fulfil the functions of the comparatively complicated *shrapnel* and *segment* shells which have been specially designed to furnish a large number of dangerous missiles when burst during their flight.

A few experiments with ordinary cast iron shells, spherical and cylindro-conoidal, afforded conclusive demonstration of the power possessed by water, in virtue of its slight compressibility, to bring to bear uniformly in all directions upon the walls of the shell, the force developed by an explosion which is made to occur suddenly in the completely confined water-space, and showed, moreover, that the disruptive effect was proportionate not merely to the amount of explosive agent used, but also to the suddenness of the concussion imparted to the completely confined water by the explosion. In illustration of the disruptive effect of water, the following results may be quoted from a number given by Mr. Abel in his memoir. A 16-pounder (cylindro-conoidal) shell, filled with 16 ounces of gunpowder, was broken by the explosion of this charge into 29 fragments. The detonation of a quarter of an ounce of guncotton confined in a shell of precisely the same construction and weight, the chamber being filled up with water and tightly closed, burst the shell into 121 fragments, which were violently dispersed. A corresponding charge of gun-cotton, confined in a third similar shell, the chamber being filled with air, did not burst the shell when detonated; the resulting gases found vent through a minute perforation in the plug or screw-stopper of the shell. One ounce of gun-cotton confined in a similar shell, filled up with water, broke it up into 300 fragments, but in addition there were 2 lb. 1 oz. of the shell almost pulverised by the force of the explosion brought to bear upon the metal through the agency of the confined water.

The manner in which Mr. Abel has applied this system of bursting shells is very simple. The fuse which is used in field-artillery service for bursting shrapnel-shells or the common shell (when the latter is filled with gunpowder and used as a mine or an incendiary projectile), has fitted to it a small metal cylinder closed at one end, into which is tightly packed from a quarter to one-half ounce of dry compressed gun-cotton. The open end of the cylinder is closed with a screw plug containing a small chamber filled with fulminate of mercury, the upper side of which is in close contact with the fuse when the cylinder has been attached to the latter. To employ common shells as *water-shells* it is now only necessary to fill them completely with water, and then to insert and screw down firmly the fuse with its little detonating cylinder attached, when the detonating charge is fired by the action of the fuse, the shell is instantaneously burst into a large number of fragments by the concussion transmitted by the water.

Mr. Abel's prediction that this plan of bursting shells would be found most effective, is amply borne out by the magnificent practice made by the field-guns at Okehampton. Of the two batteries of Royal Artillery which have carried on the experiments during the past week, one has done more mischief with the "water-shells" than with the delicately constructed shrapnel, with the nature of which the gunners are intimately acquainted; while with the other battery of heavier field-guns the practice made was but little inferior. A little better acquaintance on the part of artillerymen with the new system of using shells will, it is anticipated, still further increase the deadly effect of these terrible weapons. Moreover, the water-shell has hitherto only been used in conjunction with a percussion fuse, while it is with the time-fuse that the shrapnel-shell is found the most effective. With the percussion-fuse the two shells are about on an equality, while the water-shell has the advantage of greater simplicity.

NOTES FROM THE "CHALLENGER"

THE following extracts from a letter dated Yeddo, June 9, 1875, addressed to me by Prof. Wyville Thomson, will, I think, interest the readers of NATURE:—

"In a note lately published in the proceedings of the Royal Society on the nature of our soundings in the Southern Sea, I stated that up to that time we had never seen any trace of the pseudopodia of Globigerina. I have now to tell a different tale, for we have seen them very many times, and their condition and the entire appearance and behaviour of the sarcode are, in a high degree, characteristic and peculiar. When the living Globigerina is examined under very favourable circumstances; that is to say, when it can at once be transferred from the tow-net and placed under a tolerably high power in fresh, still sea-water, the sarcodic contents of the chambers may be seen to exude gradually through the pores of the shell and spread out until they form a gelatinous fringe or border round the shell, filling up the spaces among the roots of the spines and rising up a little way along their length. This external coating of sarcode is rendered very visible by the oil-globules, which are oval and of considerable size, and filled with intensely coloured secondary globules; they are drawn along by the sarcode, and may be observed, with a little care, following its spreading or contracting movements. At the same time, an infinitely delicate sheath of sarcode containing minute transparent granules, but no oil-globules, rises on each of the spines to its extremity, and may be seen creeping up one side and down the other of the spine, with the peculiar flowing movement with which we are so familiar in the pseudopodia of Gromia, and of the Radiolarians. If the cell in which the Globigerina is floating receive a sudden shock, or if a drop of some irritating liquid be added to the water, the whole mass of protoplasm retreats into the shell with great rapidity, drawing the oil-globules along with it, and the outline of the surface of the shell and of the hair-like spines is left as sharp as before the exodus of the sarcode. We are getting sketches carefully prepared of the details of this process, and either Mr. Murray or I will shortly describe it more in full. . . .

"Our soundings in the Atlantic certainly gave us the impression that the siliceous bodies, including the spicules of Sponges, the spicules and tests of Radiolarians, and the Pustules of Diatoms which occur in appreciable proportions in Globigerina ooze diminish in number, and that

the more delicate of them disappear, in the transition from the calcareous ooze to the 'red clay;' and it is only by this light of later observations that we are now aware that this is by no means necessarily the case. On the 23rd of March, 1875, in the Pacific, in lat. 11° 24′ N., long. 143° 16′ E., between the Carolines and the Ladrones, we sounded in 4,574 fathoms. The bottom was what might naturally have been marked on the chart 'red clay;' it was a fine deposit, reddish brown in colour, and it contained scarcely a trace of lime. It was different, however, from the ordinary 'red clay,'—more gritty—and the lower part of the contents of the sounding tube seemed to have been compacted into a somewhat coherent cake, as if already a stage towards hardening into stone. When placed under the microscope, it was found to contain so large a proportion of the tests of Radiolarians, that Murray proposes for it the name 'Radiolarian ooze.' This observation led to the reconsideration of the deposits from the deepest soundings, and Murray thinks that he has every reason to believe (and in this I entirely agree with him) that, shortly after the 'red clay' has assumed its most characteristic form, by the removal of the calcareous matter of the shells of the Foraminifera, at a depth of say 3,000 fathoms, the deposit begins gradually to alter again by the increasing proportion of the tests of Radiolarians, until, at such extreme depths as that of the sounding of the 23rd of March, it has once more assumed the character of an almost purely organic formation, the shells of which it is mainly composed being however in this case siliceous, while in the former they were calcareous. The 'Radiolarian ooze,' although consisting chiefly of the tests of Radiolarians, contains, even in its present condition, a very considerable proportion of red clay. I believe that the explanation of this change, which was suggested by Murray, and was indeed almost a necessary sequence to his investigations, is the true one. We have every reason to believe, from a series of observations, as yet very incomplete, which have been made with the tow-net at different depths, that Radiolarians exist at all depths in the water of the ocean, while Foraminifera are confined to a comparatively superficial belt. At the surface and a little below it, the tow-net yields certain species; when sunk to greater depths, additional species are constantly found, and, in the deposits at the bottom, new forms occur, which are met with neither at the surface nor at intermediate depths. It would seem also that the species increase in number, and that the individuals are of larger size as the depth becomes greater; but many more observations are required before this can be stated with certainty. Now, if the belt of Foraminifera which, by their decomposition, according to our view, yield the 'red clay,' be restricted and constant in thickness, and if the Radiolaria live from the surface to the bottom, it is clear that, if the depth be enormously increased, the accumulation of the Radiolarian tests must gain upon that of the 'red clay,' and finally swamp and mask it."

Prof. Wyville Thomson further informs me that the best efforts of the *Challenger's* staff have failed to discover *Bathybius* in a fresh state, and that it is seriously suspected that the thing to which I gave that name is little more than sulphate of lime, precipitated in a flocculent state from the sea-water by the strong alcohol in which the specimens of the deep-sea soundings which I examined were preserved.

"The strange thing is, that this inorganic precipitated is scarcely to be distinguished from precipitated albumen, and it resembles, perhaps even more closely, the proligerous pellicle on the surface of a putrescent infusion (except in the absence of all moving particles), colouring irregularly but very fully with carmine, running into patches with defined edges, and in every way comporting itself like an organic thing."

Prof. Thomson speaks very guardedly, and does not consider the fate of *Bathybius* to be as yet absolutely decided. But since I am mainly responsible for the mistake, if it be one, of introducing this singular substance into the list of living things, I think I shall err on the right side in attaching even greater weight than he does to the view which he suggests.

T. H. HUXLEY

THE INTERNATIONAL CONGRESS AND EXHIBITION OF GEOGRAPHY

AT the distribution of prizes the Ordnance Survey obtained a letter of distinction, although it was not an exhibitor. It is the only instance in which such an honour was awarded. M. Quatrefages, in the name of the governing body of the society, awarded two exceptional prizes, one to MM. Payer and Weyprecht for the discovery of Francis-Joseph Land, and the other to M. Delaporte for the foundation of the Cambodian Museum at Compiègne. Admiral la Roncière, le Nourry closed the meeting by a very impressive address reviewing the characteristics of the Congress.

The success of the Exhibition is so great that it will be kept open up to the 19th of September. The number of visitors is greater than ever now that the Congress is over, and many fresh attractions have been added to several sections. M. Buys Ballot, the director of the Utrecht Meteorological Institution, has sent a board used by him for better indicating the direction of winds and distribution of pressure. Small holes are perforated in a map at the places occupied by the several stations. In these holes are placed small needles whose height indicates the barometrical height, and whose head is an arrow showing the actual direction of the wind.

In the French annexe has been exhibited a drawing of a machine for manufacturing relief maps out of a block of plaster. The knife is movable by a kind of pantograph, and can be conducted alongside the several *lines of level* (lignes de niveau) of a map which is seen by reflection in a plate of glass placed in a suitable position.

Peter the Great having been appointed a member of the Academy of Paris in 1717, ordered a map of the Caspian Sea to be drawn, which he sent to his fellow-members of the Academy as a proof of his zeal for the progress of science, and to justify the honour which had been conferred upon him. This map was lodged in the archives of the Academy, engraved and published in the volume of 1721, with a report written by Dellile the astronomer. It happens that the same map is exhibited at the Russian annexe, and the circumstances connected with it having become generally known, it has given rise to the report that the Grand Duke Constantine will be elected a member of the Academy, like his ancestor and the Emperor of Brazil. It is something more than an idle rumour.

A banquet was given by the Section of Commercial Geography, and some resolutions were adopted *inter poculas*. The most notable is in reference to the establishment of a *fonda* in the centre of the Sahara for the use of all civilised nations. But although adopted unanimously, the motion is not likely to be carried into execution very speedily.

SCIENCE IN GERMANY

(*From German Correspondents.*)

IT was the phenomenon of the motion of glaciers which caused most of the scientific men, that studied its details, to make experiments on the behaviour of snow and ice under pressure. The brothers Von Schlagintweit and Prof. Tyndall were the first who made such experiments with regard to glacial phenomena. Later on Helmholtz described a series of investigations, which proved amongst other things that snow is changed into ice by high pressure, that ice broken into little pieces can again be pressed into a homogeneous ice cylinder, that

such a cylinder can be pressed through openings of smaller diameter, &c. It was thus shown that under a strong pressure ice can be formed into any desired shape, that it behaves plastically even on a small scale, in the same way as the gigantic ice-rivers of glaciers do on a large one, adapting themselves to the narrower or wider parts of the valleys through which they flow. The phenomenon discovered by Faraday in the year 1850, which was afterwards widely discussed, and which was called regelation, formed the key for the explanation of this behaviour. Not one, however, of the men of science mentioned has tried to determine the exact pressure under which ice changes its form; all of them have worked with very high pressure, which in fact is necessary to obtain results that are visible in a short time. Only Moseley has made several series of experiments, to ascertain at what pressure or draught ice tears, is crushed, or when its plasticity becomes perceptible, *i.e.* at what pressure a dislocation of the ice-particles takes place. He found, that to tear an ice-cylinder apart, for each square inch of its base a weight of from 70 to 116 lbs. was necessary according to the higher or lower temperature (representing a pressure of $5\frac{1}{2}$ to 9 atmospheres). To break an ice cylinder by pressure, 101·8 lbs. were necessary for each square inch; and to cause a dislocation of the ice-particles, from 97·89 lbs. to 118 lbs. were required ($7\frac{1}{2}$ to 9 atmospheres).

Herr Pfaff, of Erlangen, has lately made a series of experiments in order to obtain some more exact numerical values for the degrees of pressure which change the form of ice to any apparent extent; it is particularly interesting to know with reference to the glacier motion, what is the *minimum* of pressure at which ice still remains plastic, *i.e.* yields to pressure. It was found that even the *smallest* pressure was sufficient to dislocate ice-particles *if it acted continuously, and if the temperature of the ice and its surroundings was near the melting-point.* At a pressure of two atmospheres ice showed itself so yielding, that for instance a hollow iron cylinder of 11·5 mm. diameter and 1·7 mm. thickness of side entered 3 mm. deep into the ice within two hours, and at a temperature of between $-1°$ and $+0·5°$. The following will show the influence of temperature. The same iron cylinder under the same pressure entered 1·25 mm. deep into the ice in twelve hours at a temperature of between $-1°$ and $-4°$; while at a temperature varying between $-6°$ and $-12°$ it only entered 1 mm. deep in five days, at a pressure of five atmospheres, or only 0·1 mm. in twelve hours. If the temperature of the surroundings rises beyond the melting-point the ice becomes so soft that in one hour the same iron cylinder under the same low pressure entered 3 cm. deep into the ice, although it was completely surrounded by snow in order to prevent the temperature of the cylinder itself rising beyond 0°. In all these experiments a one-armed lever was used to regulate the pressure; it consisted of a steel rod of 86 cm. length, which had a boring at its end and was fastened to a steel plug round which it could easily be turned. By this simple contrivance any desired pressure could be maintained for any length of time. These and other experiments (which were made with a pressure of only $\frac{1}{3}$ atmosphere) show that the plasticity of ice at a temperature near its melting-point is very great even at the lowest degrees of pressure. Herr Pfaff is of opinion that at this temperature the plasticity of the ice only becomes *nil* when the pressure itself is *nil*, but that it decreases very quickly as the temperature gets lower.

The opinion is still widely spread, based upon some experiments of Tyndall, that ice is not in the least flexible or ductile, although lately several observations have been made which force us to ascribe some flexibility to that substance. Kane observed, for instance, that a large slab of ice resting with its edges on two other blocks, bent itself under its own weight after a lapse of several months. Herr Pfaff experimented with a parallelopiped of ice of 52 cm. length, 2·5 cm. breadth, and 1·3 cm. thickness. It was placed with its two ends on wooden supports, so that on each side 5 mm. were resting on wood. From Feb. 8th to Feb. 15th, when the temperature remained between $-12°$ and $-3·5°$, the middle sunk very little, on the average 2 or 3 mm. in twenty-four hours, so that on Feb. 15th the total bend amounted to 11·5 mm. Then the temperature rose but still remained under 0°; yet this rise caused a great increase in the bending, as it reached the value of 9 mm. in twenty-four hours (therefore 20·5 in all). Nowhere could any crack or tear in the ice be seen; the lower surface was examined with particular care, and did not show the trace of a crack!

Herr Pfaff has also succeeded in proving the expansion of ice by draught. It appears therefore that near its melting-point ice, like other bodies, yields to pressure and to draught, and must be looked upon, particularly with reference to the former, as an eminently plastic substance. This behaviour of ice towards pressure at different temperatures throws a new light upon the fact that the velocity in the motion of glaciers increases with temperature. As the glacier ice and the air over it possess a temperature, in the summer months at least, which lies very near the freezing point, it is evident that a very small pressure suffices to cause the glaciers to move. S. W.

At present a question is being discussed by morphologists, which seriously affects in more than one direction some traditional maxims of experience which were apparently confirmed long ago. It treats of the way and means by which cells, the foundation-stones as it were of the animal organism, are formed during the first process of the development of the ovum, viz., during its continually progressing division. The views of Remak, Kölliker, and others were generally adopted and often repeated until lately, namely, that the ripe and fertilised ovum, when it lost its former nucleus, the "germ bubble," received a new one, and that the division of this new nucleus caused that of the ovum itself; the further divisions were represented by the simple idea of a division of cells. Although Goette already, in the year 1870 ("Centralblatt für die medicinischen Wissenschaften," No. 38), and later, Bütschli ("Beiträge zur Kenntniss der freilebenden Nematoden," in "Nova acta der Leop. Carol. Deutschen Akademie der Naturforscher," 1873), and Fol ("Die erste Entwickelung des Geryonidencies; Jenaische Zeitschrift für Medicin und Naturwissenschaft," 1873) had opposed these views on the basis of new observations, yet general attention was only obtained by Auerbach in his work, "Organologische Studien" (1874), as the question at stake was treated in a more detailed manner. Auerbach examined the same animals which Bütschli had observed, viz., that order of Entozoa known as Nematoidea; he found that in their fertilised ovum, after the germ bubble has disappeared, two new nuclei are formed at two opposite poles of the ovum, which then approach each other towards the middle of the ovum and unite into *one;* this, however, soon disappears again, and a less sharply defined clear substance takes its place; this then extends longitudinally and takes a star-shaped form at each end, so that the two stars are connected by a thin stem. Now the division of the ovum begins to take place through the middle of that stem, while in each half of the same, by the confluence of little bubbles, a nucleus forms, which initiates the same phenomena for the further divisions as those which precede and accompany the first one. The result, therefore, would be as follows:—1. In the division of the ova of Nematoidea the nuclei disappear before each stage of the division, and form anew after each stage. 2. This formation takes place through the confluence of two or more bubble-shaped or nucleus-like

new forms. 3. The disappearance of the nuclei is accompanied by a peculiar star-shaped formation, which Auerbach deduces from the flowing apart of the nucleus matter. Bütschli has lately published new observations on the same subject ("Siebold's und Kölliker's Zeitschrift für wissenschaftliche Zoologie," 1875), from which it must be specially pointed out that even the first nucleus of the fertilished ovum of some Nematoidea, and of the freshwater mollusc, Limnæus, results from the confluence of several little bubbles. Flemming has found Auerbach's observations confirmed with the fresh-water shell, Anodonta ("Archiv für mikroskopische Anatomie," band x., and "Sitzungsberichte der Akademie der Wissenschaften zu Wien III. Abtheilung," 1875"); he only differs so far from Auerbach in the interpretation of what he saw, that he does not deduce the "carpolytical figures" of the latter from the nucleus matter which radiates from the centre of the nucleus, but from a peculiar structure in the surrounding yolk-protoplasm, which he considers to be in connection with each division of the yolk and the new formation of the nuclei. But he does not interpret the process of this new formation. Flemming, in his second paper, describes the observations on a radiated arrangement of the yolk, which had previously been made occasionally with several other animals, without the observers being able to explain these phenomena or trying to investigate them further. We must, however, remark here that Goette, in the work we mentioned in our last report, has not only completely described the interior process of the division of the ovum of *Reptilia*, but has also attempted a uniform explanation of the same. According to his experience no nuclei at all are formed for some time in the division parts of the yolk, but only nuclei-shaped interior transformation products of the yolk, which are only apparently separated from their surroundings, but are in reality in continuous connection with them. These interior formations originate as collecting points of a radiated and universal protoplasm current in the yolk, which in turn results from the reciprocal action of the ovum and the surrounding medium. The difference in the currents is said to cause (in a manner described in detail) the division of these interior formations, and, as a consequence, the division of the surrounding yolk material. The radiated arrangement of the latter round the brighter centres is only imperfectly visible in *Batrachia*; but Goette has observed it in the ova of *Ascidia*, and interpreted it in the way just described. The definite nuclei of embryo cells, which result immediately from the division of the yolk, Goette supposes to be formed within those centres from a number of grains, which are at first greatly augmented, and then finally unite completely. But these origins of the nuclei do not disappear during the divisions of the yolk. If now we compare all the observations mentioned, we first of all find them all agreeing *that the division of the yolk is no simple cell division*, such as is elsewhere found in the tissues of developed organisms; for the remainder, the observations do not agree. While Goette supposes a gradual and continual progress of the formation of cells beginning from the first division, the other observers incline to the belief that at each division an interruption and a consequent re-beginning of the formation of cells takes place, as the once formed nuclei are said to disappear continually and new ones are said to form.

NOTES

THE U.S. Government have just shown in a handsome manner their appreciation of the services rendered by Dr. Henry Draper in connection with the U.S. observation of the recent Transit of Venus, by presenting him with a gold medal made at the U.S. Mint at Philadelphia. On the obverse is the motto, from Virgil, "Famam extendere factis hoc virtutis opus est," and in the centre a figure of the heliostat which was used by Dr. Draper in training the photographers. On the reverse is the inscription, "Veneris in sole spectandæ curatores, R. P. F. S. Henrico Draper, M.D., Dec. viii. MDCCCLXXIV." The phrase around the edge of the reverse, "Decori decus addit avito," conveys a tribute of praise to the literary and scientific attainments of Dr. Draper, sen. The Transit Commission have also sent Dr. Draper a handsomely bound set of resolutions illuminated in mediæval style, with a telescope, camera, &c. We are sure all scientific men will join in congratulating Dr. Draper on his well-deserved honour, and at the same time the U.S. Government on their enlightenment in thus acknowledging the glory which the triumphs of pure science have shed upon a nation; they have set a striking example to our own and other European Governments.

THE fifth session of the French Association for the Advancement of Science, as we intimated in our last number, will be opened to-day at Nantes. The principal attraction will be the excursions; one of them will last for more than three days, a war-steamer having been placed at the service of the Association by the Minister of Marine. The excursionists will visit Vannes and its prehistorical museums, the megalithic monuments of Locmariaques, the celebrated remains at Carnac, the sland of Belle-ile, and Lorient. No doubt there will be a great rush for the excursion. The list of papers to be read is a very long one. In the Mathematical Section a large number of the papers are on engineering subjects, and in the Natural Science Section a large proportion are on medical subjects, besides a good many on prehistoric archæology. Among the latter class are the following:—Dr. Broca, On the anthropology of Brittany; The Dolmens of the Lozère, by Dr. Prunières; On the funeral rites of prehistoric times in Scandinavia, by M. Waldemar-Schmidt. Other papers in this section are: On a new elementary theory of botany, by Dr. Ecorchard; On the meaning which it is proper to attach to the word "Mollusc" as a taxonomic term, and On the organisation of Rhizomes, by Dr. Gulland; On the Fauna of the Lake of Tiberias, by Dr. Lortet; On the pressure and rate of the blood in the arteries, by M. Marey. In the Section of Physical and Chemical Sciences we note the following:—On Microzymes in their relation to fermentation and physiology, On two new principles of wine, and On the origin of Bacteria, by Prof. Béchamp; Experiments on the rate of light between the Paris Observatory and Montlhéry, by M. A. Cornu; On the use of the spectroscope in the manufacture of Bessemer steel, by M. V. Deshayes; The meteorology and physics of the Polar Regions, by the Abbé Durand; On molecular combinations, by M. C. Friedel; On the limits of permanent snow and ice on the surface of the globe, On a magneto-dynamic galvanoscope, and On the chemical constitution of albuminoid matters, by M. P. Schützenberger; On a polymer of the oxide of ethylene, and on the dissociation of the salts ot aniline, by M. A. Wurtz. There will be two public lectures—one by Prof. Bureau, of the Paris Museum, On the Natural Sciences at Nantes, and the other, On Acoustics—the *timbre* of sounds, by Dr. Gavarret.

THE above Association is not the only French institution which was created after the model of the British Association. M. de Caumont, who died four years ago, instituted another annual scientific congress, which will hold its forty-first session at Perigueux, in the department of Dordogne. Every year this association meets in a provincial town during summer, and at Paris during the recess of Easter. The members are mostly Legitimists and Roman Catholics.

THE forty-eighth meeting of the German Scientific and Medical Association will commence this year on the 17th of September at Graz (Austria). The two branches will be

presided over by Drs. Rollet and von Tebal of that University, who have issued the following programme: Sept. 17, 8 P.M.—Preliminary Meeting. Sept. 18, 10 A.M.—First General Meeting; 1 P.M.—Sectional Meetings; 8 P.M.—Reunion; Sept. 19.—Excursion to the Castle, Sectional Meetings, Evening Concert at the Theatre. Sept. 20.—Sectional Meetings and Excursions. Sept. 21.—Second General Meeting, Sectional Meetings, Festive Performance in two Theatres. Sept. 22.—Excursions. Sept. 23.—Sectional Meetings, Banquet. Sept. 24.—Third and Concluding General Meeting, Ball. The Sections will be divided as follows: (1) Mathematics and Astronomy. (2) Natural Philosophy and Meteorology. (3) Chemistry. (4) Mineralogy, Geology, and Palæontology. (5) Botany. (6) Zoology. (7) Anatomy and Physiology. (8) Medicine. (9) Surgery. (10) Ophthalmology and Otiatry. (11) Midwifery. (12) Psychiatry. (13) Public Health. (14) Military Surgery. (15) General Pathology. (16) The Teaching of Science. (17) Agriculture.

A CONGRESS has been held at Nancy on the history, archæology, and languages of the American continent. The city was illuminated, and a banquet was given by the municipality to the foreign members of the Congress. A most interesting exhibition took place, principally of American stone implements, Peruvian mummies, Columbian idols, and skulls of a number of the aborigines. The Congress discussed the questions relating to the discovery of America before Columbus, by Norwegians, Phœnicians, and Buddhists, and did not appear inclined to believe in the reality of any of the traditions. There were also discussed at some length the relations of Esquimaux tribes with those of Northern Asia, traditions as to white men, the monuments of the Mississippi Valley, and the rock inscriptions, without coming to any definite conclusions.

THE observation of meteors has been organised in France by the Association Scientifique under M. Leverrier; this organisation numbers more than 6,000 members, but has no annual meeting. About forty stations keep watch on critical nights. The results of the observations during the time of the August shower have been unusually good. At Rochefort and Rouen alone more than 160 tracks were mapped during the nights of the 9th and 10th of August, mostly connected with the Perseus radiant.

THE preparations for the Scientific and Agricultural Congress at Palermo on the 29th inst. are proceeding with unabated activity. Many *savants*, particularly from Germany, have intimated their intention to assist at the proceedings. Father Secchi will preside in the department of Astronomy.

FROM observations made upon the Manatee living in the Zoological Gardens, Regent's Park, the Society's Prosector has had the opportunity of presenting a paper to be read during the next session of the Scientific Committee of the Society, on the peculiar prehensile power of the upper lip of that animal, by which it seizes its food between the two lateral bristle-covered pads with which that organ is provided, and which it can move laterally.

THE *Journal of Anatomy and Physiology*, which till now has done much service to biologists under the able editorship of Prof. Humphry, of Cambridge, and Prof. Turner, of Edinburgh, is to be further strengthened in the Physiological Section by the extra editorial assistance of Dr. Michael Foster, of Cambridge, and Prof. Rutherford, of Edinburgh. The journal is also to appear quarterly, not half-yearly, as heretofore.

THE Transactions of the Zoological Society, vol. ix. Part iv., just issued, comprises a memoir, by Mr. Sclater, F.R.S., "On the Curassows now or lately living in the Society's Gardens." It is illustrated with thirteen coloured quarto plates from the pencil of Mr. Smit, and forms a complete monograph of all the known species of true curassows.

M. E. MULSANT, Conservator of the Library of the City of Lyons, is on a visit to this country for the purpose of examining Messrs. Salvin and Godman's, as well as other collections of birds, in order to render more complete his "Histoire Naturelle des Oiseaux-Mouches," now in course of publication.

CAPT. BURTON and party have just returned from Iceland. The immediate object of the visit was to examine the extensive sulphur mines which were worked in the north-eastern part of the island about the beginning of the present century, and for the reopening of which a company has recently been formed. The result of the visit seems in this respect to have been satisfactory. Mr. W. L. Watts met Capt. Burton's party, just after he had performed the remarkable feat of crossing the Vatna Jokul, an immense snowy table-land in the S.E. corner of the island. Mr. Watts has been the first to accomplish this feat.

IN the note concerning a shower of hay in Denbighshire in last week's NATURE, p. 298, we omitted to say that the year in which the occurrence took place was 1857.

THIS year's meeting of the British Archæological Association was opened at Evesham on Monday by the President, the Marquis of Hertford, who reviewed the several points of interest which the Association intended to visit in Warwickshire and Worcestershire.

THE most important paper in the July number of the *Bulletin* of the French Geographical Society is on the geography of the Athabasca-Mackenzie region, by the Abbé E. Petitot, who has spent twelve years as a missionary in that inhospitable portion of North America, making many journeys to all parts of the district indicated, lying between the Coppermine River and the Rocky Mountains, and the Great Slave Lake and the Arctic Ocean. The Abbé gives a brief *résumé* of discovery in this region, and a short sketch of the various journeys he himself made, to be followed by further details. An excellent map accompanies the narrative, and although the explorer's instruments were rather scanty, it is evident that he has added largely to our knowledge of the geography of the district of country referred to.

ANOTHER interesting paper in the same number is on the Lyssous of Lin-tze-Kiang, by another missionary, the Abbé Dubernard. It is notable how large a number of French explorers have been missionaries.

A RETURN has been presented to Parliament giving a statement of all the weather telegrams issued by the Meteorological Office, and also of all the storms experienced on the coasts of the British Islands during 1874, from which it appears that of the warnings issued, 78·2 per cent. were justified by subsequent gales or strong winds, and that 16·4 per cent. were not justified by the subsequent weather. This percentage of success in the warnings issued, which is slightly in excess of the last two years' of Fitzroy's management, considerably in excess of 1870 and 1871, and about equal to the results for 1872 and 1873, is perhaps as good as may reasonably be expected until the system be further extended and developed.

WE have received a circular calling attention to the success attending the working of Dr. Herman Sprengel's improvement in the manufacture of sulphuric acid. The process was patented in 1873, and consists in injecting water in the form of spray into the chambers instead of steam. To effect this a jet of steam escapes from a platinum nozzle at a pressure of about two pounds, and blows through the centre of a flowing jet of water by means of an apparatus similar in principle to Herapath's blow-pipe. These jets are let into the side of the chamber at distances of 40 feet. The advantages gained are economy of

fuel, nitric acid, and pyrites. The method has been in use at the works of the "Lawes Chemical Manure Company" at Barking, and the returns show that a saving of coal to the amount of $\frac{2}{3}$ of the quantity formerly burned has been effected—the total saving in steam, nitric acid, and labour during three months, amounting to five shillings per ton of acid of sp. gr. 1·6 made from pyrites. The patentee just points out that a saving of even one shilling per ton means in this country an annual gain of 50,000*l*.

THE Rev. N. M. Ferrers, of Cambridge, author of "A Treatise on Trilinear Co-ordinates," is preparing for the press a work on Spherical Harmonics. The plan adopted in this work will be first to discuss thoroughly the properties of the Zonal Harmonic, for which various expressions will be given, and general formulæ investigated, by which any rational integral function of one independent variable may be expressed in a series of Zonal Harmonics. The properties of Tesseral and Sectorial Harmonics will then be deduced from these. The expression of a discontinuous function by means of Spherical Harmonics will be discussed; and various examples will be given of the use of Spherical Harmonics in their applications to the theories of attraction, and of electricity and magnetism. The book will be published by Messrs. Macmillan and Co.

"PYTHAGOREAN Triangles" is the title of a paper which was read by W. Allen Whitworth, M.A., before the Literary and Philosophical Society of Liverpool in February of the present year. A Pythagorean triangle is a right-angled triangle having all its sides commensurable. The most familiar instance is that triangle whose sides are in the ratio of the numbers 3, 4, 5. The author shows that one of the sides must be even (a multiple of 4), one a multiple of 3, and that either a side or the hypotenuse must be divisible by 5. Making use of a discovery of Fermat's, he further shows that every prime number of the form $4N + 1$ is the hypotenuse of such a triangle. The most general results obtained are "the product of n prime hypotenuses, all different, will be itself the hypotenuse of 2^{n-1} Pythagorean triangles;" this result is modified if m only are different, to 2^{m-1} Pythagorean triangles. With the aid of these results he presents, in a tabulated form, 395 such triangles, with hypotenuses less than 2,500. We may mention that in Tebay's Mensuration a table of some 200 of these triangles is given, but with no indication as to how they are obtained. A great deal of information on the subject of these triangles is given in vol. xx. of "Mathematics from the *Educational Times*," at pp. 20, 54, 75, 76, 87, 97–100, to which we refer such of our readers as may be interested in the matter.

THE West Riding Consolidated Naturalists' Society have published the first number of a new monthly journal, the *Naturalist*. A journal with a similar title was published in the same district during the years 1865-6-7; we hope the present one will have a much longer life. Its principal object is to afford a means of communication among all Natural History Societies, either within or outside the county of York.

FROM the fourth Annual Report of the Chester Society of Natural Science, we are glad to see that the Society is prosperous and in good working order. The members now number 541, and during the past year several excursions have been made, several general meetings held for lectures, and the regular work of the sections carried on. Altogether this Society seems in a hopeful condition. The same Report contains a brief report of the Wrexham Society of Natural Science, which seems to some extent to be under the fostering care of its more prosperous Chester sister. It seems to be, on the whole, doing well.

MAJOR WOOD has sent us a reprint of two papers, with a map, on the Aralo-Caspian region; they originally appeared in the *Globe*, the journal of the Geographical Society of Geneva. Ramboz and Schuchardt, of Geneva, are the publishers.

THE additions to the Zoological Society's Gardens during the past week include a Red Deer (*Cervus elaphus*), European, presented by Mr. Samuel Carter; a Malabar Squirrel (*Sciurus maximus*) from S. India, presented by the Chevalier Blondin; two Purple Cow Birds (*Molothrus purpureus*) from Peru, presented by Prof. W. Nation; a Yellow-fronted Amazon (*Chrysotis ochrocephala*) from Guiana, presented by Mrs. Bolton; a Crested Peacock Pheasant (*Polyplectron chinquis*) from Malacca, purchased; three Hoffmann's Sloths (*Cholopus hoffmanni*) from Panama; three Spotted Cavies (*Cœlogenys paca*), a Coypu (*Myopotamus coypus*) from S. America, an Argus Pheasant (*Argus giganteus*) from Malacca, deposited.

ON THE ACTION OF URARI ON THE CENTRAL NERVOUS SYSTEM

SINCE the introduction of urari twenty years back it has become more and more employed as an anæsthetic for physiological experiments. Its effects on the peripheral portions of the nervous system have been carefully studied, and are most distinct and peculiar, so much so that they seem to have diverted attention from its action on the central organs. Its effect, briefly, when injected subcutaneously, is to produce a paralysis of the motor nerves by attacking their ultimate branches. Dr. Foster, at whose suggestion these experiments were undertaken, and to whom I am indebted for much assistance, in the "Handbook for the Physiological Laboratory" establishes the following propositions:—1. "The effect of urari is to destroy or suspend the irritability of nerves, but not of muscles." 2. "With moderate doses of urari the small branches appear to be poisoned and to have lost their irritability, while the trunks are still intact." He also points out that "in order to bring these results out well, the dose of poison must not be more than sufficient to poison the motor nerves. Subsequent or stronger action of the poison affects the central nervous system as well." Now it is perfectly clear that the poison produces no appreciable effect on the sensory nerves, and in consequence rash conclusions have been drawn that it also has no effect on the sensorium, and is, in fact, not an anæsthetic at all.

The method of investigation employed was to take two frogs, as nearly as possible alike in size and vigour, and to pass a ligature round the whole abdomen (on Bernard's plan), taking care to exclude from the ligature the sciatic plexus and to include the blood-vessels. To one of the frogs a dose of urari was then administered, and the two placed under similar conditions and watched. The ligature in the poisoned frog of course prevented the urari from gaining access to the hinder limbs, while it could act fully on the nerve centres; and the behaviour of this frog could be compared with one which had merely undergone the operation, and was clearly possessed of consciousness and volition. We will call the two frogs A and B, B being the one which has the dose of urari. Now as soon as the poison took effect, movements of respiration of course ceased, and the frog lost control over its fore-limbs. On placing them side by side in an unconstrained position, A constantly moved, executing large and small movements with precision; its actions seemed in no way different from those of an uninjured frog. During this time the frog B never moved, and although quite capable of using its hind limbs, never did so; at rare intervals (perhaps half an hour), however, a movement was executed, but of a very distinct kind, a mere kick, such as a frog gives after the removal of its brain, in virtue of pure reflex action; now the innervation of the hind limbs was quite intact; the animal, if possessed of any wish to move them, was quite able to do so, so far as its structural arrangements were concerned. Indeed, the frog bore a striking resemblance to one which had had its brain removed; it behaved in almost every respect in the same manner.

If the two frogs be now laid on their face, a most convincing experiment can now be tried. If the leg of A be forcibly extended and let go, it is drawn up; it it be extended and held for a short time, it is again drawn up. Now if the leg of B be extended and at once released, it is also drawn up; but if it be held for a second against the efforts of the animal to withdraw it, these efforts cease and the limb retains its position for an almost indefinite period. Now there can be only one explanation of the behaviour of the frog B, namely, that the urari destroys consciousness and volition at an early period; that on extending

the hind limb the mere act of extension is sufficient stimulus to call forth a definite amount of response which takes the form of a simple contraction, but that if the limb be held until this reflex act has passed off there is no consciousness on the part of the brain that the limb is in an unusual position, and consequently no volition is exerted to remove it.

It cannot be objected to this experiment that the stoppage of the circulation in the hind limbs has diminished their irritability because the frog A has perfect control over his; and, moreover, the vigour with which the reflex acts are executed in B precludes this idea. Again, it might be said that the stoppage of the respiration by the urari, and consequent supply of ill-aërated blood to the brain has injured the volition of the animal; to meet this, two counter experiments have been tried: in one a frog was gagged so as to keep its mouth open for some hours, and in the other a frog was kept under well-aërated water for two hours (a period equal to the duration of the chief experiment), and in neither case did the frogs seem to suffer any inconvenience whatever, least of all did they lose their volition.

In order to investigate the action of urari on the spinal cord, two similar frogs were taken as before; but previously to being ligatured they were pithed and had their brains destroyed; they were then suspended, and the state of the cord, as manifested by reflex action, tested; dilute sulphuric acid was used as stimulus; the numbers represent quarter seconds.

	h, m.	A*	B	
α	3 30	9	8	
	3 35	7	6	
	3 40	8	6	
		A* Lost blood.		
β	3 40	Urari was given to B.		
	4 15	8	5	
	4 20	8	7	
	4 25	8	6	
	4 30	8	8	
	4 35	9	9	
γ	4 35	A second dose to B.		
	4 40	7	14	
	4 45	8	26	
	4 50	9	22	
	4 55	7	27	Not strong.
	5 0	9	60	Weak.
	5 5	8		No action after 220.
	5 10	...	...	

From this it would appear that the first effect of urari is to make the action of the cord uncertain, then to delay the reflex action, and finally to destroy it entirely. The table has been divided into three parts, α, β, and γ, which seem to represent in a tolerably typical manner the three stages into which the phenomena are always divisible; sometimes the animal recovered after the stage γ.

This short account of the above experiments is intended as a preliminary notice. I am continuing investigations on mammals, and purpose hereafter to publish a more complete account of my results.

C. YULE

Physiological Laboratory, Cambridge

P.S.—Since writing the above my attention has been called to a paper by Dr. J. Steiner, in *Reichart's und Du Bois-Raymond's Archiv* for July. He investigates the action of urari on Invertebrates and fishes, and finds that among the latter its effect is to destroy volition before the peripheral motor fibres are attacked.

WEATHER AND EPIDEMICS OF SCARLET FEVER IN LONDON DURING THE PAST THIRTY-FIVE YEARS*

THIS paper gives the results of an investigation, the purpose of which was to determine whether the seasonal influence of weather on deaths from scarlet fever, as shown by the curve constructed from the figures of thirty years, would present itself if the period were broken up and curves constructed for the several smaller periods embraced in the long one. In other words, the object was to determine whether, in the case of a disease which is strongly epidemic, the obedience to seasonal influences, would exhibit a steadiness and uniformity of character, such as is presented in the case of pulmonary diseases. In London there have been six epidemics of scarlet fever during the last thirty-five years, reaching their maxima in 1844, 1848, 1854, 1859, 1863, and 1870. Curves were constructed representing the average weekly deaths from scarlet fever for each of the six periods embracing these epidemics. These curves were then compared with the curve for the thirty years, 1845–74, the leading features of which are that it is above the average from the beginning of September to the end of the year, and below the average during the rest of the year; and that the period of highest death-rate is from the beginning of October to the end of November, when it rises to about 60 per cent. above the average, and the period of lowest death-rate in March, April, and May, when it is about 33 per cent. below the average.

On comparing the curves for the six short portions of the thirty-five years, each dealing only with four, five, or six years, with the general curve for the long period of thirty years, a remarkable similarity is found to occur. They are all substantially the same curve. The description of the general curve given above applies almost literally to every one of the six curves for short periods, and indeed so close is the correspondence that they all cross their mean almost in the same week of the year. In every case the maximum occurs in October and November, and the only point of difference among them is that while the general curve rises at the maximum period to 60 per cent. above the average, during the first epidemic it rose only to 40 per cent., and in one or two of the others it rose to 80 per cent. above the average. The steady obedience to climatic influences in the fatality from a disease so decidedly epidemic as scarlet fever is very remarkable, and the more so inasmuch as no other disease, with the single exception of typhoid fever, attains to its maximum fatality in London under the conditions of weather peculiar to October and November.

* Abstract of a paper read by Dr. Arthur Mitchell at the general meeting of the Scottish Meteorological Society, July 13.

PHYSICAL PROPERTIES OF MATTER IN THE LIQUID AND GASEOUS STATES*

II.

Law of Gay-Lussac.—That the law of Gay-Lussac in the case of the so-called permanent gases, or in general terms of gases greatly above their critical points, holds good at least at ordinary pressures, within the limits of experimental error, is highly probable from the experiments of Regnault; but the results I have obtained with carbonic acid will show that this law, like that of Boyle, is true only in certain limiting conditions of gaseous matter, and that it wholly fails in others. It will be shown that not only does the coefficient of expansion change rapidly with the pressure, but that, *the pressure or volume remaining constant, the coefficient changes with the temperature.* The latter result was first obtained from a set of preliminary experiments, in which the expansion of carbonic acid under a pressure of seventeen atmospheres was observed at 4°, 20°, and 54°; and it has since been fully confirmed by a large number of experiments made at different pressures and well-defined temperatures. These experiments were conducted by the two methods commonly known as the method of constant pressure and the method of constant volume. The two methods, except in the limiting conditions, do not give the same values for the coefficient of expansion; but they agree in this respect, that at high pressures the value of that coefficient changes with the temperature. While I have confined this statement to the actual results of experiment, I have no doubt that future observations will discover, in the case, at least, of such gases as carbonic acid, a similar but smaller change in the value of the co-efficient for heat at low pressures. The numerous experiments I have made on this subject will shortly be communicated in detail to the Society; and for the present I will only give the following results:—

Expansion of Heat of Carbonic Acid Gas under high pressures.

Pressure.	Vol. CO_2 at 0_2 and 760 millims. = 1.	Vol. CO_2 at. 6°·05 and 22·26 at. = 1.	Temperature.

22·26	0·05909	1·5020	100·10	

* "Preliminary Notice of further Researches on the Physical Properties of Matter in the Liquid and Gaseous States under varied conditions of Pressure and Temperature." Paper read before the Royal Society by Dr. Andrews, F.R.S., Vice-President of Queen's College, Belfast. Continued from p. 301.

Pressure. at.	Vol. CO_2 at 0° & 760 millims. = 1.	Vol. CO_2 at 6°·62 and 31·06 at. = 1.	Temperature.	
31·06	0·02589	1·0000	6·62	... (B)
31·06	0·03600	1·3905	63·83	
31·06	0·04160	1·6068	100·64	

Pressure. at.	Vol. CO_2 at 0° and 760 millims. = 1.	Vol. CO_2 at. 6°.01 and 40·06 at. = 1.	Temperature.	
40·06	0·01744	1·0000	6·01	... (C)
40·06	0·02697	1·5464	63·64	
40·06	0·03161	1·8123	100·60	

Taking as unit 1 vol. of carbonic acid at 6°·05 and 22·26 atmospheres, we obtain from series A the following values for the coefficient of heat for different ranges of temperature :—

α = 0·005499 from 6°·05 to 63°·79
α = 0·005081 from 63°·79 to 100°·1

From series B, with the corresponding unit volume at 6°·62 and 31°·06 atmospheres, we find :—

α = 0·006826 from 6°·62 to 63°·83
α = 0·005876 from 63°·83 to 100°·64

And in like manner from series C with the unit volume at 6°·01 and 40·06 atmospheres :—

α = 0·009481 from 6°·01 to 63°·64
α = 0·007194 from 63°·64 to 100°·60

The co-efficient of carbonic acid under one atmosphere referred to a unit volume at 6° is

α = 0·003629

From these experiments it appears that the co-efficient of expansion increases rapidly with the pressure. Between the temperatures of 6° and 64° it is once and a half as great under 22 atmospheres, and more than two and a half times as great under 40 atmospheres, as at the pressure of 1 atmosphere. Still more important is the change in the value of the co-efficient at different parts of the thermometric scale, the pressure remaining the same. An inspection of the figures will also show that this change of value at different temperatures increases with the pressure.

Another interesting question, and one of great importance in reference to the laws of molecular action, is the relation between the elastic forces of a gas at different temperatures while the volume remains constant. The experiments which I have made in this part of the inquiry are only preliminary, and were performed not with pure carbonic acid, but with a mixture of about 11 volumes of carbonic acid and 1 volume of air. It will be convenient, for the sake of comparison, to calculate, as is usually done, the values of α from these experiments; but it must be remembered that α here represents no longer a coefficient of volume, but a coefficient of elastic force.

Elastic force of a mixture of 11 vol. CO_2 and 1 vol. air heated under a constant volume to different temperatures.

Vol. CO_2.	Temperature.	Elastic Force. at.	
366·1	13·70	22·90	... (A)
366·2	40·63	25·74	
366·2	99·73	31·65	
256·8	13·70	31·18	... (B)
256·8	40·66	35·44	
256·8	99·75	44·29	

From series A we deduce for a unit at 13°·70 and 22°·90 atmospheres :—

α = 0·004604 from 13°·70 to 40°·63
α = 0·004367 from 40°·63 to 99°·73

And from series B :—

α = 0·005067 from 13°·70 to 40°·66
α = 0·004804 from 40°·66 to 99°·75

The coefficient at 13°·70 and 1 atmosphere is

α = 0·003513

It is clear that the changes in the values of α, calculated from the elastic forces under a constant volume, are in the same direction as those already deduced from the expansion of the gas under a constant pressure. The value of α increases with the pressure, and it is greater at lower than at higher temperatures. But a remarkable relation exists between the coefficients in the present case which does not exist between the coefficients obtained from the expansion of the gas. The values of α, deduced for the same range of temperature from the elastic forces at different pressures, are directly proportional to one another. We have, in short—

$$\frac{0·004367}{0.004604} = 0·9485, \qquad \frac{0·04804}{0·05067} = 0·9481.$$

How far this relation will be found to exist under other conditions of temperature and pressure will appear when experiments now in progress are brought to a conclusion.

Law of Dalton.—This law, as originally enunciated by its author, is, that the particles of one gas possess no repulsive or attractive power with regard to the particles of another. "Oxygen gas," he states, "azotic gas, hydrogenous gas, carbonic acid gas, aqueous vapour, and probably several other elastic fluids may exist in company under any pressure and at any temperature without any regard to their specific gravities, and without any pressure upon one another." The experiments which I have made on mixtures of carbonic acid and nitrogen have occupied a larger portion of time than all I have yet referred to. They have been carried to the great pressure of 283·9 atmospheres, as measured in glass tubes by a hydrogen manometer, at which pressure a mixture of three volumes carbonic acid and four volumes nitrogen was reduced at 7°·6 to $\frac{1}{378}$ of its volume without liquefaction of the carbonic acid. As this note has already extended to an unusual length, I will not now attempt to give an analysis of these experiments, but shall briefly state their general results. The most important of these results is *the lowering of the critical point by admixture with a non-condensable gas.* Thus in the mixture mentioned above of carbonic acid and nitrogen, no liquid was formed at any pressure till the temperature was reduced below − 20° C. Even the addition of only $\frac{1}{10}$ of its volume of air or nitrogen to carbonic acid gas will lower the critical point several degrees. Finally, these experiments leave no doubt that the law of Dalton entirely fails under high pressures, where one of the gases is at a temperature not greatly above its critical point. The anomalies observed in the tension of the vapour of water, when alone and when mixed with air, find their real explanation in the fact that the law of Dalton is only approximately true in the case of mixtures of air and aqueous vapour at the ordinary pressure and temperature of the atmosphere, and do not depend, as has been alleged, on any disturbing influence produced by a hygroscopic action of the sides of the containing vessel. The law of Dalton, in short, like the laws of Boyle and Gay-Lussac, only holds good in the case of gaseous bodies which are at feeble pressures and at temperatures greatly above their critical points. Under other conditions these laws are interfered with; and in certain conditions (such as some of those described in this note) the interfering causes become so powerful as practically to efface them.

SCIENTIFIC SERIALS

Poggendorff's Annalen der Physik und Chemie, Nos. 5 and 6.—These parts contain the following papers:—No. 5: On the variations in the phases of light when reflected from glass, by P. Glan; account of experiments made in the physical laboratory of Berlin University, under the direction of Prof. Helmholtz.—On some remarkable growths of quartz crystals on calcareous spar from Schneeberg in Saxony, by Aug. Frenzel of Freiberg, and G. vom Rath of Bonn.—Mineralogical researches, by G. vom Rath. This paper treats of pseudomorphous monticellite from Pesmeda, on the Monzoni Mountain in Tyrol, of rhombic sulphur, of calcareous spar from Ahren (Tyrol), and of a peculiar specimen of quartz from Japan.—On a method to determine extra currents electroscopically, by Dr. F. Fuchs.—On the electric conduction resistance of air, by A. Oberbeck.—On the absorption and refraction of light in metallic opaque bodies, by W. Werniche.—On the changes which take place in temperature at the passage of an electric current from one metal to another, by Dr. Heinr. Buff.—On the isodynamical planes round a vertical magnetic rod, and their application in an investigation of iron ore deposits, based upon magnetic measurements, by Rob. Thalén.—A paper on the same subject, by Th. Dang. Both these papers are from the *Kongl. Vetenskaps Förhandlingar.*—Spectroscopic Notes, by J. Norman Lockyer: On the evidence of variation in molecular structure, and On the molecular structure of vapours in connection with their densities. These Notes are translated from the Proceedings of the Royal Society, June 11, 1874.—On the distribution of heat in the normal spectrum, by G. Lundquist.—On the time of attraction and repulsion of electro-magnets, by Dr. Schneebeli.—On the mathematical

determination of the places of deviation in telegraph lines, by Fr. Schaak.—Experiments on the plasticity of ice, by Prof. F. Pfaff. These experiments have been minutely described under our heading "Science in Germany."—On the behaviour of certain fluorescent bodies towards oleum ricini, by Ch. Horner.—On a new source of magnetism, by Donato Tommasi.—No. 6: On the temporary course of the polarisation current, by Prof. J. Bernstein.—On the objections raised against Weber's law by Tait, Thomson, and Helmholtz, by C. Neumann.—Researches in spectrum analysis, by R. Bunsen. This paper will also appear in detailed extract under our heading "Science in Germany."—On the evidence of alternation of electricity by means of flames, by F. Fuchs.—On the variations in the phases of light when reflected from glass, by P. Glan (second paper).—On the theory of laying and examining submarine telegraph lines, by W. Siemens.—Researches on the magnetism of steel rods, by C. Fromme.—On the permanently magnetic moments of magnetic rods and Häcker's formula: $T = p \sqrt[3]{Q} \times \sqrt[3]{l}$, by L. Külp.—On the influence of the texture of iron on its magnetism, by the same.—On the passage of gases through thin layers of liquids, by F. Exner.

THE *Naturforscher*, June.—From this part we note the following papers:—On some phenomena of interference in circular nets, by M. Soret.—On the simultaneous formation of two microscopic minerals, by H. Fischer.—On the distortion of the images reflected from the surface of water, with reference to some phenomena observed on Lake Leman, by Ch. Dufour.—On the power of diffusion in the soil of fields, by M. Grandeau.—On the tenor of carbonic acid in the soil-gases of Klausenburg, by J. von Fodor.—On the formation of the "terra rossa" from the shells of Globigerina, by M. Neumayr.—On a strange dimorphism among walnut trees (*Juglans regia*), by F. Delpino.—On the exhalation of carbonic acid by different animals, by Rud. Pott.—On a new source of magnetism, by Donato Tommasi.—On some physical properties of collodion films, by E. Gripon.—On the influence of oxygen upon life; experiments made with frogs which were placed in an atmosphere of nitrogen for some time, by E. Pflüger.—On the action of coloured light upon the assimilation of the mineral matter in plants, by Rud. Weber.—On the principle of the dispersion of energy, by A. Fick.—Light and electro-magnetism, by Ludw. Boltzmann.—On the nitro compounds of the fatty series, by Victor Meyer (a long paper taken from Liebig's *Annalen der Chemie*).—On hearing with two ears, by F. P. le Roux.—On the adaption-power of fresh-water molluscs breathing by lungs, by Th. von Siebold.

Journal of the Franklin Institute, June.—The following are the principal original articles in this number:—"The Centennial Exhibition," with three plates.—"Account of some Experiments made for the purpose of comparing the indication of Cassella's Air Metres," by C. B. Richards, M.E.; these experiments were adverse to the trustworthiness of the metres.—"Sympathetic Vibration," by H. A. Rowland, C.E.—"A new Vertical-Lantern Galvanometer," by Prof. G. F. Barker.—"The rapid Corrosion of Iron in Railway Bridges," by W. Kent.—"Molecular Changes in Metals," by Prof. R. H. Thurston.

Proceedings of the Bristol Naturalists' Society. New edition, vol. i. Part 2.—The first thing that strikes one on opening this part of the Bristol Society's *Proceedings* is the number of *errata*, there being a list of about eighty mistakes which have been allowed to slip into this and the previous number; this is very bad. The following are the titles of the papers contained in this part:—"On Fish Remains in the Bristol Old Red Sandstone," by S. Martyn, M.D.; "On *Ceratodus Forsteri*," by W. W. Stoddart, F.G.S.; "On the Physical Theory of Under-currents and of Oceanic Circulation," by W. Lant Carpenter, B.A., B.Sc.; "Bristol Rotifers: their Haunts and Habits," by C. Hudson, LL.D.; "Notes on Trias Dykes," by E. B. Tawney, F.G.S.; "Notes on the Radstock Lias," by E. B. Tawney, F.G.S.; "On the Geological Distribution of some of the Bristol Mosses," by W. W. Stoddart, F.G.S.; "A Contribution to the Theory of the Microscope and of Microscopic Vision. After Dr. E. Abbe, Professor in Jena," by H. E. Fripp, M.D.; "The Geology of the Bristol Coal-field (Part II.)," by W. W. Stoddart, F.G.S.; "The Land and Fresh-water Mollusca of the Bristol District," by A. Leipner; "Notes on Bristol Fungi," by C. E. Broome, F.L.S.; "The Rainfall in Bristol during 1874," by G. F. Burder, M.D.

THE numbers of the *Nuovo Giornale Botanico Italiano* for January—July 1875 give evidence of the impulse given to the study of lichens by the recent theory as to their compound and parasitic nature. We have in these numbers two elaborate papers on this subject, based on careful elaborate research, and both well illustrated, but coming to opposite conclusions. A. Borzi adopts the theory of Schwendener and Sachs that the gonidia of lichens have no genetic affinity with the hyphæ, but that the latter are of the nature of ascomycetous fungi parasitic on the former. G. Arcangeli, on the other hand, inclines to the views of Nylander and Tulasne that many algæ belonging to the families Protococcaceæ, Nostocaceæ, and Rivularieæ, are nothing but special forms of the gonidia of lichens; but that the gonidia are true lichen-organs. Prof. Caruel has a short note on the so-called viviparous leaves of *Begonia*, in which he shows that the adventitious buds are in reality metamorphosed hairs. Prof. Beccari has some remarks on the Rafflesiaceæ, supplementary to Dr. Hooker's monograph of the order in De Candolle's "Prodromus." He makes five species of *Rafflesia*—*R. Arnoldii*, *R. Titan*, *R. Patma*, *R. Rochussenii*, and *R. Cumingii*, besides a doubtful one, *R. Horsfieldii*; four of *Hydnora*, viz., *H. africana*, *H. abysinica*, *H. bogociensis*, *H. triceps*; and one *Prosopanche*—*P. Burmeisterii* (*Hydnora americana*). These three numbers contain, in addition, many other useful and important papers.

Zeitschrift der Oesterreichischen Gesellschaft für Meteorologie, July 15.—This number contains an article on the calculation of the arithmetical mean of constant quantities, by Herr Wilczek, and another on the ventilation of the St. Gothard Tunnel.

Bulletin of the Essex Institute, 1874 (Salem, U.S.)—A notable incident in the history of this excellent American Society during 1874, was a visit from the late Rev. C. Kingsley, who delivered a lecture on Westminster Abbey, and in whose honour a reception was afterwards held. The following are the principal scientific papers in the *Bulletin*:—Mr. F. W. Putnam, one of the most active members of the Society, contributes the following:—"Rare Fishes taken in Salem, Beverly, and Marblehead Harbours; "On Black Fish taken in Salem Harbour;" "Notice of a Skull from shell-bed, in Rock Island;" "On Teeth of a large Shark, probably *Carcharis* (*Prionodon*) *lamia*;" "On the Shell-heaps at Eagle Hill;" "Notice of some important Discoveries of the Hayden Exploring Expedition;" "Remarks on a Collection of living specimens of Fishes and Cray pikes from Mammoth Cave." Other papers are:—"Notes on the Mammals of portions of Kansas, Colorado, Wyoming, and Utah," by J. A. Allen; "On the Fertilisation of Flowers," by E. S. Morse; "Notes on examination of four species of Chitons," by W. H. Dall; "On the Change of Colour in Leaves in Autumn," by E. C. Bolles; "On the Theory of Evolution," by E. S. Morse; "Lists of Birds observed from Sacramento to Salt Lake City," by R. Ridgway.

THE *Gazzetta Chimica Italiana*, fasc. v., contains the following papers:—On the oxidation of sulphur, by E. Pollacci. The author describes some interesting experiments he made with flowers of sulphur which he oxidised into sulphuric acid in a number of different ways.—Researches on the products of the action of urea upon asparagine and on aspartic acid, by J. Guareschi.—Preliminary note upon parabanic and oxaluric acids, by the same.—On the vegetation of *Oxalis acetosella*, *Rumex acetosa*, and *acetosella* in a soil which contains no potash, by M. Mercadante.—Account of experiments made with artificial soils and of the anomalies observed in the plants obtained.—On some properties of ferric orthophosphate, by F. Sestini.—Extract of some memoirs read at the Academy of Sciences at Bologna on researches on the poisonous alkaloids, by F. Selmi. These were on some new distinguishing properties and some newly discovered reactions.—There is the usual number of extracts from other journals.

Kongl. Vetenskaps Akademiens Fördhandlingar (Stockholm), Feb. 10.—This part contains the following papers:—On the introduction of elliptic functions into astronomical problems, by H. Gylden.—Hepaticæ Pyranaicæ circa Luchon crescentes, by J. E. Zetterstedt.—Researches on the chemical composition of magnetic iron ore, by G. Lindström.—On the Oniscoideæ of North America, by A. Stuxberg.—On some new Lithiobiæ of the same country, by the same.—On a Lithobius borealis Meinert, found in Sweden, by the same.—Researches on the Syrphus butterfly in its three states of development, by F. Trybom (with plate).—On the Arachnidæ of Gotland and Öland, by G. F. Neuman.—On old ore deposits and their present uses, by O. Gumaelius.

SOCIETIES AND ACADEMIES

VIENNA

Imperial Academy of Sciences, April 22.—Researches on the epithelium of the stomach, by W. Biedermann.—On the formation of meteorites, by G. Tschermak.—On some measurements of temperature made in the first half of April in the Gmunden and Atter lakes, by Prof. Simony.

April 29.—On the zoological results of the Austro-Hungarian Polar Expedition, by Prof. C. Heller.—Ichthyological researches, by Prof. F. Steindachner.—On the orbit of Planet (138) Tolosa, by Director von Littrow and Dr. L. Gruber.—On the fermentation gases from marsh and water plants, by Prof. J. Boehm.

May 13.—On the genetic classification of the flora of the Cape, by Dr. von Ettingshausen.—On the lichens of Spitzbergen and Novaja Semlja, by Dr. von Hochstetter.—On the orbit of Planet (118) Peitho, by Dr. J. Holetschek.—On the galvanic dilatation of metallic wires, by Prof. Exner.—On the respiration of water plants, and on a fermentation which includes an absorption of hydrogen, by Prof. J. Boehm.—On chalk ammonites, by Dr. Neumayer.

BERLIN

German Chemical Society, July 26.—P. Behrend described a method for preparing chloride of sulphuryl by heating Williamson's oxychloride $SO_2OH\,Cl$ in sealed tubes to 180°.—V. Meyer gave an account of an apparatus for determining the solubilities of salts at 100°.—J. Beckmann, by treating benzophenone $C_{13}H_{10}O$ with sulphuric acid, produced a neutral body $C_{13}H_8SO_3$, while sodic benzophenondisulphate, treated with PCl_5, yielded two chlorides, $C_{13}H_8O_5S_2Cl_2$ and $C_{13}H_8O_5S_2Cl_4$.—F. Tiemann and Haarmann published a method for determining the quantity of vanilline in vanilla, by precipitating its solution in ether with bisulphite of soda. Mexican vanilla gave 1·6, best Bourbon vanilla 2·3, Tavavanilla 2·6 p.c. of vanilline. Tavavanilla is less esteemed, on account of other ingredients which affect its fragrance.—F. Tiemann has transformed vanilline, $C_6H_3\begin{matrix}OH\\OCH_3\\COH\end{matrix}$ into the corresponding acid and alcohol, the latter by the action of hydrogen, produced by sodium-amalgam. This reagent yields also a body $\left(C_6H_3\begin{matrix}OH\\OCH_3\\CH.OH\end{matrix}\right)_2$, hydrovanilloin. He has likewise introduced ethyl and methyl into the group OH.—C. Raab has treated cuminic aldehyde with hydrocyanic acid and hydrochloric acid, obtaining the corresponding amygdalic acid. By the action of hydrogen he obtained a higher hydrobenzoin.—C. Jackson has obtained tribromonitrobenzol and tribromodinitrobenzol.—The same chemist refuted a pretended reaction of acetanilide. This body does not yield a nitrile and water when heated, as published by Mr. Brackebusch.—A. Steiner has found that NH_3 dissolves fulminate of silver below 40° without alteration. He has also studied the action of sulphocyanide of ammonium on fulminates.—A. W. Hofmann has transformed methyl-xylidine by means of heat into a number of highly carbonated ammonias, chiefly into $C_6(CH_3)_5NH_2$.—A. Oppenheim and L. Jackson described two new derivatives of mercaptan, viz. C_2H_5SHgBr, a white amorphous powder and a combination of iodoform with two molecules of mercuric mercaptide, crystallising in yellow needles. No tribasic thioformate of ethyl could be produced from these compounds.—The following communications were sent by T. Wislicenus:—Under his guidance allyl-aceto-acetic ether has been transformed by F. Zeidler into allylacetic acid and allyl-acetone. L. Ehrlich produced dibenzil-acetic ether and benzyl-oxybutyric ether. H. Rohrbeck, by treating methylacetoacetic ether with hydrogen, produced methyloxybutyric acid, which, when heated, yields methyl-crotonic acid. E. Waldschmidt has obtained the corresponding ethyl-compounds. M. Conrad, by treating aceto-acetic ether with chlorine, obtained substitution compounds and dichloracetone. F. Hermann has studied the action of sodium of succinic ether. The next meeting will take place on the 11th of October.

PARIS

Academy of Sciences, Aug. 9.—M. Frémy in the chair.—The following papers were read:—Application of the method of correspondence to questions of the magnitude of segments on tangents of curves, by M. Chasles.—Remarks on the note of M. Nicolaides read at the last meeting, by M. O. Bonnet.—A note by M. Thenard, on some blue substance found in clay.—Three reports by M. Janssen concerning the expedition sent to Japan to observe the transit of Venus across the sun's disc.—Calorimetric researches on the siliciurets of iron and manganese, by MM. Troost and T. Hautefeuille.—Researches on niobates and tantalates, by M. A. Joly.—Facts relating to the investigation of polyatomic alcohols, and their application to a new method for obtaining crystallised formic acid, by M. Lorin.—MM. G. Baker, Decoster de Wilder, Garcia de los Rios, Imbert, and Bordet then made some communications regarding Phylloxera.—M. Reech then presented a new edition of his memoir on surfaces which can be superposed on themselves, each in all its parts.—The Minister of Public Instruction sent the translation of an article, published by the Ministerial journal of Copenhagen, and treating of the volcanic phenomena which in the course of last winter have occurred in Iceland.—Discovery of Planet (148), made at Paris Observatory, by M. Prosper Henry, on the night of Aug. 7 last.—Observations of Planet (148) at the equatorial, by M. M. Henry.—Ephemerides of Planet (103), Hera, for the opposition of 1876, by M. Lereau.—Experiments with gas under high pressure, by M. Andrews.—On a property of an electrified surface of water, by M. G. Lippmann.—A note on sulphocarbonates, by M. A. Gélis.—On the preparation of crystallised monobromide of camphor, by M. Clin.—On some points in the physiological and therapeutic action of monobromide of camphor, by M. Bourneville.—On Marsh's apparatus and on its application for the determination of arsenic contained in organic matter, by M. Arm. Gautier.—On the larva forms of Bryozoa, by M. Barrois.—Observations by M. C. Dareste, on a recent communication of M. Joly.—On the temperature of the Mediterranean Sea along the coasts of Algeria, by MM. Ch. Grad and P. Hagenmüller.—On a waterspout observed at Morges on Aug. 4 last, by M. A. Foret.—On the identity in the mode of formation of the earth and the sun, by M. Gazan.

BOOKS AND PAMPHLETS RECEIVED

AMERICAN.—Report upon the Reconnaissance of the North-Western Wyoming and Yellowstone National Park: Wm. A. Jones (Washington).—The Geological Story briefly told: James D. Dana, LL.D. (Trübner and Co.)—Proceedings of the American Academy of Arts and Sciences, N.S. Vol. ii.—Third Report of the Zoological Society of Philadelphia.—Chronological Observations on Introduced Animals and Plants: Chas. Pickering, M.D. (Boston: Little, Brown and Co.)—Report of the U.S. Geological Survey of the Territories. Vol. vi.: F. V. Hayden (Washington).—How to use the Microscope: John Phin (Industrial Publishing Company, N.Y.)—Proceedings of the Academy of Natural Sciences of Philadelphia. Part I.

COLONIAL.—Report of Neilgherry Loranthageous Parasitical Plants destructive to Exotic Forest and Fruit Trees: George Bidie, M.B. (Government Press, Madras).

FOREIGN.—Bulletin de l'Académie Impériale des Sciences de St. Petersbourg. Tome xix. Feuilles 22-37, Tome xx. Feuilles 1-21.—Der Ursprung der Wirbelthiere und das Princip des Functionswechsels: von Anton Dohrn (Leipzig, Engelmann).—Die Geologie und Ihre Anwendung auf die Kenntniss der Bodenbeschaffenheit der Oesterr.-Ungar. SCIENTIFIC WORTHIES

VI.—Sir Charles Lyell, born Nov. 14, 1797; died Feb. 22, 1875.

SINCE its last meeting the British Association has lost one of its oldest members and most illustrious presidents. There are some men the story of whose mental development and progress in scientific research may be taken as almost embracing the history, during their lives, of the science to which they devoted themselves. Of such men we have not many brighter examples than that of Sir Charles Lyell. For somewhere about half a century he continued in the van of English geologists, and so identified himself with them and their pursuits as to be justly taken as the leader of geological speculation in this country. The time has probably not yet come when his true position in the roll of scientific worthies can be definitely fixed. The revolutions of thought which have taken place within the last fifteen years, and in which, let it never be forgotten, Lyell himself bore a conspicuous and indeed heroic part, have so shaken old beliefs which once seemed securely based on the most cautious induction from well-ascertained facts, that even they who have most closely watched the march of events will probably shrink most from the attempt to estimate the full and true value of the work of his long and honoured life. It is not, then, with any aim at such an estimate, but rather to recall some of the leading characters of his work, that this brief *in memoriam* is now written.

Perhaps the best idea of the solid services rendered by Lyell to Geology is obtained by looking back at the condition of the science when he first began to study it, and by contrasting that state with the same subject as treated by him in the early editions of his "Principles." To men who had been compelled to gain their general view of geology from such works as Daubuisson's "Traité," the appearance of Lyell's volumes must have been of the nature of a new revelation. From vague statements about early convulsions and a former higher intensity of all terrestrial energy, they were led back with rare sagacity and eloquence to the living, moving world around them, and taught to find there in actual progress now the analogues of all that they could discover to have been effected in the geological past. The key-note which Lyell struck at the very outset and which sounded through all the work of his career was, that in geology we must explain the past by the present;—that the forces now in operation are quite powerful enough to produce changes as stupendous as any which have taken place in former times, provided only that they get time enough for their task.

These views were not promulgated for the first time by the author of the "Principles of Geology." In cruder form they had been earnestly urged by Hutton, and eloquently illustrated and extended by Playfair. But after much turmoil and conflict of opinion, they had very generally been allowed to sink out of sight. On the Continent, indeed, they had never excited much attention, and were for the most part ignored as mere vague speculation. Even in this country they had only been partially adopted even by those who professed to belong to the Huttonian school. So that it was in one sense as a new doctrine that they were taken up by Lyell and enforced with a wealth of illustration and cogency of argument which rapidly gained acceptance for them in Britain, and eventually led to their development in every country where the science is cultivated.

In one important respect, however, the doctrines taught by Sir Charles Lyell differed from those of his predecessors. Hutton and Playfair knew almost nothing of fossil organic remains. They were necessarily ignorant of the light which these can cast upon the past history of the globe. They had but a dim perception of the long and varied succession of the stratified formations embraced by their own terms Primary and Secondary. After their days, however, the labours of William Smith among the Secondary rocks of England showed that the strata of the earth's crust could be identified and classified in their order of age by means of the fossil animal remains contained in them. Then came the brilliant discoveries of Cuvier in the Tertiary basin of Paris and the rise of the science of Palæontology. It was now seen that the discussion of theoretical questions in cosmogony and the collection and description of minerals and rocks did not comprise by any means the whole of geology. Year by year it became more evident that, besides all its records of physical revolutions, the crust of the earth contained materials for a history of organic nature from early geological times down to the present day. In this transition state of the science there was manifestly needed some leisured thinker who could devote a calm judgment and a facile pen to the task of codifying the scattered observations which had accumulated to so vast an extent, and of evolving from them the general principles which they seemed to establish, and which, when clearly announced, could not fail greatly to assist and stimulate the future progress of geology. Such was the task which Lyell set before himself, somewhere about half a century ago, and in fulfilment of which his "Principles" appeared.

In that great work the twofold aspect of geology—its inorganic or physical side and its organic or biological side—was recognised and admirably illustrated. It was in the treatment of the first of these that the earlier editions of the "Principles" stood specially distinguished from previous writings. The leading idea of their author was, as already remarked, not original on his part. Besides the writings of Hutton, Playfair, and their followers, the appeal to history and to everyday experience as to the true nature and results of the present working of the various terrestrial agents had already been made in considerable detail by Von Hoff in Germany. Nevertheless, until the advent of Lyell's work the views he adopted had got no real hold of men's minds. It was his enforcement of them which secured for them first a careful examination, and ultimately a very general acceptance. In explaining former revolutions of the globe, geologists had usually proceeded on the tacit assumption that no serious argument was required to prove these revolutions to have been far more violent in their progress and stupendous in their results than could possibly have been

achieved by any such energy as is still left upon the earth. Accordingly, on the whole they were disposed to neglect the consideration of proofs of modern changes on the earth's surface, looking upon these as mere faded relics of the power with which geological changes were formerly effected. It is impossible to exaggerate the service which Lyell did to the cause of truth by boldly striking at the very root of this fundamental postulate of his contemporaries, and showing, by a wide induction of facts from all parts of the world, how really potent were the present apparently quiet and ineffective processes of change. With most uncompromising logic he drove it home to the hearts and consciences even of sturdy convulsionists, that they had all along been reasoning in a circle, and that the evidence on which they so confidently relied demanded and could receive another and very different interpretation.

It was a great matter to shake the old convulsionist faith and bring men back to the study of the actual operations of nature at the present time. Greatly more difficult, however, was the task to build up another creed and gain adherents to it. Yet this was accomplished by Lyell with an abundant measure of success. He came to be recognised as the great reformer in geology, the high priest of the Uniformitarian school, the leader under whom in this country the younger men eagerly ranged themselves. Through the influence of his writings a fresh and healthy spirit of scrutiny and observation spread through the study of geology. And as edition after edition of his work appeared, each more richly laden than its predecessors with stores of facts gathered from all branches of science in illustration of his subject, men were led to realise how narrow had been the old conception which limited the scope of geology merely to the study of minerals and rocks and the elaboration of cosmological theories. Every department of nature which could throw light upon the terrestrial changes now in progress and thereby elucidate the history of those which had taken place in former times was made to yield its quota of evidence. Hence it came about that the study of geology received in Britain a breadth of treatment which had never before been given to it either in this or any other country. The main share in this reform must be assigned to the genius and perseverance of Lyell.

But in science as in politics no reform can provide for all the requirements of the future. In proportion to the zeal with which the new creed is adopted and proclaimed, there may be and often is an inability to recognise such measure of truth as may have underlain the older faiths, as well as to realise the weak points in that which is set up in their place. The essential doctrine of the Uniformitarian School was in reality based on an assumption not less than those of the older dogmas. It was an assumption indeed which did not rest on mere crude speculation, but on a wide range of observation and induction, and it claimed to be borne out by all that was known regarding the present economy of nature. It professed to be in accordance with the logical method of reasoning from the known to the unknown. Nevertheless, in the course of years the Uniformitarians gradually lost sight of the fact that the present order of nature on which they asserted that their system rested could not, without a manifest and perhaps in the end an unwarrantable assumption, be taken as the standard whereby the order of nature in all past geological time was to be gauged. The information gained by human observation during the few centuries in which man had taken intelligent interest in the world around him was valuable as a basis for hypothesis, but only for hypothesis which should be cast aside so soon as the requirements of a wider knowledge might demand. The Uniformitarians, however, gradually slid into the belief that though perchance they had not absolutely proved terrestrial energy never to have been more powerful than at present, yet they had shown that the supposed proofs of former greater intensity were illusory, and hence that their own doctrines should be accepted as by far the most reasonable, and indeed as the only safe guide in the interpretation of the past history of the earth. Most admirable has been the work done by the Uniformitarians, and deep are the obligations under which Geology must ever lie to them. But in the onward march of mental progress it is now their turn to have their confident belief called in question. Another School is rising among them, accepting from them by far the larger part of their doctrines, but in their own spirit of bold inquiry and with their own zeal in the cause of truth, seeking to enlarge the basis on which our ideas of the full sweep of nature's operations are to rest.

The other, or biological side of geological science, owes much of its development to the skill with which it was handled in the successive editions of the "Principles." Though not himself in the strict sense either a zoologist or botanist, Sir Charles Lyell throughout his life kept himself abreast of the progress of the biological sciences and on terms of intimate relationship with those by whom that progress was sustained in this country and abroad. He was in the true meaning of the word a naturalist. He had in his day few equals in the grasp which he could take of natural history subjects in their geological aspects. The geographical distribution of plants and animals was one of those subjects which received more and more ample treatment from him as he advanced in years. The succession of living forms in time was another theme which gave him full scope for accurate and eloquent description. In fact, the breadth of his conception of what geology ought to be was not less conspicuously marked in this than in the physical department of the science. He enlisted in his service every branch of biological inquiry which could elucidate the former history of the earth and its inhabitants. And not merely the published information on these questions, but many of the floating ideas of discoverers found exposition and illustration in his pages.

One of the biological subjects to which he devoted much time and thought was one which in recent years has received renewed attention and provoked increased discussion—the origin of the successive species of plants and animals which have appeared upon the earth. During the greater part of his career Sir Charles Lyell distinguished himself as one of the most uncompromising opponents of development theories such as those of Lamarck and the author of the "Vestiges of Creation." Such views ran counter to his uniformitarian faith, and he brought against them a large armoury of geological weapons. The non-appearance of higher

types of life among the older formations he contended to be no evidence in favour of development. It was simply negative evidence, and could at any moment be destroyed by the discovery of one positive fact in the shape of a bone, tooth, or other fragment. No one could make better use than he of such fortunate finds as that of Dr. Dawson among the ancient carboniferous forests of Nova Scotia, when from the heart of a fossil tree quite a little museum of land-snails and lizard-like forms was obtained; or those which revealed such remarkable assemblages of little marsupial and other mammalian forms from thin and local deposits like the Stonesfield slate and Purbeck beds. But negative evidence, when multiplied enormously by observers all over the world without any important contradiction, becomes too overwhelming to be explained away. Though convinced of the untenableness of the views of development which he opposed, Sir Charles may have had his misgivings at times that the yearly increasing and enormous body of negative evidence in favour of the non-existence of higher types of life in the earlier geological periods could not be due to the mere accident of non-preservation or non-discovery. At all events, when Mr. Darwin's views as to the origin of species were made known, Sir Charles, recognising in them the same basis of wide observation and the same methods of logical analysis for which he had himself all along contended in geology, at once and zealously accepted them—a bold and candid act, seeing that it involved the surrender of opinions which he had been defending all his life. In no respect did he show his remarkable receptive power and the freshness with which he had preserved his faculty of seeing the geological bearings of new truths more conspicuously than in the courage and skill with which he espoused Mr. Darwin's hypothesis and proceeded at once to link it with the general philosophy of geology.

Of his work among the Tertiary formations, with the nomenclature by which, through that work, they are now universally known, his observations on the rise of land in Sweden, his researches into the structure of volcanic cones, and other original contributions, over and above the solid additions to science supplied by the numerous editions of his popular works, it is not needful to make mention here. Enough is gained if at this time these few lines recall some of the services to which Sir Charles Lyell devoted a long, honourable, and illustrious life, which have graven his name in large letters on the front of the temple of science, and in memory of which that name will long be remembered with gratitude and enthusiasm as a watchword among the students of geology.

ARCHIBALD GEIKIE

WATTS' DICTIONARY OF CHEMISTRY

A Dictionary of Chemistry and the Allied Branches of other Sciences. By Henry Watts, B.A., F.R.S., &c. Second Supplement. (Longmans, Green, and Co., 1875.)

THE appearance of the second supplement to Watts' "Dictionary of Chemistry" is an event in the history of chemical literature which will certainly be elcomed by all English chemists. Although it may be said with truth that no great generalisations have been made of late years in chemistry, the science is nevertheless advancing with gigantic strides so far as the accumulation of facts is concerned. Perhaps no science possesses such an extensive journalistic literature as Chemistry; month after month the journals of the Chemical Societies of London and Berlin, the *Gazzetta Chimica Italiana*, the *Annalen der Chemie*, *Poggendorff's Annalen*, the *Annales de Chemie*, the proceedings and transactions of the various learned Societies, as well as numerous smaller chemical publications, all contribute to the vast store of facts already recorded. It is not to be wondered, then, that during the nine years which Mr. Watts devoted to the compilation of his dictionary, the science should have continued its growth at such a pace that the author found it necessary to promise on the completion of the work (Preface to Vol. V., 1869) a supplementary volume bringing the record of discovery down to the existing state of knowledge. The first supplement accordingly appeared in 1872, bringing the history of the science down to the end of 1869. The volume now before us carries the record of discovery down to the end of 1872, and includes some of the more important discoveries made in 1873 and 1874.

From the contents of the present supplement we cannot select more than a few of the longer articles for notice here.

Turning first to the article on benzene, one cannot fail to be struck with the rapid growth of our knowledge of this body and its derivatives within the last few years. The list of haloid, nitro-haloid, &c., derivatives has been considerably increased since the publication of the last supplement by the discovery of new isomeric modifications of these bodies—modifications the discovery of which cannot but be regarded as signal triumphs to chemical theory when we call to mind the fact that the impetus given to the study of benzene, the fundamental hydrocarbon of the aromatic series, arose from the theoretical speculations of Kekulé and his school.

The subject of capillarity is treated of with considerable detail in an article some nine pages in length. The development of this subject is due to the researches of Quincke, Karmarsch, Buliginsky, Valson, and others. The article on chemical action contributes much of importance to the subject: we may particularly mention Mill's researches on the co-efficient of chemical activity, the numerous researches by Berthelot, in conjunction with Jungfleisch on the division of a body between two solvents, and with St. Martin on the state of salts in solution; likewise Favre and Valson's experiments on crystalline dissociation. Passing on to the cinchona alkaloids, we find that three new substances—quinamine, paricine, and paycine—have been added to the list by Hesse. The "constitution" of these cinchona alkaloids is among the problems still awaiting solution at the hands of chemists—may it not be hoped that the synthesis of quinine will one day—as that of alizarine—be a chemical possibility? In electricity, the chief additions to our knowledge are Becquerel's experiments on electro-capillary action, Quincke's theory of electrolysis, and Guthrie's experiments on the relationship between heat and electricity. The mechanical theory of gases has developed into a separate article of considerable importance in our eyes.

Avogadro's law—the safest foundation on which to build modern chemistry—is directly deducible from the fundamental equation of Clausius :—

$$p = \frac{nmc^2}{3v}$$

so that not only does our modern system of chemistry rest on a thermodynamical basis, but the future of chemical generalisation—judging from the tendency of recent research—lies in this direction also. The subject of heat has received great additions ; the laborious determinations of the specific heats of solutions by Thomsen furnish material for three pages. The "heat of chemical action" has developed enormously through the labours of Thomsen, Hautefeuille, Ditte, and Marignac. Berthelot has also contributed largely to the subject by his thermochemical researches. In industrial chemistry we find much valuable matter added to the metallurgy of iron, the article bringing us down to the invention of Siemens' rotative furnace for obtaining malleable iron and steel directly from the ore. In light, perhaps the most substantial additions to science are to be found in Gladstone's calculations of refraction equivalents, Christiansen, Kundt, Soret, and Sellmeier's researches on anomalous dispersion, and Rammelsberg's researches on the relations between circular polarisation and crystalline form. The articles on the chemical action of light and spectral analysis, contributed by Prof. Roscoe, are excellent *résumés* of the present state of knowledge in these branches of chemical physics. In the latter subject great progress has been made through the labours of Lockyer (discovery of long and short lines in metallic spectra), Roscoe and Schuster (new absorption spectra of potassium and sodium), and Lockyer and Roberts (new absorption spectra of various metals—suggestions for a possible quantitative spectrum analysis).

Prof. G. C. Foster contributes the article on magnetism, and Prof. Armstrong that on the phenols. Most of the articles on physiological chemistry are from the pen of Dr. H. Newell Martin ; and Mr. R. Warington furnishes some valuable articles on subjects relating to agricultural chemistry.

The second supplement exhibits all the care and painstaking conscientiousness of the former volumes, and will be found of invaluable service both to teachers and workers. The names of Mr. Watts and his coadjutors sufficiently guarantee the reliability of the work ; the "Dictionary" has in fact justly taken its rank as one of the standard works of reference in this country.

Seeing that the results of chemical research are flowing into the scientific world in a continuous and ever increasing polyglot stream, both professors and students of the science are indebted to Mr. Watts for the laborious task which he has accomplished for their benefit.

For our own part we look with eager interest upon the continuous encroachment of physics upon chemistry, and venture to hope that the time may not be far distant when generalisation may lead to natural classifications, causing the handbooks and dictionaries of the future to be for the same quantity of information somewhat less bulky in volume.

R. MELDOLA

HIS ON MORPHOLOGICAL CAUSATION

Unsere Körperform und das physiologische Problem ihrer Enstehung. Briefe an einen befreundeten Naturforscher, von Wilhelm His. (Leipzig : Vogel, 1875. London : Williams and Norgate.)

THIS is not, as might perhaps (from its title and from a hasty glance at its contents) be imagined, a popular exposition of the main facts of Embryology as ordinarily understood. Prof. His has been led by his researches to adopt peculiar views concerning the causation of animal forms. These he has explained at some considerable length in his great work on the "Development of the Chick," and elsewhere, but they have not met with very general acceptance ; and the little work we are noticing has for its object a popular and somewhat fuller explanation of these views, and a defence of them against various critics. Among these critics the most conspicuous is Haeckel, whose, to say the least, severe remarks on the author have occasioned a very spirited retaliation. In fact the work, small as it is and popular as it is intended to be, is very largely controversial ; and it has always appeared to us a sign of weakness when a scientific combatant brings his quarrel before a general public.

Without going at all fully into the views of our author, we may say that he strives to explain many of the facts of animal morphology by the agency of mechanical causes acting directly on the growing germ or embryo. Thus, for him the large eyes of the young chick are the direct cause, by compression, of the sharp beak of the bird ; and more generally the unequal tensions produced by unequal growth in the initial flat blastoderm determine, through the agency of certain folds, the form of the animal which springs from it.

As might be expected, many pages of the book are devoted to an attempt at reconciling these views with a modified theory of descent. Speaking broadly, the views of the author may be said to differ from those generally entertained, chiefly on the question whether it is the horse which pulls the cart or the cart the horse, or perhaps rather on the point which is the cart and which the horse. We very much fear that Prof. His's horse is really the cart.

M. F.

OUR BOOK SHELF

Bristol and its Environs, Historical and Descriptive. Published under the sanction of the Local Executive Committee of the British Association. (London : Houlston and Sons. Bristol : Wright and Co., 1875.)

IT was some time ago announced that a Guide to Bristol was being prepared for visitors to the British Association Meeting. This is now published, and appears as an 8vo volume of 475 pages bound in cloth. In many respects the local committee have made great exertions to make the visit in every way a pleasant one, and this has been pretty well known, but so voluminous a guide as this is certainly a surprise. It is well got up, and is illustrated both with views of the buildings in the town and with diagrams illustrative of the geology of the district. Many pens have been employed in its preparation. "The contributions," the Introduction states, "are honorary—the several authors have written with pure love of their subject, and for the sake of doing homage to the occasion that has called forth the volume."

The first two sections, both of them on Ancient Bristol, are by Mr. J. Taylor, of the Bristol Library. Section 3, on Modern Bristol, is by Mr. J. F. Nicholls, of the City Library. The fourth section, on Local Government and Taxation, is by Mr. H. Naish: and then follows a section on Educational Organisations, to which there are several contributors. Mr. D. Davies, the medical officer of health, has supplied the section on Sanitary Condition and Arrangements, after which comes Section 7, on Physical Geography and Geology. This occupies sixty-four pages, and would perhaps have been of more practical use if printed as a separate pamphlet that could be conveniently carried in the pocket. Mr. Tawney has written the Introduction; the Silurian, the Carboniferous, and Millstone Grit is by Mr. Stoddart; the part on the Coal Measures and "New Red Period" is written by Mr. Tawney; that on the Rhætic and Liassic by Mr. Ralph Tate, and the concluding part on the Inferior Oolite is again by Mr. Tawney.

Bristol is better off for geological maps than any other part of the country, for not only are there the sheets of the Geological Survey, but there is Mr. Sanders' splendid map of six inches to the mile, which includes the whole of the Bristol coal-field.

It is a pity there was not a sketch map introduced in the guide, with just the names given of the places referred to and an indication of the spots where the sections are taken from. As it is, strangers to the district will experience some difficulty in following the text, as many of the names are not on the published maps. With regard to the sections, too, there is no indication of the direction in which they are taken, nor of the scale to which they are drawn. One of the most useful features of the geological portion is that which gives the localities where the sections of the strata can be seen; and, as the district within a short distance contains from the Silurian up to the Oolites, omitting the Permian, is of interest. There are many references to the more important papers that have been printed, and in cases of difference of opinion the writer has added his own views. The much vexed question of the age of the "dolomitic," "triassic," "magnesian," or "reptilian" conglomerate, is duly referred to.

The notes on anthropology have reference to the tumuli and chambered barrows, and to the present condition of Bristolians. "A certain amount of physical degeneration has taken place among the native Bristolians, as among the natives of other British cities; 300 of them yielded to me an average stature and weight of 5 feet 5·8 inches and 132½ lbs., after deductions made for shoes and clothing. The average height of men in the surrounding counties may fairly be put at half an inch more."

The book has one serious defect, for which the compiler and not the authors are responsible; there is no index.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*]

"Climate and Time"

THE review of "Climate and Time" in NATURE, vol. xii. p. 121, contains some remarks in reference to my tables of the eccentricity of the earth's orbit, to which, in justice to myself, I must refer, the more so as they relate to points which comparatively few of your readers have it within their power to determine whether or not the reviewer was justified in making the remarks in question.

"We have repeated," says the reviewer, "the calculations for two of the most remarkable dates, viz., 850,000 and 900,000 years ago respectively, and find that at the former date the eccentricity was ·0697 instead of ·0747, and at the latter date was ·0278 instead of ·0102 as expressed in the table."

What proof does the reviewer give that his results are correc and mine incorrect? The following is the reason he assigns:—"To satisfy ourselves," he says, "that the mistakes are Mr. Croll's and not ours, we have recalculated also one of Mr. Stone's and one of M. Leverrier's, and in both instances have exactly verified them." This can hardly be accepted as sufficient evidence, for I had myself recalculated one of Mr. Stone's and no fewer than five of M. Leverrier's, "and exactly verified them."

I suspect that the reviewer has made his calculations somewhat too hastily; for if he will go over them a little more carefully, he will, I have no doubt, find that after all my results are perfectly correct, excepting only a trifling typographical error, to which I shall presently refer.

The value for 900,000 years ago ought to be ·0109 instead of ·0102, as stated in the table. This mistake arose out of the curious circumstance of a small speck of ink having been dropped on the tail of the 9, which led to its having been substituted for a 2, ten years ago when the tables were first published—a fact of which I was not aware till a week or two ago, when looking over the manuscripts of my original calculations, all of which I have preserved. Since my calculations were called in question by your reviewer, I have had them examined by three experienced mathematicians, and the conclusion at which each of them has arrived is that they are perfectly correct.

The reviewer continues:—"The fact that the eccentricity was large when he represents it so, and small when he makes it small, seems to indicate that some approximating progress [process?] has been followed, and that possibly his diagram may give a *rough* idea of the changes of eccentricity for past time."

I can assure the reviewer that nothing could be further from the truth than this assumption. I have computed the eccentricity and longitude of the perihelion for no fewer than 129 separate periods, and in every case Leverrier's formulæ have been rigidly followed, and I have every reason to believe that the diagram gives not a *rough* but an *accurate* idea of the changes of eccentricity. The values given in the tables will, I trust, be found to be perfectly accurate up to at least the fourth place of decimals, which is as far as these formulæ can be relied upon to yield correct results.

The following are the results which, considering the trouble that has been given to their verification, I think will stand the most severe scrutiny:—

Period 850,000 years ago.	Period 900,000 years ago.
$h^2 = \cdot00413927$	$h^2 = \cdot000059858$
$l^2 = \cdot00144124$	$l^2 = \cdot000059812$
$h^2 + l^2 = \cdot00558051$	$h^2 + l^2 = \cdot000119670$
$\sqrt{h^2 + l^2} = \cdot0747 =$ Eccentricity	$\sqrt{h^2 + l^2} = \cdot010939 =$ Eccentricity

Edinburgh, August 10 JAMES CROLL

A Lunar Rainbow, or an Intra-lunar convergence of Streams of slightly illuminated Cosmic Dust?

ABOUT 8.30 P.M. yesterday a large zone of the sky, from the horizon at W.N.W. to the horizon at E. by S., was illuminated in a very remarkable manner, and this illumination lasted about three-quarters of an hour, when it gradually died out.

During all this time the sky was very clear and cloudless, thereby forming a dark back-ground, on which the phenomenon, whether lunar rainbow, or many rainbows, or intra-lunar converging streams of cosmic matter, was splendidly projected.

This exhibition consisted of one grand central feather springing out of the horizon at W.N.W. and crossing this meridian at about 20° north of the zenith. The width of this stream, with little variation throughout its length, was 7° or 8°. Its light was that of a *very bright* white cloud, its edges most beautifully defined; its form that of a very elongated feather, but without any shaft. On either side of this main feather was a system of seven or eight minor and fainter streams, threads, or beams of light, all more or less extending from the western to the eastern horizon, subtending a chord common to themselves and to the main stream of light, and converging towards the axis of the central stream so as apparently to intersect it at a point about 30° or 40° below the western horizon, at which the whole system subtended an azimuth of about 20°; and near the zenith, where its transverse section was a maximum, that section subtended an angle of about 40°. At this time the moon was about 15° east of the meridian, and her declination about 9° S. Both systems of the minor streams of light on the sides of the main stream appeared to have a slight

libratory motion, or to slew upwards towards the main stream, and therefore perpendicularly to their length.

Nothing could suggest to the mind more strongly the idea of converging streams of infinitely minute particles of matter passing through space at a distance from the earth less than that of the moon, and at which the earth's aërial envelope may still have a density sufficient, by its resistance, to give to cosmic dust passing through it with planetary velocity that slight illumination which it possessed.

The rapid development of the luminosity of these streams on this occasion is evidenced by the fact that they were observed at the time of leaving church, namely, 8 P.M. to 8.20 P.M., by none of the several congregations of this town and Perth, but were observed by many persons from a quarter to half an hour after that time, so far as I have yet been able to ascertain by a rather extensive inquiry. On coming out of church I myself certainly looked round the whole visible horizon and the higher portion of the heavens, and I made to a companion some observations on the clearness of the stars and dark blue colour of the sky; but about twenty minutes after my exit from church these streams of light had attained their maximum of illumination.

Their apparent figure was that of a nearly circular (slightly flattened) arc of an amplitude of 15° or 20°, as viewed from the middle point of its chord. Both the brightness and the convergence of the streams towards the western horizon were more marked than those towards the eastern horizon.

Fremantle, West Australia, May 17 J. W. N. LEFROY

PS.—Since writing the above, in the Supplement of the *South Australian Register* of Thursday, May 20, I have found the following paragraph:—

"A beautiful lunar rainbow was visible in the western heavens on the evening of Sunday, the 16th inst., a few minutes after 8 o'clock. For a short time the arch was nearly perfect, but for upwards of fifteen minutes the limbs were very bright. The southern limb also appeared visible for some time after the upper portion of the arch had faded away."

Now, allowing for the difference of local time between Fremantle and Adelaide, I think it fairly assumable that this paragraph must refer to the same phenomenon which I have attempted to describe as above; and, if so, it clearly shows that it was *not* a lunar rainbow. I can find no allusion to it in any Melbourne paper yet received here, and which reach to the 19th inst. There the sky may that evening have been cloudy, and thus have rendered it invisible. All intelligent persons here who observed it, and with whom I have had opportunity of conversing since the 16th inst. to this day, concur in my impression that minor lateral streams or feathers of light on the north side of the main stream intervened between the earth and the moon, and one or more of them in its slow librations swept the surface of the moon and sensibly obscured its light.—J. W. N. L.

May 31

"Instinct" and "Reason"

A FEW facts came under my observation during the spring of this year that strikingly illustrate this subject. A pair of blackbirds built a nest on the top of my garden wall, which is thickly covered with ivy and within three yards of the drawing-room window. When the young birds were about three parts fledged one of them by some mishap left the nest and fell into the flower garden. My cat (seven years old, and which has killed scores of small birds) immediately found it, and at the same time a kitten (about three months old, but not belonging to the cat) began to pay rather rude attentions to the young blackbird, and would have used it as kittens are wont, but the old cat would not suffer her to touch it. The cause of this was the old cock blackbird, being aware of the peril of its young, made a great noise and kept flying here and there around the scene of action, crying and scolding with might and main. It then became evident to me that the cat had two or three objects in view, and a purpose to gain. Firstly, not to allow the kitten to touch, or kill, or make off with the young bird. Secondly, to use the young bird as a decoy to entrap the old one. Thirdly, to make the young bird cry sufficiently from fear or pain to induce the parent's affection to overcome its discretion.

During the manœuvres old Tom repeatedly made unsuccessful springs to catch the cock-bird, alternately running to give the kitten a lesson of patience, or self-denial, or impose a fear of punishment. The young bird repeatedly hopped out of sight amongst the flowers and stinted its cries; then anon the cat touched it again and made it flutter about and cry again, which from time to time brought the old bird down with cries of terror, or wrath, or a blending of both emotions, and almost into the very mouth of the cat. Two or three times I thought old Tom was successful, but no, he missed his object most surprisingly. It became evident to me that the cat was using the young bird as a decoy to catch the old one. After I had watched some ten or fifteen minutes, it became too painful for me to witness, so I caught the young bird and put it again into its nest, which was about ten feet from the ground.

In less than an hour the young bird was again on the ground, the cat, kitten, and parent bird performing the same drama, with this difference in the acting: the cat lay down, rolled about, or sat at a convenient distance from the young bird, yet with eyes alert, though half shut, and otherwise giving an assurance that he did not intend to make another bound without succeeding to catch his prey. He was, however, disappointed, and made four without achieving his purpose. At this juncture the mother-bird came on the stage with cries of distress, but kept aloof on the branches of a tall cherry-tree that rises above the wall; and if her boldness were less than the cock-bird's, her discretion was greater, for she kept far aloft. Once it seemed to me that the cock-bird actually struck the back or head of the cat with his wing and mandible. This scene continued about seven or ten minutes, when I again caught the young bird and threw it over the wall, and the exhibition of animal thought, emotion, and passion ceased.

Here were manifested phenomena of a more remarkable kind than those seen in the cases cited by the Duke of Argyll in the *Contemporary Review* for July, in an article to illustrate "Animal Instinct in relation to the Mind of Man," for the cat showed an amount of reasoning which he probably never before exercised, because never before placed in the same circumstances. That he had used young sparrows, of which he must have caught scores, as decoys to catch the old ones is possible, but I am perfectly sure that no kitten ever was in the garden during his reign as "monarch of all he surveyed" in the shape of birds. Hence his authority over the kitten, which was full of life and eagerness to appropriate the young bird, the killing of which would have defeated the purpose of the cat in using the young bird as a decoy to catch the old one, was indeed remarkable, and disclosed a combination of mental forces of self-conscious reason of no trifling order, and, as it appears to me, conclusive that the difference—and only difference—between instinct and reason is one of degree. JAMES HUTCHINGS

Banbury, Aug. 16

OUR ASTRONOMICAL COLUMN

DOUBLE STARS.—Dr. Doberck, of Markree Observatory, has published a first approximation to the elements of ζ Aquarii, on measures between 1781 and 1870, in which long interval, however, the angle of position has only changed 45°—a case where very great latitude must be allowed to any orbit that may be deduced. Dr. Doberck fixes the peri-astron passage to 1924·15, and assigns a period of revolution of upwards of 1,500 years. The latest measures we have met with are those of Nobile, taken at the Observatory of Naples in November 1873, giving the angle 335°·5, or 3°·4 greater than that calculated.—There appears now a probability that the smaller component of 44 Bootis has passed its greatest apparent distance from the primary several years since: if good measures of distance have been made this year, they ought to be sufficient to enable us to pronounce definitely upon this point. That this star forms a true binary there can be no doubt, though it is Sir W. Herschel's measures in 1781 and 1802 alone, that afford conclusive evidence of the physical connection of the components. Thus we might represent the measures between Struve's earliest in 1819 and the present time by the formulæ

$$\Delta\,\alpha = -\,3''\!\cdot\!4233 - [8\cdot8968]\,(t - 1830\cdot88)$$
$$\Delta\,\delta = -\,1\cdot6979 - [8\cdot3115]\,(t - 1830\cdot88)$$

But if we calculate from the same formulæ for Sir W. Herschel's epochs we find,

1781·62	Position	156°·1	Distance	0''·75
1802·25	,,	214·8	,,	1·35

These are greatly at variance with the positions observed, which show that the companion was then in the following semi-circle, and by the estimates of distance had approached the primary between 1781 and 1802. Barclay's epoch 1871·4 assigns a distance less by 0″·35 than was observed at Leyton in 1866, which is confirmed by Dembowski's measures about the same time. There is in the case of this star a very unusual discordance between the distances of Struve and Dawes, which attains a maximum, 0″·45, about 1836·5; in deducing the above formulæ Struve's measures were employed. The rate of increase in the distance has been diminishing, until by Dembowski's measures, 1863-68, it was less than 0″·01 annually; the orbit is evidently inclined only a few degrees to the line of sight, so that the companion made a very close approach between 1802 and 1819.—If the angles of position, in the case of Σ 1819 between 1828 and 1870 are projected, it will appear that the velocity has been diminishing from about 2°·1 in 1840, to 0°·85 at the end of the period, which with the accompanying increase of distance confirms Struve's judgment as to orbital motion; there is already a diminution of angle of nearly 70° since the first Dorpat measures.—It may be hoped that Σ 2107 has not been forgotten this year.

M. LEVERRIER'S THEORY AND TABLES OF SATURN.—We learn that M. Leverrier has completed his long-continued and exhaustive investigations on the motion of Saturn, and that his theory is reduced into tables, which will of course speedily take the place of those of Bouvard, or of provisional tables which have been used in the preparation of one or two of our ephemerides, pending the publication of others founded upon a more complete theory and discussion of the observations from the time of Bradley. As in all Leverrier's previous researches of a similar nature, he has made use of the rich store of observations accumulated at the Royal Observatory, Greenwich during upwards of 120 years, and also of the long series which has been formed at the Observatory of Paris. The mathematical astronomer will await the publication of M. Leverrier's researches in detail with extreme interest. The Tables of Saturn are understood to be necessarily of considerable extent, with the view to their convenient application.

THE GREAT COMET OF 1819.—The parabolic orbits so far computed for this comet, which was observed from the beginning of July to the middle of October, do not represent the observations with sufficient precision, and it is probable that no parabola will be found to do so. The following may, perhaps, be closer than any yet published:—

Perihelion passage 1819, June 27·71547, Greenwich M. T.

Longitude of perihelion ...	287° 8′ 11″	Mean equinox
Ascending node	273 41 57	July 0
Inclination ...	80 44 38	
Log. perihelion distance ...	9·533233	
Heliocentric motion	direct.	

But this orbit exhibits differences from the observations of a kind that should probably be attributed to deviation from parabolic motion, and as we are in possession of many of the original observations, it would be desirable to discuss them with the view of determining the true character of the orbit in which the comet was moving. Its transit over the sun's disc, a nearly central transit, early on the morning of June 26, and the suspicion that it was actually observed upon the disc by Pastorff at Buchholz, or, as is even more probable, by Stark at Augsburg, give it a peculiar interest. The diagram of the comet's path across the sun, which appears in the "Berliner Astronomisches Jahrbuch," is erroneous; it would pass in greater longitude than that of the sun's centre, as indicated by the above elements, which in this respect are confirmed by the orbits of Nicolai, Dirksen, and Cacciatore. For the centre of the earth the ingress took place June 25 at 16h. 52m·9 mean time at Greenwich, 172° from the sun's north point towards the east (direct image), and the egress at 20h. 29m·9, about 9° from the same point to the east. For the time of transit the elements, no doubt, assign the comet's position within 15″ or 20″. The larger differences from observation are in August.

SCIENCE IN GERMANY

(*From a German Correspondent.*)

IN continuation of the previously reported investigations of the formation of cells in the ovum, we may mention some observations of Kupffer, which relate to a hitherto rather unknown yet doubtless very widely spread structure of the animal cell. ("On the differentiation of protoplasm in the cells of animal tissues," from "Schriften des naturwissenschaftlichen Vereins für Schleswig-Holstein," Heft. iii.; and "The salivary glands of *Periplaneta orientalis* and its nervous system," from "Beiträge zur Anatomie und Physiologie, als Festgabe Carl Ludwig zum 15 Oct. 1874, gewidmet von seinen Schülern.") Kupffer first discovered that the body of the cells from the liver of a frog, which coat the biliary vessels, consists of two substances which chemically and physically are widely different, while hitherto it had been considered homogeneous throughout and had been called protoplasm. A hyaline ground substance (Paraplasm) gives to the body of the cell its relatively firm exterior shape, while in its interior a moveable, grained protoplasm is found in varying arrangement. It appears as a central mass round the nucleus, from which ramified or reticular threads radiate to the exterior side of the liver-cells which is turned towards the blood-vessels, or to that which borders the biliary vessels. From this arrangement of the protoplasm, which slowly flows in the well-known manner, Kupffer surmised that these were the ways in which certain matters were conveyed from the blood into the biliary vessels; and he found his opinion confirmed when he introduced soluble colouring matter into the blood of the living animals. As the colour entered through the liver-cells into the biliary vessels, it indicated its course through the cells in most cases in exactly the same way in which formerly the protoplasm proper had been found arranged. Similar facts were found in respect to the liver and kidneys of other Vertebrata, in the young back-teeth of calves, in certain glands of insects (Malpighian bodies). In the salivary glands of the well-known "black beetle" (*Periplaneta*), Kupffer not only found a very soft net of protoplasm-threads inside the ground-substance of the cells, but he also proved their connection with nerve ends. This likewise supports the view that the substance of the animal cell is differentiated in a manner similar to that of the vegetable cell, viz., that it consists of an active material which remains moveable and fulfils the special physiological functions of the single cell (protoplasm), and of a more passive material which forms a sort of protecting receptacle, as it were, for the tender protoplasm (Kupffer's paraplasm).

The "Archiv für mikroskopische Anatomie," edited by La Valette St. George and Waldeyer, has produced the following papers in its eleventh volume, up to this date:—Part I. On Radiolaria and fresh-water Radiolaria-Rhizopoda, by Greeff.—On bone growth, by Strelzow.—Researches on the physiology of the kidneys, by Wittich.—Studies on Rhizopoda, by F. E. Schulze.—Researches on the ganglion globules of the spinal ganglia, by Arndt.—On Heitzmann's hæmatoblasts, by Neumann.—On tissue cells by Waldeyer. Part II. The Ventriculus terminalis of the spinal marrow, by Krause.—Remarks on the nerves of dura mater, by Alexander.—Studies on the development of bones and of bone-tissue, by Stieda.—On the peripherical part of vertebræ, by Ehrlich.—The perivascular lymph-spaces in the central nervous system, and in the retina, by Riedel.—On cement layers in the tissues

of vessels, by Adam-Kiewicz.—Hyalonema Siebold, Gray, by Küstermann.—Researches on the development of spermatozoa, by Neumann.—On amœboid motions of the little nucleus-body, by Eimer. Part III. Studies on Rhizopoda, by F. E. Schulze.—The relation of ciliated epithelium of the abdominal cavity to the epithelium of the ovary, by Neumann.—Researches on the first signs of the eye-lens, by Mihalkowics.—Vertebral side and cerebral appendage, by the same.—Researches on the development of cross-striped muscles and nerves of Reptilia and Amphibia, by Calberla.—On the reproduction of Arcella vulgaris, by Bütschli.—Researches on the epithelium of the nose, by Brunn.—On the nerves of the gullet, by Goniaew.—Researches on the anatomy of the human throat, by Disse.—On the structure of the Najadeuxieme, by Posner.—Supplement: On the dental system of Reptilia, and its significance with regard to the genesis of the skeleton of the oral cavity, by O. Hertwig.—The above-mentioned researches of Greeff and Schulze, which are in close relation with those made in England by Archer and Carter, treat of a class of the lower animals which only lately has attracted great attention; we therefore can hardly be astonished that in such treatises, descriptions and determinations of the different forms are in the majority, and that the particular course of life of single species remains at present still wrapped in considerable darkness. These neat little organisms consist of a very simple substance, which supports their existence (sarcode) and of a siliceous skeleton, which in some instances radiates outwardly in all directions, while in others it appears as a bag- or bottle-shaped shell, and is often adorned with relief-work well worthy of admiration. As indications seem to become more and more numerous that not only within the range of one species, but even in the development of one and the same individual animal, different forms occur, it is evident that the propagation and development of these organisms must remain difficult to understand, so long as these relative connections are not investigated. But thus much is already known, that even in the most distant localities the same forms may occur, and that the marine Radiolaria and Rhizopoda have near relations, or even identical forms, in fresh water. Besides division, the following phenomena seem to be connected with propagation: the phenomenon of conjugation (temporary union of two animals), of "encystifaction" (enclosing by a shell of the animal which is contracted into the shape of a ball), and of the formation of spores (production of interior germs, according to Bütschli).

ZOOLOGICAL STATIONS ABROAD

THE following letters from Dr. Mikluho-Maclay to Dr. Anton Dohrn, Director of the Zoological Station at Naples, have been forwarded to us for publication by Prof. Huxley. The first relates to a zoological station which Dr. Maclay has established in the Malay Archipelago, and the second to the general subject of zoological stations abroad.

"Dear Dohrn,—You are well aware that I share your views as to the great value of zoological stations to science, and you will not doubt that the account of the excellent results of the great establishment founded by you at Naples, which reached me by accident at Ternate in 1873 on my return from my first expedition to New Guinea, gave me great pleasure.

"It is now my turn to surprise you with the news of the establishment of a third (?)[1] *zoological station at the southernmost point of Asia*, on 'Selat-Tebrau,' the strait which divides the island of Singapore from the Malay Peninsula.

"This new 'station' cannot, it is true, be so called in the same sense as yours at Naples. I have taken my own requirements and customary mode of life as the standard, and have arranged the building and its fittings in accordance with it.

"It will serve in the first place as a station and *Tampat Senang* (or place of rest) for *myself;* in my absence, and after my death, I wish to place it at the disposal of any student of nature who feels himself suited for my mode of life.

"My 'Tampat Senang' has the following advantages to offer:—

"A house consisting of two fairly large rooms, each provided with two verandahs (besides the necessary offices), surrounded on three sides by the waters of the straits, and on the fourth by the primeval forest.

"The house will be simply furnished, and will contain a small library, together with the most necessary articles for housekeeping.

"It possesses, moreover, two advantages which I consider to be of no small importance, namely, the command of a fine view, and very complete isolation.

"The use of this 'Tampat Senang' is open to *any* student of nature, without the slightest regard to nationality, provided only he be of the male sex (for I confess to a decided repugnance to all stages of development and differentiation of the genus 'blue stocking.') The presence of a woman as visitor, or as supplement of the one student of nature for whom the place affords room—for in this case a wife must be so regarded—is not forbidden; but since 'Tampat Senang' must remain true to its name and to my idea, no children can possibly be allowed there.

"I have purchased the piece of land on which the house is to stand, from H.H. the Maharajah of Johore. It is a small hill which forms a cape projecting into the Selat Tebrau. In my will I have made such provisions that my family, into whose hands it will pass, will be precluded from *ever* selling it, or allowing it to be used for *any other* purpose than as a station for scientific research; or from cutting down, or even thinning the primeval woods standing upon it; the utmost that will be allowed is the clearance of one or two footpaths through the wood, which is always to remain as a specimen of the untouched primeval forest. And although 'Tampat Senang' may be hereafter rebuilt in stone, and made more elegant or convenient, it is *never* to be enlarged, lest it should lose its character of an isolated abode for *one* student of nature.

"I lose no time in writing to you, although the ground is only just purchased and the house is not yet built, because I think the plan of establishing such outposts for students of nature in these parts of the world (the East Indian Archipelago, Australia, the islands in the Pacific Ocean, Japan, &c., &c.) likely to be *very useful*, and also because, on account of my present ailment (an injured foot), I have more leisure than usual.

"Hotels can never afford suitable places of study on account of the noise and confusion inseparable from them; nor can the hospitality of friends, however kindly it may be offered, supply all that the student of nature needs. Such unpretending stations as my future 'Tampat Senang,' where he can work in absolute quiet, neither disturbing others, nor suffering interruptions, without the need of asking favours or incurring obligations, will I think commend themselves to many persons interested in the advancement of science.

"A principal reason for my choice of Johore is the neighbourhood of Singapore, from which place 'Tampat Senang' can be reached in three or four hours. The advantages of this position are that all products of European industry can be easily procured; that by means of the frequent mails communication can be maintained with

[1] I have not heard whether the station which you and I began at Messina in 1867-68 arrived at any high degree of development, or whether it shrank into a mere rudiment. My nomad life has prevented news of any other than yours at Naples from reaching me; for example, I do not know whether he station on the Black Sea, which I advocated at the meeting of Russian naturalists at Moscow in 1868, ever came into existence.

all parts of the world; that very fair libraries are accessible at Singapore and Batavia; and that, at the latter place, scientific papers can be published in French, German, or Dutch, in the *Natuurkundig Tijdschrift*, while the *Journal of Eastern Asia*, of Singapore, publishes similar works in English.

"In the hope that you may be one of those who will make use of my 'Tampat Senang,' I remain, with all respect and friendship, "N. N. MIKLUHO-MACLAY

"28th April, 1875, Istana Johore,
"Residence of H.H. the Maharajah of Johore."

"In life, as in everything else, it is important to distinguish main points from secondary matter, and to act accordingly. Main points always remain main points, however important secondary objects may sometimes be. On account of this evidently correct view, I continue my journey into the interior of the Malayian peninsula, as my health is improving; to-morrow I shall go to Pahang, and for the moment I give up building the 'Tampat Senang.' It is possible that I must try and find some other locality than Johore for this, because the Maharajah of Johore, after nearly two months' talking, in which time I had made out all the plans and had completely gone through all the details of the proposed building, has at last declared to me that he only could let me have that tract of land which I had chosen for the 'Tampat Senang' for a certain number of years, and that he must retain certain rights on the same. As all this does not agree with my plans, and as the locality is not of decisive importance, I shall, in case the Maharajah does not decide differently, construct my 'Tampat Senang' somewhere else.

"I consider the foundation of Zoological Stations in the tropics (however simply and poorly they may be fitted out, if they are otherwise quiet and comfortable places for work) as of the greatest importance for zoology and botany, since museum collections and preparations in spirits cannot afford sufficient material for investigation either with regard to quantity or quality.

"I have sent a proposal to the Society of Naturalists at Batavia, to found a 'Tampat Senang'[1] for naturalists in the Moluccas (at Amboina or at Ternate), and I intend to send similar proposals to scientific societies at Calcutta, and in Australia, and to some friends in Chile. If Russian Societies of Naturalists assist me I intend eventually to found a Zoological Station at the Sea of Ochotsk, or on the Pacific Ocean, myself.

"Zoological Stations in the Moluccas, in the Himalayan Mountains, in Tasmania, in the Fiji Islands, in Magellan's Straits, in Kamtschatka, &c., will yield not a few important results for all natural sciences. These stations will be particularly important for those naturalists who travel not only as tourists or as trade travellers of science, as it were, but who are engaged on some special work which requires large and fresh materials. Upon my return (which, however, is very uncertain at present) I will communicate to you my plans on the 'Tampat Senang' (the name seems to me to be quite appropriate) in detail. As it seems to me, they must be somewhat different from such Zoological Stations as your own at Naples, or we shall have to wait too long for their foundation. On my part I shall do all in my power for the carrying out of this idea, which nevertheless must remain a secondary (although important) object for *myself*.

"The day before yesterday I read in NATURE of May 6 of the official inauguration of your station at Naples, with much pleasure, and amongst the names I found those of several friends and acquaintances; so that I am led to hope that the scientific world will be interested in the 'Tampat Senang' in other parts of the globe.

[1] It is a matter of course that what I expect from my future "Tampat Senang" cannot apply to others. Only mine shall remain true to its name, whether built at Johore, or at the Maclay coast in New Guinea.

"My kindest regards to yourself and all workers at the Zoological Station of Naples.

"N. N. MIKLUHO-MACLAY

"Istana, Johore, 9th May (June ?) 1875"

THE VATNA JÖKULL, ICELAND

THE following letter from Mr. W. L. Watts in reference to his journey across the Vatna Jökull has been forwarded to us by Mr. Logan Lobley. As we noted last week, this is the first time the Vatna Jökull has been crossed. The letter is dated "Grierestadir, by Jökull sá á fjöllum (Iceland), July 12, 1875."

"I am happy to say I have crossed the Vatna Jökull. It occupied between fifteen and sixteen days in bad weather. Euriffa is by no means the highest mountain in Iceland; my aneroids registered 1,250 feet above Euriffa's height, subject to their correction upon my return to England.

"I feel certain that the Jökulls of Iceland are advancing at a considerable speed. The part of the Vatua Jökull, in the south of Iceland, called Breithamerker Jökull, has advanced about one mile and a half since the 10th of May last, and threatens to cut off all communication in that direction along the shore. I think, however, its rapid advance is not, as the natives believe, owing to volcanic heat in the Vatna Jökull, but that it is caused simply by the vast increase of frozen material upon its cloud and storm-wrapped heights. This accumulation above the height of 5,000 feet goes on both in summer and winter, and below for another thousand feet the waste during the summer months by no means equals the accumulation during the rest of the year. The glacier at the north point, at which descended, by Kistufell has advanced about twelve miles since the making of Olsen's map of 1844, diverting the course of the Jökull sá á fjöllum and causing it to rise about twelve miles from where it appears to do upon the map, *i.e.* about eleven miles N.E. of Kistufell and twelve NN.W. of Kverker Jökull, instead of at the base of Kistufell. The grand old water-course it has vacated forms an excellent road for several miles. I feel sure Iceland must slowly but surely in course of time succumb to the same fate as befell the Greenland colonies.

"I am now about to proceed to the active volcanoes upon the north of Vatna Jökull. They are situated in the part of the Odalters-brauu called Dyngurfjöllum, and as I expect in the Kverker Jökull. I shall have no time to hunt for any more this year, but if time will allow I shall visit the source of the great lava stream of Skaptar Jökull, a mountain I saw from the Vatna Jökull, situated in its S.W. limb, which I think may repay inspection; and the lignite in the N.W. of Iceland.

"The destruction wrought by the eruptions of last winter is considerable. Several farms have been ruined by pumice and ash. Poor, dirty, interesting Iceland! both fire and water, the latter in all its forms, appear to conspire against it."

ON AN IMPROVED OPTICAL ARRANGEMENT FOR AZIMUTHAL CONDENSING APPARATUS FOR LIGHTHOUSES

ORDINARY optical apparatus adapted for a lighthouse which has to illuminate the whole horizon, as at rock or insular stations, is unsuitable for stations situate on the coast line, or in narrow sounds, where the light has in some azimuths to be seen at great distances, in others at smaller, and where towards the land no light is wanted at all. The problem in such cases is to allocate the rays in the different azimuths in proportion to the distances and breadths of sea in which the light requires to be seen in those directions by the sailor. Before 1855 no attempt

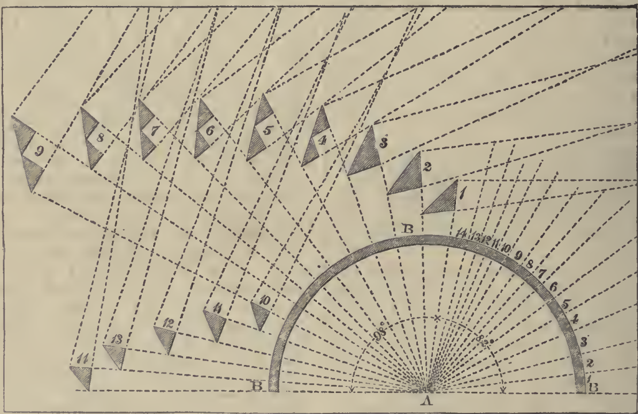
was made to deal with this question, excepting the simple expedient of placing a spherical mirror on the landward side, where no light was wanted, and thus the rays intercepted by the mirror were reflected back again through the flame, so as to be ultimately acted on by the apparatus at the seaward side. But this device did not in any way fulfil the condition of allocating the rays proportionally to the varying distances at which the light had to be seen in the different azimuths, nor to the amplitude of the arcs. What was required was *a system by which the whole light from the lamp should be spread horizontally and with strict equality over any given arc in azimuth; and at a light of unequal range, which must be seen at different distances in different azimuths, the rays should be allocated to each of such arcs in the compound ratio of the number of degrees and the distances from which the light has to be seen in such arcs.*

It is unnecessary to give a description of the various methods of solving this problem for fixed and revolving lights, which I have elsewhere published under the name of "Azimuthal Condensing Lights."[1] All that is here required is to indicate generally the mode of dealing with fixed condensing lights, which was first employed for some narrow navigable channels on the west coast of Scotland in 1857, and which is now adopted in many different countries.

We shall take a case of the simplest kind in order to illustrate the principle :—

Let a lamp be surrounded by the fixed light apparatus of Fresnel, which allows the rays to pass through it unaltered in direction in azimuth, so as thus to show a light of equal intensity all round the horizon, but which operates on the rays in altitude by bending upwards, to the horizontal, those rays which would fall on the lightroom floor and be lost, and also by bending downwards to the horizontal those rays which would naturally pass up to the clouds. This instrument then strengthens the light passing to the sailor's eye, by bending upwards and downwards those rays which would otherwise be entirely lost. Suppose, however, that the light does not require to be seen at all in an arc in the direction of the land, and that there are two other sectors in azimuth in which the light has to be seen at greater distances than any others. If we place outside of Fresnel's apparatus in the azimuths towards the land (which may therefore be made dark) straight prisms which have each the property of spreading the light that falls on them over the sectors that require most strength, and if we proportion the number of these straight prisms to the required distances and to the number of degrees which have to be illuminated, we shall then fulfil this simplest case of the problem, viz., the due strengthening of the light in the directions of the longest ranges, and its uniform distribution in azimuth over those sectors.

The diagram represents in horizontal middle section the design for a new light which is about to be erected and which requires to illuminate different arcs with light of different intensity. A is the lamp encircled in front by B, which represents part of Fresnel's



fixed light apparatus, outside of which are shown straight vertical prisms numbered 1 to 14 for condensing the rays over the arcs in azimuth that have to be strengthened, and which arcs have corresponding numbers 1 to 14. The novelty in this arrangement is the mode adopted for reducing the space which would otherwise be occupied by the condensing prisms but for which there is no room in a lantern of ordinary size.

My friend Prof. Swan, of St. Andrews, among other ingenious devices in a paper read to the Royal Scottish Society of Arts, proposed, in order to reduce the space occupied by the apparatus, to place prisms *behind* others and to project the rays from the prisms behind, forwards through spaces left between the prisms in front. In the present design I have availed myself of this proposal. The prisms 10 to 14 throw their light between the prisms 3 to 8. Owing, however, to the natural divergence due to the size of the flame, much useful light would be lost by impinging against the edges of the outer prisms unless those prisms were separated farther from each other in order to afford wider spaces for the cones of light to pass through. But this again would increase the space occupied by the apparatus. The difficulty may be overcome by cutting out the apex of the outer prisms as shown in prisms 4 to 9. This would, as in Buffon's annular lens, also materially reduce the absorption of the light which passes through them. For facility of construction, however, instead of one prism cut in this manner, two small separate prisms arranged symmetrically with the larger one have been substituted.[1] By means of these groups of *twin prisms* the apparatus is reduced within practicable dimensions, while the quantity of glass employed in the apparatus is materially lessened, and the loss from absorption is reduced by about one-tenth.

It is only necessary to add that while the cost of the first apparatus of the kind will be increased by the greater number of moulds required for casting the prisms, it will on the other hand be reduced by the smaller quantity of glass required. The amount of glass surface which has to be ground and polished is of course the same for each pair of twin prisms as for one single large prism.

The new apparatus will, in addition to what has been described, require at the back of the flame the Dioptric spherical mirror which I proposed in 1849[2] with the improvements suggested by Mr. J. T. Chance in 1862, and above the flame, prisms of the new forms suggested by Mr. Brebner and myself, and also independently by Prof. Swan, and which were first introduced at Lochindaal in Argyllshire, in 1869.[3] The apparatus will therefore embrace in all six different optical agents, and will compress into one sector of 82° light which would naturally diverge uselessly over 278°. This condensing apparatus is, however, not nearly so powerful as others now in use. In the two

[3] "Lighthouse Illumination," p. 75.

which I designed for Buddonness-on-the-Tay, one of which was exhibited at the Paris International Exhibition, the whole sphere of light was compressed into one sector of 45°, and in another design lately made for the Colonies the light is condensed into 30°. THOMAS STEVENSON

THE BRITISH ASSOCIATION

BRISTOL, *Tuesday Evening*

BRISTOL bids fair fully to accomplish its intention of giving the Association one of the best receptions it has ever received. When the visitor has laboured through the inconveniences of the railway station, and got fairly at home in this region of hills and valleys, and cliffs and quays, and churches and chimney stacks, he will find himself as happily situated as anyone but a confirmed grumbler could wish.

The local committee have evidently spared no expense to increase the comfort of visitors. The engagement of the entire Victoria Rooms for reception rooms has given ample space for almost every requirement. The great hall itself contains many of the necessary offices, including those for the local officials, sale of tickets of all kinds, distribution of printed circulars, and a telegraph and post-office; in addition, Messrs. Bingham's book-stall supplies all kinds of journals and scientific publications. A first-rate refreshment room occupies one of the smaller halls, and a reasonable tariff of prices is published. Almost every want seems to have been anticipated, and the honorary local secretaries, Messrs. W. Lant Carpenter and J. F. Clarke, with many other zealous workers, have been labouring untiringly to have everything in order. So successful were they, that the reception rooms were opened exactly at the moment previously announced—one o'clock on Monday; and the first rush to secure tickets was most satisfactorily worked off. It will be surprising if the amount expended do not exceed the local subscription of 2,400*l*. At any rate, so far as experience goes at present, that full success is likely to be realised which is worth very much more than can be measured by money. The Mayor (Mr. Thomas) to-day took up his residence at the Mansion House, where he will receive the President-elect, Lady Hawkshaw, and other distinguished visitors. Most of the notable visitors come as invited guests.

The columns of NATURE would certainly fail me if I attempted to enumerate the objects of interest here which are thrown open freely to members of the Association. Churches, old buildings of all kinds, libraries, ships, quays, warehouses, parks, and mansions are alike at the disposal of the visitors.

Notable amongst hospitalities will be the banquet of the Merchant Venturers' Society, at which about a hundred of the leading members of the Association will be entertained on Tuesday evening next. The hall of the Merchant Venturers has lately been decorated with a magnificence worthy of their distinguished history. The sovereigns who granted them charters, the Bristol worthies, Edward Colston, Alderman Whitson, Sebastian Cabot, William Canynge, and Thomas Daniel are all commemorated by portraits or arms; while the staircase and vestibule bear significant emblems of seafaring life. Saturday next is the jubilee of the Bath Royal Literary and Scientific Institution. This will be celebrated by a public meeting and banquet, presided over by the Earl of Cork, lord-lieutenant of the county. Sir John Hawkshaw and many other distinguished guests are expected.

As a matter of course nearly all the eminent British men of science are expected to be present, and many of them have already arrived. Among foreign visitors who have arrived or are expected, there are Prof. Paul Gervais, of Paris; Chevalier Negri, President of the Geographical Society of Turin; Chevalier Bergeron, C.E., Paris; Prof. Geinitz, Dresden; Prof. Hébert, Paris; Dr. Leitner; Prof. Youmans, United States; Mr. H. A. Rowland, Baltimore; Prof. Janssen, Paris; M. Léon Vanderkinden, Brussels University; Dr. A. Oppenheim, Berlin; Colonel Carrington, Wabash College, U.S.

Of course the general meetings, inaugural address, lectures, and soirées will be given in the Colston's Hall, which can seat 3,000 persons. The sections are accommodated in a number of buildings extending along one line of thoroughfare, from the Wesleyan schoolroom in Victoria Place to the Royal Hotel at College Green. Sections A and G sit in the Fine Arts Academy; B in the Lecture Theatre, Freemasons' Hall; C in the New Museum Lecture Room; D in three departments at Hamilton's Rooms, Park Street, the Grammar School, and the Royal Hotel; E in the Blind Asylum Music Room; F in the schoolroom of Victoria Chapel. On the back of every Association Ticket a plain map of about one square mile of Clifton is printed, showing in red colours all the buildings used for meetings. This is a most valuable help for visitors.

A first-rate loan museum is exhibited in the new portion of the Museum buildings, and is well worthy of attention. Among the most interesting things to be seen are specimens from many local collieries of every vein of coal they work, local building-stones and clays; and capital illustrations of local zoology and botany. The Museum proper is noticeable for its splendid collection of Triassic reptiles, Labyrinthodonts, and Palæozoic fishes, especially *Thecodontosaurus* and *Ceratodus*. A splendid skeleton of *Ichthyosaurus platyodon* has just been mounted. It was detected by Mr. Tawney on the beach near Lyme Regis, close to low-water mark. It was brought up in large fragments of over a hundred-weight, in all over a ton, and developed under Mr. Tawney's superintendence. The skeleton is swung instead of being supported from beneath, according to an idea of Dr. H. Fripp, and it can be examined very closely, and on both sides, being placed on a stand of the ordinary height of table cases. It was an enormous individual. The present remains, although lacking the snout and much of the tail, extend to a length of about twenty-five feet.

The excursions for Thursday week are numerous and calculated to please all tastes; they are to (1) Bath, (2) Bowood and Avebury, (3) Cheddar, (4) Chepstow and Tintern, (5) Portishead, Cadbury Camp, and Clevedon, (6) Salisbury and Stonehenge, (7) Sources of Bristol Waterworks Supply, (8) Tortworth and Damery Bridge, (9) Wells and Cheddar, (10) Weston-super-Mare.

The arrangements for transit and entertainment are most complete. The soirées give promise of great success. The first is to be under the auspices of the Bristol and Bath Natural History Societies, and many specimens of living microscopic animals will be exhibited. At the second, the post office officials intend to make a very elaborate display of telegraphic instruments and processes.

It is worthy of remark that it was at the meeting of the Association at Bristol in 1836 that Section G (Mechanical) was instituted; and at that meeting Dr. Lardner expressed his opinion that the proposed scheme of crossing the Atlantic by steam was an impossibility. From Bristol, however, the first steam-ship traversed the Atlantic to New York.

It was in the Bristol district that macadamised roads were first introduced; some of the earliest docks (1803) were made there under the direction of Mr. W. Jessop; and on the Somersetshire Canal was tried Mr. Weldon's extraordinary hydrostatic lock.

To geologists there is the interesting fact that within twelve miles on the Somersetshire Coal Canal, the "father of English geology" made his discovery of the sequence of strata; and geographers will recollect that Sebastian Cabot sailed from Bristol.

INAUGURAL ADDRESS OF SIR JOHN HAWKSHAW, F.R.S., PRESIDENT.

To those on whom the British Association confers the honour of presiding over its meetings, the choice of a subject presents some difficulty.

The Presidents of Sections, at each annual meeting, give an account of what is new in their respective departments; and essays on science in general, though desirable and interesting in the earlier years of the Association, would be less appropriate to-day.

Past Presidents have already discoursed on many subjects, on things organic and inorganic, on the mind and on things perhaps beyond the reach of mind, and I have arrived at the conclusion that humbler themes will not be out of place on this occasion.

I propose in this Address to say something of a profession to which my lifetime has been devoted—a theme which cannot perhaps be expected to stand as high in your estimation as in my own, and I may have some difficulty in making it interesting; but I have chosen it because it is a subject I ought to understand better than any other. I propose to say something on its origin, its work, and kindred topics.

Rapid as has been the growth of knowledge and skill as applied to the art of the engineer during the last century, we must, if we would trace its origin, seek far back among the earliest evidences of civilisation.

In early times, when settled communities were few and isolated, the opportunities for the interchange of knowledge were scanty or wanting altogether. Often the slowly accumulated results of the experience of the wisest heads and the most skilful hands of a community were lost on its downfall. Inventions of one period were lost and found again. Many a patient investigator has puzzled his brain in trying to solve a problem which had yielded to a more fortunate labourer in the same field some centuries before.

The ancient Egyptians had a knowledge of Metallurgy, much of which was lost during the years of decline which followed the golden age of their civilisation. The art of casting bronze over iron was known to the Assyrians, though it has only lately been introduced into modern metallurgy; and patents were granted in 1609 for processes connected with the manufacture of glass, which had been practised centuries before.[1] An inventor in the reign of Tiberius devised a method of producing flexible glass, but the manufactory of the artist was totally destroyed, we are told, in order to prevent the manufacture of copper, silver, and gold from becoming depreciated.[2]

Again and again engineers as well as others have made mistakes from not knowing what those had done who have gone before them, and have had the same difficulties to contend with. In the long discussion which took place as to the practicability of making the Suez Canal, an early objection was brought against it that there was a difference of $32\frac{1}{2}$ feet between the level of the Red Sea and that of the Mediterranean. Laplace at once declared that such could not be the case, for the mean level of the sea was the same on all parts of the globe. Centuries before the time of Laplace the same objection had been raised against a project for joining the waters of these two seas. According to the old Greek and Roman historians, it was a fear of flooding Egypt with the waters of the Red Sea that made Darius, and in later times again Ptolemy, hesitate to open the canal between Suez and the Nile.[3] Yet this canal was made, and was in use some centuries before the time of Darius.

Strabo[4] tells us that the same objection, that the adjoining seas were of different levels, was made by his engineers to Demetrius,[5] who wished to cut a canal through the Isthmus of Corinth some two thousand years ago. But Strabo[6] dismisses at once this idea of a difference of level, agreeing with Archimedes that the force of gravity spreads the sea equally over the earth.

When knowledge in its higher branches was confined to a few, those who possessed it were often called upon to perform many and various services for the communities to which they belonged; and we find mathematicians and astronomers, painters and sculptors, and priests called upon to perform the duties which now pertain to the profession of the architect and the engineer. And as soon as civilisation had advanced so far as to admit of the accumulation of wealth and power, then kings and rulers sought to add to their glory while living by the erection of magnificent dwelling-places, and to provide for their aggrandizement after death by the construction of costly tombs and temples. Accordingly we soon find men of ability and learning devoting a great part of their time to building and architecture, and the post of architect became one of honour and profit. In one of the most ancient quarries of Egypt a royal high architect of the dynasty of the Psammetici has left his pedigree sculptured on the rock, extending back for twenty-three generations, all of whom held the same post in succession in connection with considerable sacerdotal offices.[1]

As there were in these remote times officers whose duty it was to design and construct, so also there were those whose duty it was to maintain and repair the royal polaces and temples. In Assyria, 700 years before our era, as we know from a tablet found in the palace of Sennacherib by Mr. Smith, there was an officer whose title was the Master of Works. The tablet I allude to is inscribed with a petition to the king from an officer in charge of a palace, requesting that the master of works may be sent to attend to some repairs which were much needed at the time.[2]

Under the Roman Empire there was almost as great a division of labour in connection with building and design as now exists. The great works of that period were executed and maintained by an army of officers and workmen, who had special duties assigned to each of them.

Passing by those early attempts at design and construction which supplied the mere wants of the individual and the household, it is to the East that we must turn if we would find the earliest works which display a knowledge of engineering. Whether the knowledge of engineering, if we may so call it, possessed by the people of Chaldæa and Babylonia was of native growth or was borrowed from Egypt is, perhaps, a question which cannot yet be answered. Both people were agricultural, dwelling on fertile plains, intersected by great rivers, with a soil requiring water only to enable it to bring forth inexhaustible crops. Similar circumstances would create similar wants, and stimulate to action similar faculties to satisfy them. Apart from the question of priority of knowledge, we know that at a very early period, some four or five thousand years ago at least, there were men in Mesopotamia and Egypt who possessed considerable mechanical knowledge, and no little skill in hydraulic engineering. Of the men themselves we know little; happily, works often remain when the names of those who conceived and executed them have long been forgotten.

It has been said that architecture had its origin not only in nature, but in religion; and if we regard the earliest works which required mechanical knowledge and skill, the same may be said of engineering. The largest stones were chosen for sacred buildings, that they might be more enduring as well as more imposing, thereby calling for improvement and invention of mechanical contrivances, to assist in transporting and elevating them to the position they were to occupy; for the same reason the hardest and most costly materials were chosen, calling for further improvement in the metal forming the tools required to work them. The working of metals was further perfected in making images of the gods, and in adorning with the more precious and ornamental sorts the interior and even external parts of their shrines.

The earliest buildings of stone to which we can assign a date with any approach to accuracy, are the pyramids of Gizeh. To their builders they were sacred buildings, even more sacred than their temples or temple palaces. They were built to preserve the royal remains, until, after a lapse of 3,000 years, which we have reason to believe was the period assigned, the spirit which had once animated the body should re-enter it.[3] Although built 5,000 years ago, the masonry of the Pyramids could not be surpassed in these days; all those who have seen and examined them, as I myself have done, agree in this; moreover, the design is perfect for the purpose for which they were intended, above all to endure. The building of pyramids in Egypt continued for some ten centuries, and from 60 to 70 still remain, but none are so admirably constructed as those of Gizeh. Still, many contain enormous blocks of granite from 30 to 40 feet long, weighing more than 300 tons, and display the greatest ingenuity in the way in which the sepulchral chambers are constructed and concealed.[4]

The genius for dealing with large masses in building did not pass away with the pyramid builders in Egypt, but their descendants continued to gain in mechanical knowledge, judging from the enormous blocks which they handled with precision. When the command of human labour was unlimited, the mere transport of such blocks as the statue of Rameses the Great, for instance, which weighed over 800 tons, need not so greatly excite our wonder; and we know how such blocks were moved from place to place, for it is shown on the wall paintings of tombs of the period which still remain.

But as the weight of the mass to be moved is increased, it becomes no longer a question of only providing force in the shape of human bone and muscle. In moving in the last century the block which now forms the base for the statue of Peter the Great, at St. Petersburg, and which weighs 1,200 tons, force could be applied as much as was wanted, but great difficulty was experienced in supporting it, and the iron balls on which it was proposed to roll the block along were crushed, and a harder metal had to be substituted.[1] To facilitate the transport of material, the Egyptians made solid causeways of granite from the Nile to the Pyramids; and in the opinion of Herodotus, who saw them, the causeways were more wonderful works than the Pyramids themselves.[2]

The Egyptians have left no record of how they accomplished a far more difficult operation than the mere transport of weight—that is, how they erected obelisks weighing more than 400 tons. Some of these obelisks must have been lifted vertically to place them in position, as they were by Fontana in Rome in later times, when the knowledge of mechanics, we know, was far advanced.[3]

The practice of using large blocks of stone either as monoliths or as forming parts of structures has existed from the earliest times in all parts of the world.

The Peruvians used blocks weighing from 15 to 20 tons, and fitted them with the greatest nicety in their cleverly designed fortifications.[4]

In India large blocks were used in bridges when the repugnance of Indian builders to the use of the arch rendered them necessary, or in temples, where, as in the Temple of the Sun at Orissa, stones weighing from 20 to 30 tons form part of the pyramidal roof at a height of from 70 to 80 feet from the ground.[5] Even as late as the last century, Indians, without the aid of machinery, were using blocks of granite above 40 feet long for the doorposts of the gateway of Seringham, and roofing blocks of the same stone for a span of 21 feet.[6]

At Persepolis, in the striking remains of the palaces of Xerxes and Darius, more than one traveller has noted the great size of the stones, some of which are stated to be 55 feet long and 6 to 10 feet broad.

So in the Greek temples of Sicily, many of the blocks in the upper parts of the temples are from 10 to 20 tons weight.

The Romans, though they did not commonly use such large stones in their own constructions, carried off the largest obelisks from Egypt and erected them at Rome, where more are now to be found than remain in Egypt. In the temples of Baalbek, erected under Roman rule, perhaps the largest stones are to be found which have been used for building since the time of the Pharaohs. The terrace wall of one of the temples is composed of three courses of stones, none of which are less than 30 feet long; and one stone still lies in the quarry squared and ready for transport, which is 70 feet long and 14 feet square, and weighs upwards of 1,135 tons, or nearly as much as one of the tubes of the Britannia Bridge.

I have not mentioned dolmens and menhirs, rude unhewn stones often weighing from 30 or 40 tons, which are found from Ireland to India, and from Scandinavia to the Atlas, in Africa. To transport and erect such rude masses required little mechanical knowledge or skill, and the operation has excited more wonder than it deserves. Moreover, Fergusson has gone far to show that the date assigned to many of them hitherto has been far too remote; most, and possibly all, of those in northern and western Europe having been erected since the time of the Roman occupation. And to this day the same author shows that menhirs, single stones often weighing over 20 tons, are erected by hill tribes of India in close proximity to stone buildings of elaborate design and finished execution, erected by another race of men.[1]

For whatever purpose these vast stones were selected—whether to enhance the value or to prolong the endurance of the buildings of which they formed a part—the tax on the ingenuity of those who moved and placed them must have tended to advance the knowledge of mechanical appliances.

The ancient Assyrians and Egyptians had possibly more knowledge of mechanical appliances than they are generally credited with. In the wall paintings and sculptures which show their mode of transporting large blocks of stone, the lever is the only mechanical power represented, and which they appear to have used in such operations; nor ought we to expect to find any other used, for, where the supply of human labour was unlimited, the most expeditious mode of dragging a heavy weight along would be by human power; to have applied pulleys and capstans, such as would now be employed in similar undertakings, would have been mere waste of time. In some countries, even now, where manual labour is more plentiful than mechanical appliances, large numbers of men are employed to transport heavy weights, and do the work in less time than it could be done with all our modern mechanical appliances. In other operations, such as raising obelisks, or the large stones used in their temple palaces, where human labour could not be applied to such advantage, it is quite possible that the Egyptians used mechanical aids. On one of the carved slabs which formed part of the wall panelling of the palace of Sardanapalus, which was built about 930 years before our era, a single pulley is clearly shown, by which a man is in the act of raising a bucket—probably drawing water from a well.[2]

It has sometimes been questioned whether the Egyptians had a knowledge of steel. It seems unreasonable to deny them this knowledge. Iron was known at the earliest times of which we have any record. It is often mentioned in the Bible, and in Homer; it is shown in the early paintings on the walls of the tombs at Thebes, where butchers are represented as sharpening their knives on pieces of metal coloured blue, which were most probably pieces of steel.[3] Iron has been found in quantity in the ruined palaces of Assyria; and in the inscriptions of that country fetters are spoken of as having been made of iron, which is also so mentioned in connection with other metals as to lead to the supposition that it was regarded as a base and common metal. Moreover, in the Great Pyramid a piece of iron was found in a place where it must have lain for 5,000 years.[4] The tendency of iron to oxidize must render its preservation for any long period rare and exceptional. The quality of iron which is now made by the native races of Africa and India is that which is known as wrought iron; in ancient times, Dr. Percy says the iron which was made was always wrought iron. It is very nearly pure iron, and a very small addition of carbon would convert it into steel. Dr. Percy says the extraction of good malleable iron directly from the ore "requires a degree of skill very far inferior to that which is implied in the manufacture of bronze."[5] And there is no great secret in making steel; the natives of India now make excellent steel in the most primitive way, which they have practised from time immemorial. When steel is to be made, the proportion of charcoal used with a given quantity of ore is somewhat larger, and the blast is applied more slowly than when wrought iron is the metal required.[6] Thus, a vigorous native working the bellows of skin would make wrought iron where a lazy one would have made steel. The only apparatus required for the manufacture of the finest steel from iron ore is some clay for making a small furnace four feet high, and from one to two broad, some charcoal for fuel, and a skin with a bamboo tuyere for creating the blast.

The supply of iron in India as early as the fourth and fifth centuries seems to have been unlimited. The iron pillar of Delhi is a remarkable work for such an early period. It is a single piece of wrought iron 50 feet in length, and it weighs not less than 17 tons.[7] How the Indians forged this large mass of iron and other heavy pieces which their distrust of the arch led them to use in the construction of roofs, we do not know. In the

temples of Orissa iron was used in large masses as beams or girders in roof-work in the thirteenth century.[1]

The influence of the discovery of iron on the progress of art and science cannot be over-estimated. India well repaid any advantage which she may have derived from the early civilised communities of the West if she were the first to supply them with iron and steel.

An interesting social problem is afforded by a comparison of the relative conditions of India and this country at the present time. India, from thirty to forty centuries ago, was skilled in the manufacture of iron and cotton goods, which manufactures, in less than a century, have done so much for this country. It is true that in India coal is not so abundant or so universally distributed as in this country. Yet, if we look still further to the East, China had probably knowledge of the use of metals as soon as India, and moreover had a boundless store of iron and coal. Baron Richthofen, who has visited and described some of the coal-fields of China, believes that one province alone, that of Southern Shanshi, could supply the world at its present rate of consumption for several thousand years. The coal is near the surface, and iron abounds with it. Marco Polo tells us that coal was universally used as fuel in the parts of China which he visited towards the end of the fourteenth century, and from other sources we have reason to believe it was used there as fuel 2,000 years ago. But what progress has China made in the last ten centuries? A great future is undoubtedly in store for that country; but can the race who now dwell there develop its resources, or must they await the aid of an Aryan race? Or is anything more necessary than a change of institutions, which might come unexpectedly, as in Japan?

The art of extracting metals from the ore was practised at a very early date in this country. The existence long ago of tin mines in Cornwall, which are so often spoken of by classical writers, is well known to all. That iron was also extracted from the ore by the ancient Britons is most probable, as it was largely used for many purposes by them before the Roman conquest. The Romans worked iron extensively in the Weald of Kent, as we assume from the large heaps of slag containing Roman coins which still remain there. The Romans always availed themselves of the mineral wealth of the countries which they conquered, and their mining operations were often carried out on the largest scale, as in Spain, for instance, where as many as forty thousand miners were regularly employed in the mines at New Carthage.[2]

Coal, which was used for ordinary purposes in England as early as the ninth century, does not appear to have been largely used for iron smelting until the eighteenth century, though a patent was granted for smelting iron with coal in the year 1611.[3] The use of charcoal for that purpose was not given up until the beginning of this century, since which period an enormous increase in the mining and metallurgical industries has taken place; the quantity of coal raised in the United Kingdom in 1873 having amounted to 127 million tons, and the quantity of pig iron to upwards of $6\frac{1}{2}$ million tons.

The early building energy of the world was chiefly spent on the erection of tombs, temples, and palaces.

While, in Egypt, as we have seen, the art of building in stone had 5,000 years ago reached the greatest perfection, so in Mesopotamia the art of building with brick, the only available material in that country, was in an equally advanced state some ten centuries later. That buildings of such a material have lasted to this day shows how well the work was done; their ruinous condition even now is owing to their having served as quarries for the last three or four thousand years, so that the name of Nebuchadnezzar, apparently one of the greatest builders of ancient times, is as common on the bricks of many modern towns in Persia as it was in old times in Babylon. The labour required to construct the brick temples and palaces of Chaldæa and Assyria must have been enormous. The mound of Koyunjik alone contained $14\frac{1}{2}$ million tons, and represents the labour of 10,000 men for twelve years. The palace of Sennacherib, which stood on this mound, was probably the largest ever built by any one monarch, containing as it did more than two miles of walls, panelled with sculptured alabaster slabs, and twenty-seven portals, formed by colossal bulls and sphinxes.[4]

The pyramidal temples of Chaldæa are not less remarkable for the labour bestowed on them, and far surpass the buildings of Assyria in the excellence of their brickwork.

The practice of building great pyramidal temples seems to have passed eastwards to India and Burmah, where it appears in buildings of a later date, in Buddhist topes and pagodas; marvels of skill in masonry, and far surpassing the old brick mounds of Chaldæa in richness of design and in workmanship. Even so late as this century a king of Burmah began to build a brick temple of the old type, the largest building, according to Fergusson, which has been attempted since the Pyramids.[1]

The mere magnitude of many of these works is not so wonderful when we take into account the abundance of labour which those rulers could command. Countries were depopulated, and their inhabitants carried off and made to labour for the conquerors. The inscriptions of Assyria describe minutely the spoils of war and the number of captives; and in Egypt we have frequent mention made of works being executed by the labour of captive peoples. Herodotus tells us that as many as 360,000 men were employed in building one palace for Sennacherib.[2] At the same time it must not be forgotten that the very character of the multitude would demand from some one the skill and brain to organise and direct, to design and plan the work.

It would be surprising if men who were capable of undertaking and successfully completing unproductive works of such magnitude did not also employ their powers on works of a more useful class. Traces still remain of such works; enough to show, when compared with the scanty records of the times which have come down to us, that the prosperity of such countries as Egypt and Mesopotamia was not wholly dependent on war and conquest, but that the reverse was more likely the case, and that the natural capabilities of those countries were greatly enlarged by the construction of useful works of such magnitude as to equal, if not in some cases surpass, those of modern times.

Egypt was probably far better irrigated in the days of the Pharaohs than it is now. To those unacquainted with the difficulties which must be met with and overcome before a successful system of irrigation can be carried out, even in countries in which the physical conditions are favourable, it may appear that nothing more is required than an adequate supply of unskilled labour. Far more than this was required: the Egyptians had some knowledge of surveying, for Eustathius says they recorded their marches on maps;[3] but such knowledge was probably in those days very limited, and it required no ordinary grasp of mind to see the utility of such extensive works as were carried out in Egypt and Mesopotamia, and, having seen the utility, to successfully design and execute them. To cite one in Egypt—Lake Mœris, of which the remains have been explored by M. Linant, was a reservoir made by one of the Pharaohs, and supplied by the flood waters of the Nile. It was 150 square miles in extent, and was retained by a bank or dam 60 yards wide and 10 high, which can be traced for a distance of thirteen miles. This reservoir was capable of irrigating 1,200 square miles of country.[4] No work of this class has been undertaken on so vast a scale since, even in these days of great works.

The prosperity of Egypt was in so great a measure dependent on its great river, that we should expect that the Egyptians, a people so advanced in art and science, would at an early period have made themselves acquainted with its *régime*. We know that they carefully registered the height of the annual rise of its waters; such registers still remain inscribed on the rocks on the banks of the Nile, with the name of the king in whose reign they were made.[5] The people of Mesopotamia were equally observant of the *régime* of their great rivers, and took advantage in designing their canals of the different periods in the rising of the waters of the Tigris and Euphrates. A special officer was appointed in Babylon, whose duty it was to measure the rise of the river; and he is mentioned in an inscription found in the ruins of that city, as recording the height of the water in the temple of Bel.[6] The Assyrians, who had a far more difficult country to deal with, owing to its rocky and uneven surface, showed even greater skill than the Babylonians in forming their canals, tunnelling through rock, and building dams of masonry across the Euphrates. While the greater number of these canals in Egypt and Mesopotamia were made for the purpose of irrigation, others seem to have been made to serve at the same time

for navigation. Such was the canal which effected a junction between the Mediterranean and the Red Sea, which was a remarkable work, having regard to the requirements of the age in which it was made. Its length was about eighty miles; its width admitted of two triremes passing one another.[1] At least one of the navigable canals of Babylonia, attributed to Nebuchadnezzar, can compare in extent with any work of later times. I believe Sir H. Rawlinson has traced the canal to which I allude throughout the greater part of its course, from Hit on the Euphrates to the Persian Gulf, a distance of between four and five hundred miles.[2] It is a proof of the estimation in which such works were held in Babylonia and Assyria, that, among the titles of the god Vul were those of "Lord of Canals," and "The Establisher of Irrigation Works."[3]

The springs of knowledge which had flowed so long in Babylonia and Assyria were dried up at an early period. With the fall of Babylon and destruction of Nineveh the settled population of the fertile plains around them disappeared, and that which was desert before man led the waters over it became desert again, affording a wide field for, and one well worthy of, the labours of engineers to come.

Such was not the case with Egypt. Long after the period of its greatest prosperity was reached, it remained the fountain head from whence knowledge flowed to Greece and Rome. The philosophers of Greece and those who, like Archimedes, were possessed of the best mechanical knowledge of the time, repaired to Egypt to study and obtain the foundation of their knowledge from thence.

Much as Greece and Rome were indebted to Egypt, it will probably be found, as the inscribed tablets met with in the mounds of Assyria and Chaldæa are deciphered, that the later civilisations owe, if not more, at least as much, to those countries as to Egypt. This is the opinion of Mr. Smith, who, in his work describing his recent interesting discoveries in the East, says that the classical nations "borrowed far more from the valley of the Euphrates than that of the Nile."[4]

In the science of astronomy, which in these days is making such marvellous discoveries, Chaldæa was undoubtedly preeminent. Among the many relics of these ancient peoples which Mr. Smith has recently brought to this country is a portion of a metal astrolabe from the palace of Sennacherib, and a tablet on which is recorded the division of the heavens according to the four seasons, and the rule for regulating the intercalary month of the year. Not only did the Chaldæans map out the heavens and arrange the stars, but they traced the motion of the planets, and observed the appearance of comets; they fixed the signs of the zodiac, and they studied the sun and moon and the periods of eclipses.[5]

But to return to that branch of knowledge to which I wish more particularly to draw your attention, as it grew and spread from east to west, from Asia over Europe. Of all nations of Europe the Greeks were most intimately connected with the civilisation of the East. A maritime people by the nature of the land they lived in, colonisation followed as a matter of course on the tracks of their trading vessels; and thus, more than any other people, they helped to spread Eastern knowledge along the shores of the Mediterranean, and throughout the south of Europe.

The early constructive works of Greece, till about the seventh century B.C., form a strong contrast to those of its more prosperous days. Commonly called Pelasgian, they are more remarkable as engineering works than admirable as those which followed them were for architectural beauty. Walls of huge unshapely stones—admirably fitted together, however—tunnels, and bridges, characterise this period. In Greece, during the few and glorious centuries which followed, the one aim in all construction was to please the eye, to gratify the sense of beauty; and in no age was that aim more thoroughly and satisfactorily attained.

In these days, when sanitary questions attract each year more attention, we may call to mind that twenty-three centuries ago the city of Agrigentum possessed a system of sewers, which, on account of their large size, were thought worthy of mention by Diodorus.[6] This is not, however, the first record of towns being drained; the well-known Cloaca Maxima, which formed part of the drainage system of Rome, was built some two centuries earlier, and great vaulted drains passed beneath the palace mounds of unburnt brick at Nimroud and Babylon; and possibly we owe the preservation of many of the interesting remains found in the brick mounds of Chaldæa to the very elaborate system of pipe drainage discovered in them, and described by Loftus.[1]

Whilst Pelasgian art was being superseded in Greece, the city of Rome was founded in the eighth century before our era; and Etruscan art in Italy, like the Pelasgian art in Greece, was slowly merged in that of an Aryan race. The Etrùscans, like the Pelasgians and the old Egyptians, were Turanians, and remarkable for their purely constructive or engineering works. Their city walls far surpass those of any other ancient race, and their drainage works and tunnels are most remarkable.

The only age which can compare with the present one in the rapid extension of utilitarian works over the face of the civilised world, is that during which the Romans, an Aryan race, as we are, were in power. As Fergusson has said, the mission of the Aryan races appears to be to pervade the world with useful and industrial arts. That the Romans adorned their bridges, their aqueducts, and their roads; that with a sound knowledge of construction they frequently made it subservient to decoration, was partly owing to the mixture of Etruscan or Turanian blood in their veins, and partly to their great wealth, which made them disregard cost in their construction, and to their love of display.

It would be impossible for me to do justice to even a small part of the engineering works which have survived fourteen centuries of strife, and remain to this day as monuments of the skill, the energy, and ability of the great Roman people. Fortunately, their works are more accessible than those of which I have spoken hitherto, and many of you are probably already familiar with them.

Conquerors of the greater part of the civilised world, the admirable organisation of the Romans enabled them to make good use of the unbounded resources which were at their disposal. Yet, while the capital was enriched, the development of the resources of the most distant provinces of the empire was never neglected.

War, with all its attendant evils, has often indirectly benefited mankind. In the long sieges which took place during the old wars of Greece and Rome, the inventive power of man was taxed to the utmost to provide machines for attack and defence. The ablest mathematicians and philosophers were pressed into the service, and helped to turn the scale in favour of their employers. The world has to regret the loss of more than one, who, like Archimedes, fell slain by the soldiery while applying the best scientific knowledge of the day to devising means of defence during the siege.[2] In these days, too, science owes much to the labours of engineers and able men, whose time is spent in making and improving guns, the materials composing them, and armour plates to resist them, or in studying the motion of ships of war in a seaway.

The necessity for roads and bridges for military purposes has led to their being made where the necessary stimulus from other causes was wanting; and so means of communication, and the interchange of commodities, so essential to the prosperity of any community, have thus been provided. Such was the case under the Roman Empire. So, too, in later times the ambition of Napoleon covered France and the countries subject to her with an admirable system of military roads. At the same time, we must do Napoleon the justice of saying that his genius and foresight gave a great impetus to the construction of all works favourable to commercial progress. So, again, in this country it was the rebellion of 1745, and the want felt of roads for military purposes, which first led to the construction of a system of roads in it unequalled since the time of the Roman occupation. And lastly, in India, in Germany, and in Russia, more than one example could be pointed out where industry will benefit by railways which have originated in military precautions rather than in commercial requirements.

But to return to Rome. Roads followed the tracks of her legions into the most distant provinces of the empire. Three hundred and seventy-two great roads are enumerated, together more than 48,000 miles in length, according to the itinerary of Antoninus.

The water supply of Rome during the first century of our era would suffice for a population of seven millions, supplied at the rate at which the present population of London is supplied. This water was conveyed to Rome by nine aqueducts; and in

later years the supply was increased by the construction of five more aqueducts. Three of the old aqueducts have sufficed to supply the wants of the city in modern times. These aqueducts of Rome are to be numbered among her grandest engineering works.[1] Time will not admit of my saying anything about her harbour works and bridges, her basilicas and baths, and numerous other works in Europe, in Asia, and in Africa. Not only were these works executed in a substantial and perfect manner, but they were maintained by an efficient staff of men divided into bodies, each having their special duties to perform. The highest officers of state superintended the construction of works, were proud to have their names associated with them, and constructed extensive works at their own expense.

Progress in Europe stopped with the fall of the Roman Empire. In the fourth and succeeding centuries the barbarian hordes of Western Asia, people who felt no want of roads and bridges, swept over Europe to plunder and destroy.

With the seventh century began the rise of the Mohammedan power, and a partial return to conditions apparently more favourable to the progress of industrial art, when widespread lands were again united under the sway of powerful rulers.[2] Science owes much to Arab scholars, who kept and handed on to us the knowledge acquired so slowly in ancient times, and much of which would have been lost but for them. Still, few useful works remain to mark the supremacy of the Mohammedan power at all comparable to those of the age which preceded its rise.

A great building age began in Europe in the tenth century, and lasted through the thirteenth. It was during this period that these great ecclesiastical buildings were erected, which are not more remarkable for artistic excellence than for boldness in design.

While the building of cathedrals progressed on all sides in Europe, works of a utilitarian character, which concern the engineer, did not receive such encouragement, excepting perhaps in Italy.

From the twelfth to the thirteenth centuries, with the revival of the arts and sciences in the Italian republics, many important works were undertaken for the improvement of the rivers and harbours of Italy. In 1481 canal locks were first used; and some of the earliest of which we have record were erected by Leonardo da Vinci, who would be remembered as a skilful engineer had he not left other greater and more attractive works to claim the homage of posterity.

The great use that has since been made of this simple means of transferring floating vessels from one water level to another, in connection not only with inland navigation, but in all the great ports and harbours of the world, renders it all the more deserving of remark.

In India, under the Moguls, irrigation works, for which they had a natural aptitude, were carried on during these centuries with vigour, and more than one emperor is noted for the numerous great works of this nature which he carried out. If the native records can be trusted, the number of hydraulic works undertaken by some rulers is surprising. Tradition relates that one king who reigned in Orissa in the twelfth century made one million tanks or reservoirs, besides building sixty temples, and erecting numerous other works.[3]

In India, the frequent overflow of the great rivers, and the periodical droughts, which rendered irrigation necessary, led to extensive protective works being undertaken at an early period; but as these works have been maintained by successive rulers, Mogul and Mohammedan, until recent times, and have not been left for our inspection, deserted and useless for 3,000 years or more, as is often the case in Egypt and Mesopotamia, there is more difficulty in ascertaining the date of such works in India.

Works of irrigation were among the earliest attempts at engineering undertaken by the least civilised inhabitants in all parts of the world. Even in Australia, where savages are found as low as any in the scale of civilisation, traces of irrigation works have been found; these works, however, must be taken to show that the natives were once somewhat more civilised than we now find them. In Feejee, our new possession, the natives occasionally irrigate their land,[4] and have executed a work of a higher class, a canal some two miles long and sixty feet wide, to shorten the distance passed over by their canoes.[1] The natives of New Caledonia irrigate their fields with great skill.[2] In Peru, the Incas excelled in irrigation as in other great and useful works, and constructed most admirable underground conduits of masonry for the purpose of increasing the fertility of the land.[3]

It is frequently easier to lead water where it is wanted than to check its irruption into places where its presence is an evil, often a disaster. For centuries the existence of a large part of Holland has been dependent on the skill of man. How soon he began in that country to contest with the sea the possession of the land we do not know, but early in the twelfth century dykes were constructed to keep back the ocean. As the prosperity of the country increased with the great extension of its commerce, and land became more valuable and necessary for an increasing population, very extensive works were undertaken. Land was reclaimed from the sea, canals were cut, and machines were designed for lifting water. To the practical knowledge acquired by the Dutch, whose method of carrying out hydraulic works is original and of native growth, much of the knowledge of the present day in embanking, and draining, and canal making is due. The North Holland Canal[4] was the largest navigable canal in existence until the Suez Canal was completed; and the Dutch have just now nearly finished making a sea canal from Amsterdam to the North Sea, which, though not equal to the Suez Canal in length, will be as great in width and depth, and involves perhaps larger and more important works of art. This country was for many years beholden to the Dutch for help in carrying out hydraulic works. In the seventeenth century much fen land in the eastern counties was drained by Dutch labour, directed by Dutch engineers, among whom Sir Cornelius Vermuyden, an old campaigner of the Thirty Years' War, and a colonel of horse under Cromwell, is the most noted.

While the Dutch were acquiring practical knowledge in dealing with water, and we in Britain among others were benefiting by their experience, the disastrous results which ensued from the inundations caused by the Italian rivers of the Alps gave a new importance to the science of hydraulics. Some of the greatest philosophers of the seventeenth century—among them Torricelli, a pupil of Galileo,[5]—were called upon to advise and to superintend engineering works; nor did they confine themselves to the construction of preventive works, but thoroughly investigated the condition pertaining to fluids at rest or in motion, and gave to the world a valuable series of works on hydraulics and hydraulic engineering, which form the basis of our knowledge of these subjects at the present day.

Some of the best scientific works (prior to the nineteenth century) on engineering subjects we owe to Italian and French writers. The writings of Belidor, an officer of artillery in France in the seventeenth century, who did not, however, confine himself to military subjects, drew attention to engineering questions. Not long after their appearance, the Ponts et Chaussées[6] were established, which has maintained ever since a body of able men specially educated for, and devoted to, the prosecution of industrial works.

The impulse given to road-making in the early part of the last century soon extended to canals and means for facilitating locomotion and transport generally. Tramways were used in connection with mines at least as early as the middle of the seventeenth century, but the rails were, in those days, of wood. The first iron rails are said to have been laid in this country as early as 1738; after which time their use was gradually extended, until it became general in mining districts.

By the beginning of this century the great ports of England were connected by a system of canals; and new harbour works became necessary, and were provided to accommodate the increase of commerce and trade, which improved means of internal transport had rendered possible. It was in the construction of these works that our own Brindley and Smeaton, Telford and Rennie, and other engineers of their time, did so much.

But it was not until the steam-engine, improved and almost created by the illustrious Watt, became such a potent instrument, that engineering works to the extent they have since been carried out became possible or necessary. It gave mankind no

new faculty, but it at once set his other faculties on an eminence, from which the extent of his future operations became almost unlimited.

Water-mills, wind-mills, and horse-machines were in most cases superseded. Deep mines, before only accessible by adits and water levels, could at once be reached with ease and economy. Lakes and fens which, but for the steam-engine, would have been left untouched, were drained and cultivated.

The slow and laborious toil of hands and fingers, bone and sinew, was turned to other employments, where, aided by ingenious mechanical contrivances, the produce of one pair of hands was multiplied a thousand-fold, and their cunning extended until results marvellous, if you consider them, were attained. Since the time of Watt the steam-engine has exerted a power, made conquests, and increased and multiplied the material interests of this globe to an extent which it is scarcely possible to realise.

But while Watt has gained a world-wide, well-earned fame, the names of those men who have provided the machines to utilise the energies of the steam-engine are too often forgotten. Of their inventions the majority of mankind know little. They worked silently at home, in the mill, or in the factory, observed by few. Indeed, in most cases these silent workers had no wish to expose their work to public gaze. Were it not so, the factory and the mill are not places where people go to take the air. How long in the silent night the inventors of these machines sat and pondered; how often they had to cast aside some long-sought mechanical movement and seek another and a better arrangement of parts, none but themselves could ever know. They were unseen workers, who succeeded by rare genius, long patience, and indomitable perseverance.

More ingenuity and creative mechanical genius is perhaps displayed in machines used for the manufacture of textile fabrics than by those used in any other industry. It was not until late in historical times that the manufacture of such fabrics became established on a large scale in Europe. Although in China man was clothed in silk long ago, and although Confucius, in a work written 2,300 years ago, orders with the greatest minuteness the rules to be observed in the production and manufacture of silk, yet it was worth nearly its weight in gold in Europe in the time of Aurelian, whose empress had to forego the luxury of a silk gown on account of its cost?[1] Through Constantinople and Italy the manufacture passed slowly westwards, and was not established in France until the sixteenth century, and arrived at a still later period in this country. It is related that James V. had to borrow a pair of silk hose from the Earl of Mar, in order that he might not, as he expressed it, appear as a scrub before strangers.

So cotton, of which the manufacture in India dates from before historical times, had scarcely by the Christian era reached Persia and Egypt. Spain in the tenth and Italy in the fourteenth century manufactured it, but Manchester, which is now the great metropolis of the trade, not until the latter half of the seventeenth century.

Linen was worn by the old Egyptians, and some of their linen mummy cloths surpass in fineness any linen fabrics made in later days.[2] The Babylonians wore linen also and wool, and obtained a widespread fame for skill in workmanship and beauty in design.

In this country wool once formed the staple for clothing. Silk was the first rival, but its costliness placed it beyond the reach of the many. To introduce a new material or improved machine into this or other countries a century or more ago was no light undertaking. Inventors, and would-be benefactors alike, ran the risk of loss of life. Loud was the outcry made in the early part of the eighteenth century against the introduction of Indian cottons and Dutch calicoes.

Until 1738, in which year the improvements in spinning machinery were begun, each thread of worsted or cotton wool had been spun between the fingers in this and all other countries. Wyatt, in 1738, invented spinning by rollers instead of fingers, and his invention was further improved by Arkwright. In 1770 Hargreaves patented the spinning jenny, and Crompton the mule in 1775, a machine which combined the advantages of the frames of both Hargreaves and Arkwright. In less than a century after the first invention by Wyatt, double mules were working in Manchester with over 2,000 spindles. Improvements in machines for weaving were begun at an earlier date. In 1579 a ribbon loom is said to have been invented at Dantzic, by which from four to

[1] Manufacture of silk brought from China to Constantinople A.D. 522.

[2] Wilkinson's "Ancient Egyptians;" Pliny, bk. xix. c. ii.

six pieces could be woven at one time, but the machine was destroyed and the inventor lost his life.[1] In 1800 Jacquard's most ingenious invention was brought into use, which, by a simple mechanical operation, determines the movements of the threads which form the pattern in weaving. But the greatest discovery in the art of weaving was wrought by Cartwright's discovery of the power loom, which led eventually to the substitution of steam for manual labour, and enabled a boy with a steam loom to do fifteen times the work of a man with a hand loom.

For complex ingenuity few machines will compare with those used in the manufacture of lace and bobbin net. Hammond, in 1768, attempted to adapt the stocking frame to this manufacture, which had hitherto been conducted by hand. It remained for John Heathcoat to complete the adaptation in 1809, and to revolutionise this branch of industry, reducing the cost of its produce to one-fortieth of what the cost had been before Heathcoat's improvements were effected.

Most of these ingenious machines were in use before Watt's genius gave the world a new motive power in the steam-engine; and, had the steam-engine never been perfected, they would still have enormously increased the productive power of mankind. Water power was applied to many of them; in the first silk-thread mill erected at Derby in 1738, 318 million yards of silk thread were spun daily with one water-wheel.

These are happier times for inventors: keen competition among manufacturers does not let a good invention lie idle now. That which was rejected by old machines as waste is now worked up into useful fabrics by new ones. From all parts of the world new products come—jute from India, flax from New Zealand, and many others which demand new adaptations of old machines or new and untried mechanical arrangements to utilise them. Time would fail me if I were to attempt to enumerate one tithe of these rare combinations of mechanical skill; and, indeed, no one will ever appreciate the labour and supreme mental effort required for their construction who has not himself seen them and their wondrous achievements.

Steamboats, the electric telegraph, and railways, are more within the cognisance of the world at large, and the progress that has been made in them in little more than one generation is better known and appreciated.

It is not more than forty years since one of our scientific men, and an able one too, declared at a meeting of this Association that no steamboat would ever cross the Atlantic; founding his statement on the impracticability, in his view, of a steamboat carrying sufficient coal, profitably, I presume, for the voyage. Yet, soon after this statement was made, the *Sirius* steamed from Bristol to New York in seventeen days,[2] and was soon followed by the *Great Western*, which made the homeward pasage in thirteen-and-a-half days; and with these voyages the era of steamboats began. Like most important inventions, that of the steamboat was a long time in assuming a form capable of being profitably utilised; and even when it had assumed such a form, the objections of commercial and scientific men had still to be overcome.

Among the many names connected with the early progress in the construction of steamboats, perhaps none is more worthy of remembrance than that of Patrick Miller, who, with the assistance of Symington, an engineer, and Taylor, who, was his children's tutor, constructed a small steamboat. Shortly afterwards Lord Dundas, who saw the value of the application of steam for the propulsion of boats, had the first really practical steamboat constructed with a view to using it on the Forth and Clyde Canal. The proprietors, however, objected, and the boat lay idle. Again another attempt to make practical use of the steamboat failed through the death of the Duke of Bridgewater, who, with his characteristic foresight, had seen the value of steam as a motive power for boats, and had determined to introduce steamboats on the canal which bears his name.

The increase in the number of steamboats since the time when the *Sirius* first crossed the Atlantic has been very great. Whereas in 1814 the United Kingdom only possessed two steam vessels, of together 456 tons burden, in 1872 there were on the register of the United Kingdom 3,662 steam vessels, of which the registered tonnage amounted to over a million and a half of tons,[3] or to nearly half the whole steam tonnage of the world, which did not at that time greatly exceed three million tons.

As the number of steamboats has largely increased, so also

[1] Beckman's "History of Inventions," vol. ii. p. 528.

[2] First steamer crossed the Atlantic by steam alone in 1838.

[3] Board of Trade Return, 15th of July, 1874, Table 8.

gradually has their size increased until it culminated in the hands of Brunel in the *Great Eastern*.

A triumph of engineering skill in ship-building, the *Great Eastern* has not been commercially so successful. In this, as in many other engineering problems, the question is not how large a thing can be made, but how large, having regard to other circumstances, it is proper at the time to make it.

If, as regards the dimensions of steamboats, we have at present somewhat overstepped the limits in the *Great Eastern*, much still remains to be done in perfecting the form of vessels, whether propelled by steam or driven by the force of the wind. A distinguished member of this Association, Mr. Froude, has now for some years devoted himself to investigations carried on with a view to ascertain the form of vessel which will offer the least resistance to the water through which it must pass. So many of us in these days are called upon to make journeys by sea as well as by land, that we can well appreciate the value of Mr. Froude's labours, so far as they tend to curtail the time which we must spend on our ocean journeys; and we should all feel grateful to him if from another branch of his investigations, which relates to the rolling of ships, it should result that the movement in passenger vessels could be reduced. A gallant attempt in this direction has lately been made by Mr. Bessemer; whether a successful one yet remains to be proved. In any event, he and those who have acted with him deserve our praise for an experiment which must add to our knowledge.

It is a question of vital importance to the steamboat that the consumption of fuel should be reduced to the smallest possible amount, inasmuch as each ton of fuel excludes a ton of cargo.

As improvements in the form of the hull are effected, less power—that is, less fuel—will be required to propel the vessel through the water for a given distance. Great as have been the improvements effected in marine engines to this end, much still remains to be done. Wolf's compound engine, so long overlooked, is, with some improvements, being at last applied. Whereas the consumption of fuel in such vessels as the *Himalaya* used to be from 5 to 6 lbs. of fuel per effective horse-power, it has been reduced, by working steam more expansively in vessels of a later date, to 2 lbs. Yet, comparing this with the total amount of energy of 2 lbs. of coal, it will be found that not a tenth part of the power is obtained which that amount of coal would theoretically call into action.[1]

We live in an age when great discoveries are made, and when they are speedily taken advantage of if they are likely to be of service to mankind.

In former times man's inventions were frequently in advance of the age, and they were laid aside to await a happier era. There were in those earlier days too few persons who cared to, or who could, avail themselves of the proffered boon, and there was no sufficient accumulation of wealth to justify its being appropriated to schemes which are always in their early stage more or less speculative.

There is no more remarkable instance of the rapid utilisation of what was in the first instance regarded by most men as a mere scientific idea, than the adoption and extension of the electric telegraph.

Those who read Odier's letter written in 1773, in which he made known his idea of a telegraph which would enable the inhabitants of Europe to converse with the Emperor of Mogul, little thought that in less than a century a conversation between persons at points so far distant would be possible. Still less did those who saw in the following year messages sent from one room to another by Lesage in the presence of Friedrich of Prussia, realise that they had before them the germ of one of the most extraordinary inventions among the many that will render this century famous.

I should weary you were I to follow the slow steps by which the electric telegraph of to-day was brought to its present state of efficiency. In the present century few years have passed without new workers appearing in the field; some whose object was to utilise the new-found power for the benefit of mankind, others—and their work was not the least important in the end—whose object was to investigate magnetism and electrical phenomena as presenting scientific problems still unsolved. Galvani, Volta, Oersted, Arago, Sturgeon, and Faraday, by their labours, helped to make known the elements which rendered it possible to construct the electric telegraph. With the battery, the electric coil, and the electro-magnet, the elements were complete, and it only remained for Sir Charles Wheatstone and others to combine them in a useful and practically valuable form. The inventions of Alexander, Steinheil, and those of similar nature to that of Sir Charles Wheatstone, were made known at a later date in the same year, which will ever be memorable in the annals of telegraphy.[1]

The first useful telegraph was constructed upon the Blackwall Railway in 1838, Messrs. Wheatstone's and Cooke's instruments being employed. From that time to this the progress of the electric telegraph has been so rapid, that at the present time, including land lines and submarine cables, there are in use in different parts of the world not less than 400,000 miles of telegraph.

Among the numerous inventions of late years, the automatic telegraph of Mr. Alexander Bain, of Dr. Werner Siemens, and of Sir Charles Wheatstone, are especially worthy of notice. Mr. Bain's machine is chiefly used in the United States, that of Dr. Werner Siemens in Germany. In this country the machine invented by Sir Charles Wheatstone, to whom telegraphy owes so much, is chiefly employed. By his machine, after the message has been punched out in a paper ribbon by one machine on a system analogous to the dot and dash of Morse, the sequence of the currents requisite to transmit the message along the wire is automatically determined in a second machine by this perforated ribbon. This second operation is analogous to that by which in Jacquard's loom the motions of the threads requisite to produce the pattern is determined by perforated cards. By Wheatstone's machine errors inseparable from manual labour are avoided; and what is of even more importance in a commercial point of view, the time during which the wire is occupied in the transmission of a message is considerably diminished.

By the application of these automatic systems to telegraphy, the speed of transmission has been wonderfully accelerated, being equal to 200 words a minute, that is, faster than a shorthand writer can transcribe; and, in fact, words can now be passed along the wires of land lines with a velocity greater than can be dealt with by the human agency at either end.

Owing partly to the retarding effects of induction and other causes, the speed of transmission by long submarine cables is much smaller. With the cable of 1858 only 2½ words per minute were got through. The average with the Atlantic cable, Dr. C. W. Siemens informs me, is now seventeen words, but twenty-four words per minute can be read.

One of the most striking phenomena in telegraphy is that known as the duplex system, which enables messages to be sent from each end of the same wire at the same time. This simultaneous transmission from both ends of a wire was proposed in the early days of telegraphy, but, owing to imperfect insulation, was not then found to be practicable; but since then telegraphic wires have been better insulated, and the system is now becoming of great utility, as it nearly doubles the capacity for work of every wire.

And yet within how short a period of time has all the wonderful progress in telegraphy been achieved! How incredulous the world a few years ago would have been if then told of the marvels which in so short a space of time were to be accomplished by its agency!

It is not long ago—1823—that Mr. (now Sir Francis) Ronald, one of the early pioneers in this field of science, published a description of an electric telegraph. He communicated his views to Lord Melville, and that nobleman was obliging enough to reply that the subject should be inquired into; but before the nature of Sir Francis Ronald's suggestions could be known,

[1] Theoretical Energy of 1 lb of Coal:—

The proportions of heat expended in generating saturated steam at 212° Fahr., and at 14·7 lbs. pressure per square inch, from water at 212° are:—

	Units of heat.	Mechanical equivalent in foot lbs.
I. In the formation of steam	892·8	689,242
II. In resisting the incumbent pressure of 14·7 lbs. per square inch ...	72·3	55,815
	965.1	745,057

One pound of Welsh coal will theoretically evaporate 15 lbs. of water at 212° to steam at 212°. Therefore, the full theoretical value of the combustion of 2 lbs. of Welsh coal is—

$$2 \times 15 \times 745{,}057 \text{ foot pounds,}$$

or,

$$\frac{2 \times 15 \times 745{,}057}{60 \times 33{,}000} \text{ horse-power, if consumed in 1 hour.}$$

$$= 11 \cdot 2 \text{ horse-power.}$$

As the consumption of coal per effective horse-power in a marine engine is 2 lbs., the power obtained is to the whole theoretical power as 1 is to 11.

[1] Dates of patents: Wheatstone, March 1, 1837; Alexander, April 22, 1837; Steinheil, July 1, 1837: Morse, October 1837.

except to a few, that gentleman received a reply from Mr. Barrow, "that telegraphs of any kind were then wholly unnecessary, and that no other than the one then in use would be adopted;" the one then in use being the old semaphore, which, crowning the tops of hills between London and Portsmouth, seemed perfection to the Admiralty of that day.

I am acquainted with some who, when the first Transatlantic cable was proposed, contributed towards that undertaking with the consciousness that it was only an experiment, and that subscribing to it was much the same thing as throwing their money into the sea. Much of this cable was lost in the first attempt to lay it; but its promoters, nothing daunted, made 900 miles more cable, and finally laid it successfully in the following year, 1858.

The telegraphic system of the world comprises almost a complete girdle round the earth; and it is probable that the missing link will be supplied by a cable between San Francisco in California and Yokohama in Japan.

How resolute and courageous those who engaged in submarine telegraphy have been will appear from the fact that, though we have now 50,000 miles of cable in use, to get at this result nearly 70,000 miles were constructed and laid. This large percentage of failure, in the opinion of Dr. C. W. Siemens (to whom I am much indebted for information on this subject), was partly due to the late introduction of testing a cable under water before it is laid, and to the use of too light iron sheathing.

Of immense importance in connection with the subsequent extension of submarine cables have been the discoveries of Ohm and Sir William Thomson, and the knowledge obtained that the resistance in wire of homogeneous metal is directly proportional to the length, so that the place of a fault in a cable of many thousand miles in length can be ascertained with so much precision as to enable you to go at once to repair it, although the damaged cable may lie in some thousands of fathoms of water.

Of railways the progress has been enormous, but I do not know that in a scientific point of view a railway is so marvellous in its character as the electric telegraph. The results, however, of the construction and use of railways are more extensive and widespread, and their utility and convenience brought home to a larger portion of mankind. It has come to pass, therefore, that the name of George Stephenson has been placed second only to that of James Watt; and as men are and will be estimated by the advantages which their labours confer on mankind, he will remain in that niche, unless indeed some greater luminary should arise to outshine him. The merit of George Stephenson consisted, among other things, in this, that he saw more clearly than any other engineer of his time the sort of thing that the world wanted, and that he persevered in despite of learned objectors with the firm conviction that he was right and they were wrong, and that there was within himself the power to demonstrate the accuracy of his convictions.

Railways are a subject on which I may (I hope without tiring you) speak somewhat more at length. The British Association is peripatetic, and without railways its meetings, if held at all, would, I fear, be greatly reduced in numbers. Moreover, you have all an interest in them: you all demand to be carried safely, and you insist on being carried fast. Besides, everybody understands, or thinks he understands, a railway, and therefore I shall be speaking on a subject common to all of us, and shall possibly only put before you ideas which others as well as myself have already entertained.

We who live in these days of roads and railways, and can move with a fair degree of comfort, speed, and safety, almost where we will, can scarcely realise the state of England two centuries ago, when the years of opposition which preceded the era of coaches began; when, as in 1662, there were but six stages in all England, and John Crossdell, of the Charterhouse, thought there were six too many; when Sir Henry Herbert, a member of the House of Commons, could say, "If a man were to propose to carry us regularly to Edinburgh in coaches in seven days, and bring us back in seven more, should we not vote him to Bedlam?"

In spite of short-sighted opposition, coaches made their way; but it was not till a century later, in 1784—and then I believe it was in this city of Bristol—that coaches were first established for the conveyance of mails. Those here who have experienced, as I have, what the discomforts were of long journeys inside the old coaches, will agree with me that they were very great; and I believe, if returns could be obtained of the accidents which happened to coaches, it would be found that many more people were injured and killed in proportion to the number that travelled by that mode than by the railways of to-day.

No sooner had our ancestors settled down with what comfort was possible in their coaches, well satisfied that twelve miles an hour was the maximum speed to be obtained or that was desirable, than they were told that steam conveyance on iron railways would supersede their "present pitiful" methods of conveyance. Such was the opinion of Thomas Gray, the first promoter of railways, who published his work on a general iron railway in 1819. Gray was looked on as little better than a madman. "When Gray first proposed his great scheme to the public," said Chevalier Wilson, in a letter to Sir Robert Peel in 1845, "people were disposed to treat it as an effusion of insanity." I shall not enter on a history of the struggles which preceded the opening of the first railway. They were brought to a successful issue by the determination of a few able and far-seeing men. The names of Thomas Gray and Joseph Sandars, of William James and Edward Pease, should always be remembered in connection with the early history of railways, for it was they who first made the nation familiar with the idea. There is no fear that the name of Stephenson will be forgotten, whose practical genius made the realisation of the idea possible.

The Stockton and Darlington Railway was opened in 1825, the Liverpool and Manchester Railway in 1830, and in the short time which has since elapsed, railways have been extended to every quarter of the globe. No nation possessing wealth and population can afford to be without them; and though at present in different countries there is in the aggregate about 160,000 miles of railway, it is certain that in the course of a very few years this quantity, large as it is, will be very greatly exceeded.

Railways add enormously to the national wealth. More than twenty-five years ago it was proved to the satisfaction of a committee of the House of Commons, from facts and figures which I then adduced, that the Lancashire and Yorkshire Railway, of which I was the engineer, and which then formed the principal railway connection between the populous towns of Lancashire and Yorkshire, effected a saving to the public using the railway of more than the whole amount of the dividend which was received by the proprietors. These calculations were based solely on the amount of traffic carried by the railway, and on the difference between the railway rate of charge and the charges by the modes of conveyance anterior to railways. No credit whatever was taken for the saving of time, though in England pre-eminently time is money.

Considering that railway charges on many items have been considerably reduced since that day, it may be safely assumed that the railways in the British Islands now produce, or rather save to the nation, a much larger sum annually than the gross amount of all the dividends payable to the proprietors, without at all taking into account the benefit arising from the saving in time. The benefits under that head defy calculation, and cannot with any accuracy be put into money; but it would not be at all over-estimating this question to say that in time and money the nation gains at least what is equivalent to 10 per cent. on all the capital expended on railways. I do not urge this on the part of railway proprietors, for they did not embark in these undertakings with a view to the national gain, but for the expected profit to themselves. Yet it is as well it should be noted, for railway proprietors appear sometimes by some people to be regarded in the light of public enemies.

It follows from these facts that whenever a railway can be made at a cost to yield the ordinary interest of money, it is in the national interest that it should be made. Further, that though its cost might be such as to leave a smaller dividend than that to its proprietors, the loss of wealth to so small a section of the community will be more than supplemented by the national gain, and therefore there may be cases where a Government may wisely contribute in some form to undertakings which, without such aid, would fail to obtain the necessary support.

And so some countries, Russia for instance, to which improved means of transport are of vital importance, have wisely, in my opinion, caused lines to be made which, having regard to their own expenditure and receipts, would be unprofitable works, but in a national point of view are or speedily will be highly advantageous.

The Empire of Brazil, which I have lately visited, is arriving at the conclusion, which I think not an unwise one, that the State can afford, and will be benefited in the end, by guaranteeing 7 per cent. upon any railway that can of itself be shown to produce a net income of 4 per cent., on the assumption that the nation will be benefited at least to the extent of the difference.

A question more important probably in the eyes of many—safety of railway travelling—may not be inappropriate. At all

events, it is well that the elements on which it depends should be clearly understood. It will be thought that longer experience in the management of railways should go to ensure greater safety, but there are other elements of the question which go to counteract this in some degree.

The safety of railway travelling depends on the perfection of the machine in all its parts, including the whole railway, with its movable plant, in that term; it depends also on the nature and quantity of traffic, and lastly, on human care and attention.

With regard to what is human, it may be said that so many of these accidents as arise from the fallibility of men will never be eliminated until the race be improved.

The liability to accident will also increase with the speed, and might be reduced by slackening that speed. It increases with the extent and variety of the traffic on the same line. The public, I fear, will rather run the risk than consent to be carried at a slower rate. The increase in extent and variety of traffic is not likely to receive any diminution; on the contrary, it is certain to augment.

I should be sorry to say that human care may not do something, and I am not among those who object to appeals through the press, and otherwise, to railway companies, though sometimes perhaps they may appear in an unreasonable form. I see no harm in men being urged in every way to do their utmost in a matter so vital to many.

A question may arise whether, if the railways were in the hands of the Government, they could not be worked with greater safety. Government would not pay their officers better, or perhaps so well, as the companies do, and it is doubtful whether they would succeed in attracting to the service abler men. They might do the work with a smaller number of chief officers, for much of the time of the companies' managers is occupied in internecine disputes. They might handle the traffic more despotically, diminishing the number of trains, or the accommodation afforded by them, or in other ways, to ensure more safety; but would the public bear any curtailment of convenience?

One thing they could, and perhaps would do. In cases where the traffic is varied, and could more safely be conducted with the aid of relief lines, which hold out no sufficient inducement to the companies to make, the Government, being content with a lower rate of interest, might undertake to make them, though then comes the question whether, when the whole of this vast machine came to depend for supplies on annual votes of Parliament, money would be forthcoming in greater abundance than it is under the present system.

But the consideration of this subject involves other and more difficult questions.

Where are the labours of Government to stop? The cares of State which cannot be avoided are already heavy and will grow heavier every year. Dockyard establishments are trifling to what the railway establishments, which already employ 250,000 men, would be. The assumption of all the railways would bring Government into conflict with every passenger, every trader, and every manufacturer. With the railway companies there would be no difficulty; they would sell their undertakings to anyone, provided the price was ample.

Looking at the vast growth of railway traffic, one measure occurs to me as conducive to the safety of railway passengers, and likely to be demanded some day; it is to construct between important places railways which should carry passengers only or coals only, or be set apart for some special separation of traffic; though there will be some difficulty in accomplishing this. Landowners, through whose properties such lines would pass, would probably wish to use such lines for general purposes. Nevertheless, it may have to be tried some day.

It would be instructive, were it practicable, to compare the relative proportion of accidents by railway and by the old stage-coaches, but no records that I am aware of exist of the latter that would enable such a comparison to be made. It is practicable to make some sort of comparison between the accidents in the earlier day of our own railways and the accidents occurring at a ater date

The Board of Trade have unfortunately abandoned the custom, which they adopted from 1852 to 1859, of returning the passenger mileage, which is given in the German returns, and is the proper basis upon which to found the proportion of accidents, and not on the number of passengers without any regard to distance travelled, which has altered very much, the average journey per passenger being nearly half in 1873 what it was in 1846.

It would be erroneous to compare the proportions of accidents to passengers carried in various years, even if the correct number of passengers travelling were given. But a figure is always omitted from the Board of Trade return, which makes the proportion of accidents to passengers appear larger than it is; this is the number of journeys performed by season-ticket holders. Some estimate could be made of the journeys of season-ticket holders by dividing the receipts by an estimated average fare, or the companies could make an approximate estimate, and the passenger mileage could be readily obtained by the railway companies from the tickets. These additions would greatly add to the value of the railway returns as statistical documents, and render the deductions made from them correct.

Though it has been a work of labour, I have endeavoured to supply these deficiencies, and I believe the results arrived at may be taken as fairly accurate.[1]

From the figures so arrived at, it appears the passenger mileage has doubled between 1861 and 1873; and at the rate of increase between 1870 and 1873 it would become double what it was in 1873 in twelve years from that time, namely in 1885.

The number of passengers has doubled between 1864 and 1873, and at the rate of increase between 1870 and 1873 it would become double what it was in 1873 in eleven-and-a-half years, or in 1885.

It must, however, be remembered that the rate of increase since 1870, though very regular for 1871, 1872, and 1873, is greater than in previous years, being probably due to the rise of wages and the great development of third-class traffic, and it would not be safe to assume this rate of increase will continue.

Supposing no improvement had been effected in the working of railway traffic, by the interlocking of points, the block system, &c., the increase of accidents should have borne some proportion to the passenger mileage, multiplied by the proportion between the train mileage and the length of line open, as the number of trains passing over the same line of rails would tend to multiply accidents in an increasing proportion, especially where the trains run at different speeds.

The number of accidents varies considerably from year to year, but taking two averages of ten years each, it appears that the proportion of deaths of passengers from causes beyond their control to passenger miles travelled in the ten years ending December 31, 1873, was only two-thirds of the same proportion in the ten years ending December 31, 1861; the proportion of all accidents to passengers from causes beyond their own control was one-ninth more in the last ten years than in the earlier, whereas the frequency of trains had increased on the average one-fourth.

The limit, however, of considerable improvements in signalling, increased brake power, &c., will probably be reached before long, and the increase of accidents will depend on the increase of traffic, together with the increased frequency of trains.

The large growth of railway traffic, which we may assume will double in twenty years, will evidently greatly tax the resources of the railway companies; and unless the present companies increase the number of the lines of way, as some have commenced to do, or new railways are made, the system of expeditious and safe railway travelling will be imperilled. Up to the present time, however, the improvements in regulating the traffic appear to have kept pace with the increase of traffic and of speed, as the slight increase in the proportion of railway accidents to passenger miles is probably chiefly due to a larger number of trifling bruises being reported now than formerly.

I believe it was a former President of the Board of Trade who said to an alarmed deputation, who waited upon him on the subject of railway travelling, that he thought he was safer in a railway carriage than anywhere else.

If he gave any such opinion he was not far wrong, as is sufficiently evident when it can be said that there is only one passenger injured in every four million miles travelled, or that, on an average, a person may travel 100,000 miles each year for forty years, and the chances be slightly in his favour of his not receiving the slightest injury.

A pressing subject of the present time is the economy of fuel. Members of the British Association have not neglected this momentous question.

At the meeting held at Newcastle-on-Tyne in 1863, Sir William Armstrong sounded an alarm as to the proximate exhaustion of our coal-fields.

Table on opposite page

Mr. Bramwell, when presiding over the Mechanical Section at Brighton, drew attention to the waste of fuel.

Dr. Siemens, in an able lecture he delivered by request of the Association to the operative classes at the meeting at Bradford, pointed out the waste of fuel in special branches of the iron trade, to which he has devoted so much attention.

He showed on that occasion that, in the ordinary re-heating furnace, the coal consumed did not produce the twentieth part of its theoretical effect, and in melting steel in pots in the ordinary way not more than one-seventieth part; in melting one ton of steel in pots about $2\frac{1}{2}$ tons of coke being consumed. Dr. Siemens further stated that, in his regenerative gas furnace, one ton of steel was melted with 12 cwt. of small coal.

Mr. Lowthian Bell, who combines chemical knowledge with the practical experience of an ironmaster, in his Presidential address to the members of the Iron and Steel Institute in 1873, stated that, with the perfect mode of withdrawing and utilising the gases and the improvement in the furnaces adopted in the Cleveland district, the present make of pig-iron in Cleveland is produced with $3\frac{1}{2}$ million tons of coal less than would have been needed fifteen years ago; this being equivalent to a saving of 45 per cent. of the quantity formerly used. He shows by figures, with which he has favoured me, that the calorific power of the waste gases from the furnaces is sufficient for raising all the steam and heating all the air the furnaces require.

It has already been stated that by working steam more expansively, either in double or single engines, the consumption of fuel in improved modern engines compared with the older forms may be reduced to one-third.

All these reductions still fall far short of the theoretical effect of fuel which may be never reached. Mr. Lowthian Bell's figures go to show that in the interior of the blast furnace, as improved in Cleveland, there is not much more to be done in reducing the consumption of fuel; but much has already been done, and could the reductions now attainable, and all the information already acquired be universally applied, the saving in fuel would be enormous.

How many open blast furnaces still belch forth flame and gas and smoke as uselessly, and with nearly as much mischief to the surrounding neighbourhood, as the fires of Etna or Vesuvius? How many of the older and more extravagant forms of steam-engine still exist?

What is to be done with the intractable householder, with the domestic hearth, where, without going to German stoves, but by using Galton's grates and other improvements, everything necessary both for comfort and convenience could be as well attained with a much smaller consumption of coal?

If I have pointed out that we do not avail ourselves of more than a fractional part of the useful effects of fuel, it is not that I expect we shall all at once mend our ways in this respect. Many cases of waste arise from the existence of old and obsolete machines, of bad forms of furnaces, of wasteful grates, existing in most dwelling-houses; and these are not to be remedied at once, for not everyone can afford, however desirable it might be, to cast away the old and adopt the new.

In looking uneasily to the future supply and cost of fuel, it is, however, something to know what may be done even with the application of our present knowledge; and could we apply it universally to-day, all that is necessary for trade and comfort could probably be as well provided for by one-half the present consumption of fuel; and it behoves those who are beginning to build new mills, new furnaces, new steamboats, or new houses, to act as though the price of coal which obtained two years ago had been the normal and not the abnormal price.

There was in early years a battle of the gauges, and there is now a contest about guns; but your time will not permit me to say much on their manufacture.

Here again the progress made in a few years has been enormous; and in contributing to it, two men, Sir Wm. Armstrong and Sir Joseph Whitworth, both civil engineers, in this country at all events, deservedly stand foremost. The iron coil construction of Sir William Armstrong has already produced remarkable and satisfactory results; in discussing further possible improvements, the question is embarrassed by attempting to draw sharp lines between what is called steel and iron.

There is nothing that I can see to limit the size of guns, except the tenacity and endurance of the metal, whatever we may choose to call it, of which they are to be made.

Sir Joseph Whitworth, who has already done more than any other man in his department to secure good workmanship, and whose ideal of perfection is ever expanding, has long been seeking, and not without success, by enormous compression, to increase those qualities in what he calls homogeneous metal. Make the metal good enough, and call it iron if you will, and the size of a gun may be anything: the mere construction and handling of a gun of 100 tons, or of far greater weight, with suitable mechanical appliances, presents no difficulty.

Relying on the qualities of his compressed metal, Sir Joseph is now seeking by a singular experiment to limit the travel of the recoil, as far as practicable, to the elasticity of the metal. By

RAILWAY ACCIDENTS.—*Great Britain and Ireland.*

Year.	Proportion of train mileage for year to total length of single line of way, excluding sidings.	Number of accidents to passenger trains.	Average journey of passengers of all classes, exclusive of periodical ticket-holders.	Number of accidents to passengers from causes beyond their control. Killed.	Injured.	Total.	Number of miles travelled by passengers of all classes, including periodical ticket-holders.	Proportion of passengers killed from causes beyond their control to passenger miles travelled.	Proportion of passengers injured or killed from causes beyond their control to passenger miles travelled.	Proportion of passengers killed from causes beyond their control to passenger journeys.	Proportion of passengers injured or killed from causes beyond their control to passenger journeys.

1870	7,253	123	10 74	65	1084	1149	3,801,734 000	1 in 58,488,000	1 in 3,309,000	1 in 5,465,000	1 in [illegible]89,000
1871	7,894		10·53	38	1504	1542	5 060,329 000	1 in 133,167,000	1 in 3,282,000	1 in 12,683,000	1 in 3[illegible]3,000
Average	1852–61	(inclusive)		20	425	445	2,018 485,000	1 in 100,924 000	1 in 4 530,000	1 in 6,850,000	1 in 308,000
Average	1864–73	(inclusive)		26	920	946	3,826,729,000	1 in 147,182,000	1 in 4,045 000	1 in 13,165,000	1 in 362,000

(*a*) The figures in this column are obtained by dividing the total train mileage by the aggregate length of single line of way, excluding sidings, and not by the actual length of the railway.

(*b*) The passenger mileage has been calculated, as it is not given in the Board of Trade returns, except partially between 1852 and 1859 (inclusive), and since 1859 no return under this head has been made.

(*c*) The figures in column No. IX. are obtained by dividing those in column VIII. by those in column V.

(*d*) The figures in column X. are obtained by dividing those in column VIII. by those in column VII.

(*e*) The figures in column XI. are obtained by dividing the total number of passengers carried in each year (including a calculated number of journeys made by season ticket holders) by the figures in column V.

(*f*) The figures in column XII. are obtained by dividing the total number of passengers carried in each year by the figures in column VII.

N B.—The passenger mileage includes the miles estimated to have been travelled by season ticket holders. This estimate was obtained by calculating an average fare per mile for each class of passenger, and dividing the receipts from the season ticket holders by the average fare.

attaching the muzzle of the gun to an outer casing, through which the force of the recoil is carried back to the trunnions, he proposes to avail himself of this elasticity to the extent of one-and-a-half times the length of the gun; whether its elasticity alone in so short a space will suffice without aid is, perhaps, doubtful; but other aid may be applied, and the experiment, whether successful or not, will be interesting.

Docks and harbours I have no time to mention, for it is time this long and, I fear, tedious address, should close.

"Whence and whither," is an aphorism which leads us away from present and plainer objects to those which are more distant and obscure; whether we look backwards or forwards, our vision is speedily arrested by an impenetrable veil.

On the subjects I have chosen you will probably think I have travelled backwards far enough. I have dealt to some extent with the present.

The retrospect, however, may be useful to show what great works were done in former ages.

Some things have been better done than in those earlier times, but not all.

In what we choose to call the ideal we do not surpass the ancients. Poets and painters and sculptors were as great in former times as now; so, probably, were the mathematicians.

In what depends on the accumulation of experience, we ought to excel our forerunners. Engineering depends largely on experience; nevertheless, in future times, whenever difficulties shall arise or works have to be accomplished for which there is no precedent, he who has to perform the duty may step forth from any of the walks of life, as engineers have not unfrequently hitherto done.

The marvellous progress of the last two generations should make everyone cautious of predicting the future. Of engineering works, however, it may be said that their practicability or impracticability is often determined by other elements than the inherent difficulty in the works themselves. Greater works than any yet achieved remain to be accomplished—not perhaps yet awhile. Society may not yet require them; the world could not at present afford to pay for them.

The progress of engineering works, if we consider it, and the expenditure upon them, has already in our time been prodigious. One hundred and sixty thousand miles of railway alone, put into figures at 20,000*l*. a mile, amounts to 3,200 million pounds sterling; add 400,000 miles of telegraph at 100*l*. a mile, and 100 millions more for sea canals, docks, harbours, water and sanitary works constructed in the same period, and we get the enormous sum of 3,340 millions sterling expended in one generation and a half on what may undoubtedly be called useful works.

The wealth of nations may be impaired by expenditure on luxuries and war; it cannot be diminished by expenditure on works like these.

As to the future, we know we cannot create a force; we can, and no doubt shall, greatly improve the application of those with which we are acquainted. What are called inventions can do no more than this, yet how much every day is being done by new machines and instruments.

The telescope extended our vision to distant worlds. The spectroscope has far outstripped that instrument, by extending our powers of analysis to regions as remote.

Postal deliveries were and are great and able organisations, but what are they to the telegraph?

Need we try to extend our vision into futurity farther? Our present knowledge, compared to what is unknown even in physics, is infinitesimal. We may never discover a new force—yet, who can tell?

SECTION A.

Mathematical and Physical.

Opening Address by the President, Prof. Balfour Stewart.

Since the last meeting of the British Association, science has had to mourn the loss of one of its pioneers, in the death of the veteran astronomer, Schwabe, of Dessau, at a good old age, not before he had faithfully and honourably finished his work. In truth this work was of such a nature that the worker could not be expected long to survive its completion.

It is now nearly fifty years since he first began to produce daily sketches of the spots that appeared upon the sun's surface. Every day on which the sun was visible (and such days are more frequent in Germany than in this country), with hardly any intermission for forty years, this laborious and venerable observer made his sketch of the solar disc. At length this unexampled perseverance met with its reward in the discovery of the periodicity of sun-spots, a phenomenon which very speedily attracted the attention of the scientific world.

It is not easy to over-rate the importance of the step gained when a periodicity was found to rule these solar outbreaks. *A priori* we should not have expected such a phenomenon. If the old astronomers were perplexed by the discovery of sun-spots, their successors must have been equally perplexed when they ascertained their periodicity. For while all are ready to acknowledge periodicity as one of the natural conditions of terrestrial phenomena, yet everyone is inclined to ask what there can be to cause it in the behaviour of the sun himself. Manifestly it can only have two possible causes. It must either be the outcome of some strangely hidden periodical cause residing in the sun himself, or must be produced by external bodies, such as planets, acting somehow in their varied positions on the atmosphere of the sun. But whether the cause be an internal or external one—in either case we are completely ignorant of its nature.

We can easily enough imagine a cause operating from the sun himself and his relations with a surrounding medium to produce great disturbances on his surface, but we cannot easily imagine why disturbances so caused should have a periodicity. On the other hand we can easily enough attach periodicity to any effect caused by the planets, but we cannot well see why bodies comparatively so insignificant should contribute to such very violent outbreaks as we now know sun-spots to be.

If we look within we are at a loss to account for the periodicity of solar disturbances, and if we look without we are equally at a loss to account for their magnitude. But since that within the sun is hidden from our view, it cannot surely be considered blameworthy if astronomers have directed their attention to that without and have endeavoured to connect the behaviour of sun-spots with the positions of the various planets. Stimulated no doubt by the success which had attended the labours of Schwabe, an English astronomer was the next to enter the field of solar research.

The aim of Mr. Carrington was, however, rather to obtain very accurate records of the positions, the sizes, and the shapes of the various sun-spots than to make a very extensive and long-continued series of observations. He was aware that a series at once very accurate and very extended is beyond the power of a private individual, and can only be undertaken by an established institution. Nevertheless, each sun-spot that made its appearance during the seven years extending from the beginning of 1854 to the end of 1860 was sketched by Mr. Carrington with the greatest possible accuracy, and had also its heliographic position, that is to say its solar latitude and longitude, accurately determined.

One of the most prominent results of Mr. Carrington's labours was the discovery of the fact that sun-spots appear to have a proper motion of their own—those nearer the solar equator moving faster than those more remote. Another was the discovery of changes apparently periodical affecting the disposition of spots in solar latitude. It was already known that sun-spots confined themselves to the sun's equatorial regions, but Mr. Carrington showed that the region affected was liable to periodical elongations and contractions, although his observations were not sufficiently extended to determine the exact length of this period.

Before Mr. Carrington had completed his seven' years labours, celestial photography had been introduced by Mr. Warren De la Rue. Commencing with his private observatory, he next persuaded the Kew Committee of the British Association to allow the systematic photography of the sun to be carried on at their observatory under his superintendence, and in the year 1862 the first of a ten years' series of solar photographs was begun. Before this date however Mr. De la Rue had ascertained, by means of his photoheliograph, on the occasion of the total eclipse of 1860, that the red prominences surrounding the eclipsed sun, belong, without doubt, to our luminary himself.

The Kew observations are not yet finally reduced, but already several important conclusions have been obtained from them by Mr. De la Rue and the other Kew observers. In the first place the Kew photographs confirm the theory of Wilson that sun-spots are phenomena, the dark portions of which exist at a level considerably beneath the general surface of the sun; in other words, they are hollows, or pits, the interior of which is of course filled up with the solar atmosphere. The Kew observers were

likewise led to associate the low temperature of the bottom of sun-spots with the downward carriage of colder matter from the atmosphere of the sun, while the upward rush of heated matter was supposed to account for the faculæ or bright patches which almost invariably accompany spots. In the next place the Kew observers, making use not only of the Kew series but of those of Schwabe and Carrington, which were generously placed at their disposal, have discovered traces of the influence of the nearer planets upon the behaviour of sun-spots. This influence appears to be of such a nature that spots attain their maximum size when carried by rotation into positions as far as possible remote from the influencing planet—that is to say into positions where the body of the sun is between them and the planet. There is also evidence of an excess of solar action when two influential planets come near together. But although considerable light has thus been thrown on the periodicity of sun-spots, it ought to be borne in mind that the cause of the remarkable period of eleven years and a quarter, originally discovered by Schwabe, has not yet been properly explained. The Kew observers have likewise discovered traces of a peculiar oscillation of spots between the two hemispheres of the sun, and finally their researches will place at the command of the observers the data for ascertaining whether centres of greater and lesser solar activity are connected with certain heliocentric positions.

While the sun's surface was thus being examined both telescopically and photographically, the spectroscope came to be employed as an instrument of research. It had already been surmised by Prof. Stokes, that the vapour of sodium at a comparatively low temperature forms one of the constituents of the solar atmosphere, inasmuch as the dark line D in the spectrum of the sun coincides in position with the bright line given out by incandescent sodium vapour.

This method of research was greatly extended by Kirchhoff, who soon found that many of the dark lines in the solar spectrum were coincident with the bright lines of sundry incandescent metallic vapours, and a good beginning was thus made towards ascertaining the chemical constitution of the sun.

The new method soon brought forth further fruit when applied in the hands of Huggins, Miller, Secchi, and others, to the more distant heavenly bodies. It was speedily found that the fixed stars had constitutions very similar to that of the sun. But a peculiar and unexpected success was attained when some of the nebulæ were examined spectroscopically. To-day it seems (so rapidly has knowledge progressed) very much like recalling an old superstition to remind you that until the advent of the spectroscope the irresolvable nebulæ were considered to be gigantic and remote clusters of stars, the individual members of which were too distant to be separated from each other even with a telescope like that of Lord Rosse. But Mr. Huggins, by means of the spectroscope, soon found that this was not the case, and that most of the nebulæ which had defied the telescope gave indications of incandescent hydrogen gas. It was also found by this observer that the proper motions of some of the fixed stars in a direction to or from the earth might be detected by means of the displacement of their spectral lines, a method of research which was first enunciated by Fizeau. Hitherto in such applications of the spectroscope, the body to be examined was viewed as a whole. It had not yet been attempted to localise the use of this instrument so as to examine particular districts of the sun, as for instance a sun-spot, or the red flames already proved by De la Rue to belong to our luminary. This application was first made by Mr. Lockyer, who in the year 1865 examined a sun-spot spectroscopically and remarked the greater thickness of the lines in the spectrum of the darker portion of the spot.

Dr. Frankland had previously found that thick spectral lines correspond to great pressure, and hence the inference from the greater thickness of lines in the umbra of a spot is that this umbra or dark portion is subject to a greater pressure; that is to say, it exists below a greater depth of the solar atmosphere than the general surface of the sun. Thus the results derived from the Kew photoheliograph and those derived from the spectroscope were found to confirm each other. Mr. Lockyer next caused a powerful instrument to be constructed for the purpose of viewing spectroscopically the red flames round the sun's border, in the hope that if they consisted of ignited gas the spectroscope would disperse, and thus dilute and destroy the glare which prevents them from being seen on ordinary occasions.

Before this instrument was quite ready these flames had been analysed spectroscopically by Capt. Herschel, M. Janssen, and others, on the occasion of a total eclipse occurring in India, and they were found to consist of incandescent gas, most probably hydrogen. But the latter of these observers (M. Janssen) made the important observation that the bright lines in the spectrum of these flames remained visible even after the sun had reappeared, from which he argued that a solar eclipse is not necessary for the examination of this region.

Before information of the discovery made by Janssen had reached this country, the instrument of Mr. Lockyer had been completed, and he also found that by its means he was able to analyse at leisure the composition of the red flames without the necessity of a total eclipse. An atmosphere of incandescent hydrogen was found to surround our luminary into which, during the greater solar storms, sundry metallic vapours were injected, sodium, magnesium, and iron forming the three that most frequently made their appearance.

Here we come to an interesting chemical question.

It had been remarked by Maxwell and by Pierce as the result of the molecular theory of gases that the final distribution of any number of kinds of gas in a vertical direction under gravity is such that the density of each gas at a given height is the same as if all the other gases had been removed, leaving it alone. In our own atmosphere the continual disturbances prevent this arrangement from taking place, but in the sun's enormously extended atmosphere (if indeed our luminary be not nearly all gaseous) it appears to hold, inasmuch as the upper portion of this atmosphere, dealing with known elements, apparently consists entirely of hydrogen. Various other vapours are, however, as we have seen, injected from below the photosphere into the solar atmosphere on the occasion of great disturbances, and Mr. Lockyer has asked the question, whether we have not here a true indication of the relative densities of these various vapours derived from the relative heights to which they are injected on such occasions.

This question has been asked, but it has not yet received a definite solution, for chemists tell us that the vapour densities of some of the gases injected into the sun's atmosphere on the occasion of disturbances are, as far as they know from terrestrial observations, different from those which would be indicated by taking the relative heights attained in the atmosphere of the sun. Mr. Lockyer has attempted to bring this question a step nearer to its solution by showing that the vapours at the temperatures at which their vapour densities have been experimentally determined are not of similar molecular constitution, whereas in the sun we get an indication, from the fact that all the elements give us line spectra, that they are in similar molecular states.

Without, however, attempting to settle this question, I may remark that we have here an interesting example of how two branches of science—physics and chemistry—meet together in solar research.

It had already been observed by Kirchhoff that sometimes one or more of the spectral lines of an elementary vapour appeared to be reversed in the solar spectrum, while the other lines did not experience reversal. Mr. Lockyer succeeded in obtaining an explanation of this phenomenon. This explanation was found by means of the method of localisation already mentioned.

Hitherto, when taking the spectrum of the electric spark between the two metallic poles of a coil, the arrangements were such as to give an average spectrum of the metal of these poles; but it was found that when the method of localisation was employed, different portions of the spark gave a different number of lines, the regions near the terminals being rich in lines, while the midway regions give comparatively few.

If we imagine that in the midway regions the metallic vapour given off by the spark is in a rarer state than that near the poles, we are thus led to regard the short lines which cling to the poles as those which require a greater density or nearness of the vapour particles before they make their appearance; while on the other hand, those which extend all the way between the two poles come to be regarded as those which will continue to make their appearance in vapour of great tenuity.

Now it was remarked that these long lines were the very lines which were reversed in the atmosphere of the sun. Hence when we observe a single coincidence between a dark solar line and the bright line of any metal, we are further led to inquire whether this bright line is one of the long lines which will continue to exist all the way between two terminals of that metal when the spark passes.

If this be the case, then we may argue with much probability that the metal in question really occurs in the solar atmosphere; but if, on the other hand, the coincidence is merely between a solar dark line and a short bright one, then we are led to imagine that it is not a true coincidence, but something which will

probably disappear on further examination. This method has already afforded us a means of determining the relative amount of the various metallic vapours in the sun's atmosphere. Thus, in some instances all lines are reversed, whereas in others the reversal extends only to a few of the longer lines.

Several new metals have thus been added to the list of those previously detected in the solar atmosphere, and it is now certain that the vapours of hydrogen, potassium, sodium, rubidium, barium, strontium, calcium, magnesium, aluminium, iron, manganese, chromium, cobalt, nickel, titanium, lead, copper, cadmium, zinc, uranium, cerium, vanadium, and palladium occur in our luminary.

I have spoken hitherto only of telescopic spectroscopy; but photography has been found capable of performing the same good service towards the compound instrument consisting of the telescope and its attached spectroscope, which it had previously been known to perform towards the telescope alone. It is of no less importance to secure a permanent record of spectral peculiarities than it is to secure a permanent record of telescopic appearances. This application of photography to spectrum observations was first commenced on a sufficient scale by Mr. Rutherford, of New York, and already promises to be one of the most valuable aids in solar inquiry.

In connection with the spectroscope I ought here to mention the names of Respighi, and Secchi, who have done much in the examination of the solar surface from day to day. It is of great importance to the advancement of our knowledge, that two such competent observers are stationed in a country where the climate is so favourable to continued observation.

The examination of the sun's surface by the spectroscope suggests many interesting questions connected with other branches of science. One of these has already been alluded to. I may mention two others put by Mr. Lockyer, premising, however, that at present we are hardly in a position to reply to them. It has been asked whether the very high temperatures of the sun and of some of the stars may not be sufficient to produce the disassociation of those molecular structures which cannot be disassociated by any terrestrial means; in other words, the question has been raised, whether our so-called elements are really elementary bodies.

A third question is of geological interest. It has been asked whether a study of the solar atmosphere may not throw some light upon the peculiar constitution of the upper strata of the earth's surface, which are known to be of less density than the average interior of our planet.

If we have learned to be independent of total eclipses as far as the lower portions of the solar atmosphere are concerned, it must be confessed that as yet the upper portions—the outworks of the sun—can only be successfully approached on these rare and precious occasions. Thanks to the various Government expeditions despatched by Great Britain, by the United States, and by several Continental nations—thanks, also, to the exertions of Lord Lindsay and other astronomers—we are in the possession of definite information regarding the solar corona.

In the first place, we are now absolutely certain that a large part of this appendage unmistakably belongs to our luminary, and in the next place, we know that it consists, in part at least, of an ignited gas giving a peculiar spectrum, which we have not yet been able to identify with that of any known element. The temptation is great to associate this spectrum with the presence of something lighter than hydrogen, of the nature of which we are yet totally ignorant.

A peculiar physical structure of the corona has likewise been suspected. On the whole, we may say that this is the least known, while it is perhaps the most interesting, region of solar research; most assuredly it is well worthy of further investigation.

If we now turn our attention to matters nearer home, we find that there is a difficulty in grasping the facts of terrestrial meteorology no less formidable than that which assails us when we investigate solar outbreaks. The latter perplex us because the sun is so far away and because also his conditions are so different from those with which we are here familiar; while on the other hand, the former perplex us because we are so intimately mixed up with them in our daily lives and actions; because, in fact, the scale is so large and we are so near. The result has been that until quite recently our meteorological operations have been conducted by a band of isolated volunteers individually capable and skilful, but from their very isolation incapable of combining together with advantage to prosecute a scientific campaign. Of late, however, we have begun to perceive that if we are to make any advance in this very interesting and practical subject, a different method must be pursued, and we have already reaped the first fruits of a more enlightened policy; already we have gained some knowledge of the constitution and habits of our atmosphere.

The researches of Wells and Tyndall have thrown much light on the cause of dew. Humboldt, Dové, Buys Ballot, Jelinek, Quetelet, Hansteen, Kupffer, Forbes, Welsh, Glaisher, and others have done much to give us an accurate knowledge of the distribution of terrestrial temperature. Great attention has likewise been given to the rainfall of Great Britain and Ireland, chiefly through the exertions of one individual, Mr. G. J. Symons.

To Dové we are indebted for the law of rotation of the wind, to Redfield for the spiral theory of cyclones, to Francis Galton for the theory of anti-cyclones, to Buchan for an investigation into the disposition of atmospheric pressure which precedes peculiar types of weather, to Stevenson for the conception of barometric gradients, to Scott and Meldrum for an acquaintance with the disposition of winds which frequently precedes violent outbreaks; and to come to the practical application of laws, we are much indebted to the late Admiral Fitzroy and the system which he greatly helped to establish for our telegraphic warnings of coming storms.

Again, the meteorology of the ocean has not been forgotten. The well-known name of Maury will occur to every one as that of a pioneer in this branch of inquiry. Fitzroy, Leverrier, Meldrum, Toynbee, and others have likewise done much; and it is understood that the meteorological offices of this and other maritime countries are now busily engaged upon this important and practical subject. Finally, the movements of the ocean and the temperatures of the oceanic depths have recently been examined with very great success in vessels despatched by her Majesty's Government; and Dr. Carpenter has by this means been able to throw great light upon the convection currents exhibited by that vast body of water which girdles our globe.

It would be out of place to enter here more minutely into this large subject, and already it may be asked what connection has all this with that part of the address that went before it.

There are, however, strong grounds for supposing that the meteorology of the sun and that of the earth are intimately connected together. Mr. Broun has shown the existence of a meteorological period connected apparently with the sun's rotation; five successive years' observations of the barometer at Singapore all giving the period 25·74 days. Mr. Baxendell, of Manchester, was, I believe, the first to show that the convection currents of the earth appear to be connected somehow with the state of the sun's surface as regards spots; and still more recently, Mr. Meldrum, of the Mauritius Observatory, has shown by a laborious compilation of ships' logs and by utilising the meteorological records of the island, that the cyclones in the Indian Ocean are most frequent in years when there are most sunspots. He likewise affords us grounds for supposing that the rainfall, at least in the tropics, is greatest in years of maximum solar disturbance.

M. Poey has found a similar connection in the case of the West Indian hurricanes; and finally, Piazzi Smyth, Stone, Köppen, and still more recently, Blanford, have been able to bring to light a cycle of terrestrial temperature having apparent reference to the condition of the sun.

Thus, we have strong matter-of-fact grounds for presuming a connection between the meteorology of our luminary and that of our planet, even although we are in complete ignorance as to the exact nature of this bond.

If we now turn to terrestrial magnetism the same connection becomes apparent.

Sir Edward Sabine was the first to show that the disturbances of the magnetism of the earth are most violent during years of maximum sunspots. Mr. Broun has shown that there is likewise a reference in magnetic phenomena to the period of the sun's rotation about his axis, an observation recently confirmed by Hornstein; and still more recently, Mr. Broun has shown that the moon has an action upon the earth's magnetism which is not altogether of a tidal nature, but depends, in part, at least, upon the relative position of the sun and moon.

I must trust to your forbearance if I now venture to bring forward considerations of a somewhat speculative nature.

We are all familiar with the generalisation of Hadley, that is to say we know there are under-currents sweeping along the surface of the earth from the poles to the equator, and upper-currents sweeping back from the equator to the poles. We are

likewise aware that these currents are caused by the unequal temperature of the earth; they are in truth convection-currents, and their course is determined by the positions of the hottest and coldest parts of the earth's surface. We may expect them, therefore, to have a reference not so much to the geographical equator and poles as to the hottest and coldest regions. In fact, we know that the equatorial regions into which the trade winds rush and from which the anti-trades take their origin, have a certain annual oscillation depending upon the position of the sun, or in other words upon the season of the year. We may likewise imagine that the region into which the upper-currents pour themselves is not the geographical pole, but the pole of greatest cold.

In the next place we may imagine that these currents, as far as regards a particular place, have a daily oscillation. This has, I believe, been proved as regards the lower currents or trade-winds which are more powerful during the day than during the night, and we may therefore expect it to hold good with regard to the upper-currents or anti-trades; in fact, we cannot go wrong in supposing that they also, as regards any particular place, exhibit a daily variation in the intensity with which they blow.

Again, we are aware that the earth is a magnet. Let us not now concern ourselves about the origin of its magnetism, but rather let us take it as it is. We must next bear in mind that rarefied air is a good conductor of electricity; indeed, according to recent experiments, an extremely good conductor. The return trades that pass above from the hotter equatorial regions to the poles of cold, consisting of moist rarefied air, are therefore to be regarded in the light of good conductors crossing lines of magnetic force; we may therefore expect them to be the vehicle of electric currents. Such electric currents will of course react on the magnetism of the earth. Now, since the velocity of these upper currents has a daily variation, their influence as exhibited at any place upon the magnetism of the earth may be expected to have a daily variation also.

The question thus arises, Have we possibly here a cause which may account for the well-known daily magnetic variation? Are the peculiarities of this variation such as to correspond to those which might be expected to belong to such electric currents? I think it may be said that as far as we can judge there is a likeness of this kind between the peculiarities of these two things, but a more prolonged scrutiny will of course be essential before we can be absolutely certain that such currents are fitted to produce the daily variation of the earth's magnetism.

Besides the daily and yearly periodic changes in these upper convection currents we should also expect occasional and abrupt changes forming the counterparts of those disturbances in the lower strata with which we are familiar. And these may be expected in like manner to produce non-periodic occasional disturbances of the magnetism of the earth. Now it is well known that such disturbances do occur, and further that they are most frequent in those years when cyclones are most frequent, that is to say in years of maximum sunspots. In one word, it appears to be a tenable hypothesis to attribute at least the most prominent magnetic changes to atmospheric motions taking place in the upper regions of the atmosphere where each moving stratum of air becomes a conductor moving across lines of magnetic force; and it was Sir Wm. Thomson, I believe, who first suggested that the motion of conductors across the lines of the earth's magnetic force must be taken into account in any attempted explanation of terrestrial magnetism.

It thus seems possible that the excessive magnetic disturbances which take place in years of maximum sunspots may not be directly caused by any solar action, but may rather be due to the excessive meteorological disturbances which are likewise characteristic of such years. On the other hand, that magnetic and meteorological influence which Mr. Broun has found to be connected with the sun's rotation points to some unknown direct effect produced by our luminary, even if we imagine that the magnetic part of it is caused by the meteorological. Mr. Broun is of opinion that this effect of the sun does not depend upon the amount of spots on his surface.

In the next place, that influence of the sun in virtue of which we have most cyclones and greater meteorological disturbance in the years of maximum spots cannot, I think (as far as we know at present), be attributed to a change in the heating power of the sun. We have no doubt traces of a temperature effect which appears to depend upon the sun-period, but its amount is very small, whereas the variation in cyclonic disturbance is very great. We are thus tempted to associate this cyclone producing influence of the sun with something different from his light and heat. As far, therefore, as we can judge, our luminary would appear to produce three distinct effects upon our globe. In the first place, a magnetic and meteorological effect, depending somehow upon his rotation: secondly, a cyclonic effect depending somehow upon the disturbed state of his surface; and lastly, the well-known light and heat effect with which we all are familiar.

If we now turn to the sun we find that there are three distinct forms of motion which animate his surface particles. In the first place, each particle is carried round by the rotation of our luminary. Secondly, each particle is influenced by the gigantic meteorological disturbances of the surface, in virtue of which it may acquire a velocity ranging as high as 130 or 140 miles a second; and lastly, each particle, on account of its high temperature, is vibrating with extreme rapidity, and the energy of these vibrations communicated to us by means of the ethereal medium produces the well-known light and heat effect of the sun.

Now, is it philosophical to suppose that it is only the last of these three motions that influences our earth, while the other two produce absolutely no effect? On the contrary, we are, I think, compelled by considerations connected with the theory of energy, to attribute an influence, whether great or small, to the first two as well as to the last.

We are thus led to suppose that the sun must influence the earth in three ways, one depending on his rotation, another on his meteorological disturbance, and a third by means of the vibrations of his surface particles.

But we have already seen that, as a matter of fact, the sun does appear to influence the earth in three distinct ways—one magnetically and meteorologically, depending apparently on his period of rotation; a second cyclonically, depending apparently on the meteorological conditions of his surface; and a third, by means of his light and heat.

Is this merely a coincidence, or has it a meaning of its own? We cannot tell; but I may venture to think that in the pursuit of this problem we ought to be prepared at least to admit the possibility of a three-fold influence of the sun.

Even from this very meagre sketch of one of the most interesting and important of physical problems, it cannot fail to appear that while a good deal has already been done, its progress in the future will very greatly depend on the completeness of the method and continuity of the observations by which it is pursued. We have here a field which is of importance not merely to one, or even to two, but almost to every conceivable branch of research.

Why should we not erect in it a sort of science exchange into which the physicist, the chemist, and the geologist may each carry the fruits of his research, receiving back in return some suggestion, some principle, or some other scientific commodity that will aid him in his own field. But to establish such a mart must be a national undertaking, and already several nations have acknowledged their obligations in this respect.

Already the German Government have established a Sonnenwarte, the mere building and equipment of which is to cost a large sum. With an appreciation of what the spectroscope has done for this inquiry, the first directorship was offered to Kirchhoff, and on his declining it, Herr Vogel has been placed in charge. In France also a physical observatory is to be erected at Fontenay, on an equal, if not greater scale, of which Jan sen has already accepted the directorship; while in Italy there are at least three observatories exclusively devoted to this branch of research. Nor must we forget that in this country the new observatory at Oxford has been so arranged that it can be employed in such inquiries. But what has England as a nation done?

Some years since, at the Norwich meeting of this Association, a movement was set on foot by Col. Strange which resulted in the appointment of a Royal Commission on the advancement of science, with the Duke of Devonshire as chairman. This Commission have quite recently reported on the steps that ought in their opinion to be taken for the advancement of scientific research.

One of their recommendations is expressed in the following words:—

"Important classes of phenomena relating to physical meteorology and to terrestrial and astronomical physics require observations of such a character that they cannot be advantageously carried on otherwise than under the direction of Government. Institutions for the study of such phenomena should be main-

tained by the Government; and in particular an observatory should be founded specially devoted to astronomical physics."

If the men of science of this country who procured the appointment of this commission, and who subsequently gave evidence before it, will now come forward to support its recommendations, it can hardly be doubted that these will be speedily carried into effect.

But other things besides observations are necessary, if we are to pursue with advantage this great physical problem.

One of these is the removal of the intolerable burden that has hitherto been laid upon private meteorologists and magneticians. Expected to furnish their tale of bricks, they have been left to find their own straw. Nothing more wretched can be imagined than the position of an amateur—that is to say, a man who pursues science for the love of it and is unconnected with any establishment—who has set himself to promote observational inquiries, whether in meteorology or magnetism.

He has first to obtain with great expenditure of time or money, or both, copies of the individual observations taken at some recognised institution. He has next to reduce these in the way that suits his inquiry; an operation again consuming time and demanding means. Let us suppose all this to be successfully accomplished, and a valuable result obtained. It is doubtless embodied in the Transactions of some society, but it excites little enthusiasm, for it consists of something which cannot be repeated by every one for himself like a new and interesting experiment. Yet the position of such men has recently been improved. Several observatories and other institutions now publish their individual observations; this is done by our Meteorological Office, while Dr. Bergsma, Dr. Neumayer, and Mr. Broun are recent examples of magneticians who have adopted this plan. The publication of the work of the latter is due to the enlightened patronage of the Rajah of Travancore, who has thus placed himself in front of the princes of India and given them an example which it is to be hoped they will follow. But this is only one step in the right direction; another must consist in subsidising private meteorologists and magneticians in order to enable them to obtain the aid of computers in reducing the observations with which they have been furnished. The man of science would thus be able to devote his knowledge, derived from long study, to the methods by which results and the laws regulating them are to be obtained; he could be the architect and builder of a scientific structure without being forced to waste his energies on the work of a hodman.

Another hindrance consists in our deficient knowledge as to what observations of value in magnetism and meteorology have already been made. We ought to have an exhaustive catalogue of all that has been done in this respect in our globe, and of the conditions under which the various observations will be accessible to outside inquirers. A catalogue of this kind has been framed by a committee of this Association, but it is confined to the dominions of England, and requires to be supplemented by a list of that which has been done abroad.

A third drawback is the insufficient nature of the present facilities for the invention and improvement of instruments, and for their verification.

We have, no doubt, advanced greatly in the construction of instruments, especially in those which are self-recording. The names of Brooke, Robinson, Welsh, Osler, and Beckley will occur to us all as improvers of our instruments of observation. Sir W. Thomson has likewise adapted his electrometer to the wants of meteorology. Dr. Roscoe has given us a self-recording actinometer, but a good instrument for observing the sun's heat is still a desideratum. It ought likewise to be borne in mind that the standard mercurial thermometer is by no means a perfect instrument.

In conclusion, it cannot be doubted that a great generalisation is looming in the distance—a mighty law we cannot yet tell what, that will reach us, we cannot yet say when. It will involve facts hitherto inexplicable, facts that are scarcely received as such because they appear opposed to our present knowledge of their causes. It is not possible perhaps to hasten the arrival of this generalisation beyond a certain point; but we ought not to forget that we *can* hasten it, and that it is our duty to do so. It depends much on ourselves, our resolution, our earnestness; on the scientific policy we adopt, as well as on the power we may have to devote ourselves to special investigations, whether such an advent shall be realised in our day and generation, or whether it shall be indefinitely postponed. If governments would understand the ultimate *material* advantages of every step forward in science, however inapplicable each may appear for the moment to the wants or pleasures of ordinary life, they would find reasons patent to the meanest capacities for bringing the wealth of mind, now lost on the drudgery of common labours, to bear on the search for those wondrous laws which govern every movement not only of the mighty masses of our system, but of every atom distributed throughout space.

SECTION C.

Opening Address of Dr. Thomas Wright, F.R.S.E., F.G.S., President.

On the Geological and Palæontological Character of the Country around Bristol.

In taking this Chair to-day, I desire first to express my deep sense of gratitude to the Council of the British Association for the honour conferred on me, and secondly, to say how much I feel the responsibility of the position in which I am placed when I recollect the long list of distinguished *savans* who in former years have presided over this Section. The fact that Buckland, Conybeare, De la Beche, Forbes, Geikie, Hopkins, Jukes, Lyell, Murchison, Phillips, Ramsay, and other men illustrious in the annals of British Geology have filled this chair, may well make me doubt how far my own feeble powers are equal to an efficient discharge of its duties; however, I shall bring a willing mind and an honest determination to do my best on this occasion.

We have met again in one of the most interesting centres in England to all students of practical geology; for within a short distance of this spot we can examine some of the most instructive sections of Palæozoic and Mesozoic rocks, and study a magnificent collection of local fossils obtained from them. So I purpose occupying the short space of time allowed for this introductory address in attempting to give you a general outline of the geological character of the country around Bristol, with a *résumé* of some of its more remarkable Palæontological features, by way of inducing you to visit and study the admirable collection of local organic remains so well displayed in the Museum of the Bristol Philosophical Institution.

Geology is the history of the Earth; for it attempts to construct a table of phenomena, physical and chemical, organic and inorganic, which have succeeded each other from the past to the present, and on the terrestrial surface traces of its origin and progress are preserved.

That phase which we see to-day is only the most recent of its eventful history, and although the last, is not the final one, as the physical forces that are ever in action among its different parts are slowly and steadily producing new combinations, which in time will effect mutations in its structure, change its physiography, and remodel the whole.

There is probably no other place in England where, within so limited an area, typical examples of so many different formations occur as around this city; for within a short distance by road or rail we may investigate the Silurian, Devonian, Carboniferous, Triassic, Liassic, Oolitic, and Cretaceous formations, all of which will yield many interesting species for the cabinet of the palæontologist, and a valuable series of rocks and minerals for the student of Physical Geology.

These different formations in relation to the entire series of stratified rocks will be better understood by a reference to the Table on the following page, in which the periods, divisions, formations, and typical localities are given.

The localities in the Table may be grouped into six districts:—

1. Tortworth district.
2. Mendip Hills.
3. Radstock district.
4. Bristol district.
5. Dundry district.
6. Bridgewater district.

1. Tortworth District.

Silurian.—Tortworth has long been classical ground to the geologist, and was first brought into notice by Dr. Cooke, formerly (1799–1835) rector of the parish. This gentleman made an extensive collection of fossils from all the rocks in the district, which after his death passed through my hands, and I can therefore speak to the fact. A description of the Geology of Tortworth was made by Mr. Weaver,[1] and by Buckland and Conybeare.[2] These memoirs were written at a time when the

[1] Trans. Geol. Soc. vol. i. p. 317 (2nd series).
[2] Ibid. p. 210.

correlations of the then so-called Transition rocks were not understood; therefore they help us little toward a correct understanding of their age and character; it was not until Murchison had succeeded in making out the true relation and character of the upper fossiliferous beds beneath the Old Red Sandstone, and had arranged his groups by their organic remains in consecutive order under the name of the Silurian System, that the true age and relation of the Transition strata of Tortworth were understood. It then appeared that the Silurian rocks of Tortworth are the southern extension of the same formations which, extending through Micklewood Chase and the Vale of Berkeley, appear as a dome of Upper Silurian, rising near Tites Point on the left bank of the Severn near Purton Passage. The same rocks are found wrapping round the base of May Hill and Huntley Hill in the Forest of Dean, in the Valley of Woolhope, Herefordshire, on the western slopes of the Malvern Hills, and extending through Eastnor and Ledbury to Wenlock Edge, Salop. Whatever, therefore, is true relating to the Palæontological character of the Upper Silurians in these other localities, is equally correct of the same formations that lie in the miniature basin of Tortworth. The *Caradoc Sandstone*, or, as it is now called, the *Upper Llandovery Sandstone*, is the oldest rock at Tortworth, and forms the dominant stratum of the district. It covers an extensive area; and some small sections are seen at the south side of Micklewood Chase, and on both banks of the Avon near Damory Mill. Lithologically and palæontologically it is indistinguishable from hand specimens of the same formation at May Hill. It abounds in fossils: *Pentamerus*, *Strophomena*, *Orthis*, *Atrypa*, *Spirifera*, and *Leptæna*, with broken Trilobites belonging to the genera *Trinucleus*, *Calymene*, *Illænus*, and *Phacops*, are found, together with the stems of Crinoids and Tentaculites.

The *Wenlock Limestone* is exposed at Falfield Mill and Whitfield, and other places; from its various beds the characteristic Upper Silurian Corals are collected, as *Favosites*, *Syringopora*, *Halysites*, *Porites*, *Caryophyllia*, and *Acervularia*. Crinoidal stems are very abundant. Many Brachiopoda, as *Leptæna*, *Atrypa*, *Orthis orbicularis*, and Gasteropoda, as *Euomphalus discors* and *Euomphalus funatus*, are collected, with fragments of *Calymene Blumenbachii* and *Phacops caudatus*. The *Ludlow Rock* is best exposed at low-water mark on the west bank of the Severn at Purton Passage, where it rises in a dome-shaped mass, and dips away beneath the beds of Old Red Sandstone of the Devonian series on the opposite shore; the upper portion of this formation consists of greenish-grey micaceous beds, with *Leptæna lata*, *Orthis unguis*, and *Terebratula Wilsoni*, which probably represent the Aymestry limestone.

TABLE I.—Geological Formations in the Bristol Districts.

Periods.	Divisions.	Formations.	Typical Localities.
POST TERTIARY	Recent	Alluvium	Bristol, Shirehampton.
		Peat	Cheddar, Glastonbury.
	Post Pliocene	Gravel	Cheddar railway, Keynsham, Saltford.
TERTIARY	- - -	- - - -	Absent.
CRETACEOUS	- - -	Greensand	Postlebury.
JURASSIC	Upper Oolite	Coral Rag	Absent.
	Middle Oolite	Oxford Clay	Cloford.
	Lower Oolite	Cornbrash	Cloford, Marston Bigot.
		Forest Marble	Chickwell, Faulkland.
		Bradford Clay	Bradford.
		Bath Oolite	Coombedown Lansdown P.
		Fuller's Earth	North Stoke, Lansdown, Box.
		Inferior Oolite	Dundry, Cotteswold Hills.
LIASSIC	Upper Lias	Liassic Sands	Dundry, Midford, Frocester.
		Upper Lias Clay	Dundry, Midford, Frocester.
	Middle Lias	Marlstone	Dundry, Sodbury, Stinchcombe.
		Clays	Dundry, Sodbury, Stinchcombe.
	Lower Lias	Clays	Horfield, Pell.
		Limestones	Keynsham, Saltford.
TRIASSIC	Upper Trias	*Avicula contorta*	Aust, Beechum, Garden Cliff.
		Keuper	New River, Cotham.
		Dolomitic Conglomerate	Bristol, Portishead, Clevedon.
PERMIAN	- - -	- - - -	Absent.
CARBONIFEROUS	Upper	Coal Measures	Mangotsfield, Radstock, &c.
		Millstone Grit	Brandon Hill, Fish-ponds, &c.
		Upper Shales	Clifton, Ashton, Fish-ponds.
	Lower	Carboniferous Limestone	Clifton, Mendips, Tortworth.
		Lower Shales	Clifton, Clevedon, Tortworth.
DEVONIAN	Old Red	Sandstones	Clifton, Portishead, Mendips, &c.
		Conglomerates	Clifton, Portishead, Mendips, &c.
UPPER SILURIAN	- - -	Ludlow	Berkeley, Purton Passage.
		Wenlock	Tortworth, Falfield.
		Upper Llandovery	Tortworth, Damory.
IGNEOUS ROCKS	- - -	Greenstone	Damory, Charfield, Woodford.
		Basalt	Uphill, Mendips, Weston.

Devonian.—The Old Red Sandstone, in its upper parts, consists of fine-grained thin flagstones of a whitish-grey colour; and Tortworth Court is built of these fine building beds. This upper division is underlain by coarse quartzose conglomerates, and at the base by red sandstone, which rests on the Llandovery strata. The same succession of beds is very persistent, with conglomerate in the centre and lower third, and sandstone above and at the base.

Carboniferous.—The Bone Bed at the base of this formation is well developed, together with the Lower Limestone Shales. *Psammodus linearis*, *P. lævissimus*, Coprolites, and *Pileopsis angustus*, Phil., a shell of the Carboniferous Limestone, are the leading fossils here.

Millstone Grit and Coal Measures.—These beds have been fully and accurately described in the "Geological Transactions," by Weaver, Buckland, and Conybeare, accompanied by many valuable sections. They consist of Millstone Grit, Lower Coal Measures, Pennant Sandstone, and Upper Coal Measures; the whole series may be studied and examined in this district. A section constructed from Tortworth Green to Frampton Cotterell gives the following:—Tortworth Green, Old Red; the Court and Park, Lower Limestone Shales; Ley Hill and Cromhall. Carboniferous Limestone; Cromhall Heath, Millstone Grit; Sweethouse, Lower Coal Shales; Sweethouse to Robin's-wood House, Pennant, and from Robin's-wood House to Frampton Cotterell, Upper Coal Measures of the Coal-pit Heath basin

An able paper on this subject, with Map and Sections, by my friend Mr. Etheridge,[1] F.R.S., will be found in the papers of the Cotteswold Club.

Dolomitic Conglomerate.—Weaver described this formation as composed principally of "rounded and angular fragments of limestone, exceeding the size of the head, with fragments also of quartz and hornstone. These are all cemented together by a calcareous paste, which is frequently of a marly nature—or of a carbonate of lime either of an earthy or compact structure;" the cement is generally magnesian, and in this there are many cavities frequently lined with crystals of calcareous spar and quartz, and also with the sulphate of strontian.

This remarkable formation forms a kind of irregular broken fringe, hanging on the flanks of the older rocks, and resting unconformably upon them. We shall meet with this conglomerate again in connection with the beds in the Mendip Hills, and in the Clifton section.

New Red Sandstone.—The upper and central members of the New Red Sandstone are found near Tortworth; they consist chiefly of red clay and marl.

Avicula contorta beds have been found by the Earl of Ducie in the form of the Bone Bed, the series resting on the inclined edges of the Carboniferous Limestone.

2. Mendip Hills.

The Mendip Hills proper extend from Bleadon Hill near Hutton on the west, to Elm and Whatley on the east; and they strike nearly due west and east, and are about thirty miles in length, with an average breadth of five to six miles. They constitute the southern base of the Bristol Coal Field, or the base of an almost equilateral triangle, formed by the Palæozoic rocks, comprising the area from Purton Passage and Tortworth to the south slopes of the Mendips; this includes the outlier Bream Down, which is only a westerly prolongation in the Severn, separated from the main range of the Mendips by the alluvial flat of the estuary of the Axe.

The Lithology of the Mendips consists of Old Red Sandstone, Carboniferous Limestone, and Trias, the latter represented chiefly by the Dolomitic Conglomerate, which lies unconformably on the Old Red and Carboniferous, flanking nearly the entire range of hills, and in places capping their summits.

Numerous islands of Carboniferous Limestone surrounded by Triassic rocks occur east of Wells and south of Croscombe, also encircled by fringes of Dolomitic Conglomerate, of which Church Hill, Worminster, and Knowl-foot Hill are examples; these outliers testify to the southern extension of the Carboniferous Limestone beneath the New Red Sandstone and Lias south of the Mendips, and lend us aid in determining the probable position of deep-seated Coal Measures similar to those at Vobster, Colford, Edford, Holcombe, &c., north of the Mendip range.

The lower flanks of the northern portion of the range are covered by the New Red Sandstone, that of the south being a mere strip traversed by the Wells and Axbridge Railway, the peat plains and bogs of Sedgmoor covering them up to a certain level to the east of the meridian of Glastonbury. The Lias occupies an extensive plain, masking likewise the older rocks beneath.

Old Red Sandstone forms the oldest stratified rock, and is, strictly speaking, the axis of the Mendip Hills. It is exposed in four well-marked areas along the highest ridge:—(1) Blackdown; (2) North Hill and Pen Hill; (3) Beacon Hill; and (4) Downhead Common, which is the largest exposed tract. The intervening areas are occupied by a mantle of Carboniferous Limestone, which arches over and covers the underlying Old Red, denudation having yet spared the limestone.

The Old Red is exposed along two anticlinal axes, these being, indeed, the chief cause of its exposure; the axes being post-Carboniferous and pre-Triassic, are not traceable beneath or where the patches of Dolomitic Conglomerate and cherty Lias cover up the Old Red Sandstone and Carboniferous Limestone, as at Harptree Hill, Rowham, Shipham, &c.

The most northerly anticlinal brings up the fine range of Blackdown, on the north, south, and east of which occur the Lower Limestone Shales resting on Old Red.

The northern dip of the anticlinal is higher than the southern, being in places as high as 54° in the north, whilst in the south it does not exceed 20°. This anticlinal is traceable from near the exposure of the igneous rock at Uphill, along Bleadon Hill, thence under the New Red Sandstone to Padingham, and Dolomitic Conglomerate and Calamine beds of Shipham, through the Old Red Sandstone of Blackdown, and on through the Carboniferous Limestone of Lamb-bottom, where it is lost under the cherty Rhætic beds of Harptree Hill. From Little Elm on the extreme east, to Masbury Castle nearly due west of the range, the Old Red is again exposed for three miles, which is likewise due to the anticlinal axis.

At Masbury Castle we lose trace of this S.E. anticlinal, and a second and parallel one to that of Blackdown occurs, ranging from the Old Red of North Hill through the Carboniferous Limestone of Stoke Warren, and last under the Dolomitic Conglomerate of North Draycott. This may join the great anticlinal near Egar Hill. We thus see that the strike of the Mendips was induced by a force which has brought out its oldest rock to the surface, and thereby produced the present physiography of the bold range of hills we are now considering.

Carboniferous Limestone surrounds the exposed and concealed nucleus of Old Red, and is conformable therewith both in dip and strike. The Carboniferous Limestone has grand development in the Mendips, and constitutes the great mass of the chain, having a continuous spread of five miles between Westbury Beacon and Abbey, also between Croscombe and Emberrow. The Lower Limestone Shales are nowhere more finely exposed than around and resting on the upper members of the Old Red Sandstone, and are highly fossiliferous throughout, the beds being crowded with *Strophomena*, *Chonetes*, *Spirifera*, Polyzoa, the ossicula of Crinoids, and many Trilobites, presenting a strong contrast to the barren beds of the Old Red on which they conformably rest. The Shales are well developed around Blackdown, especially to the east of Charterhouse, at Rowbarrow and Priddy, west of North Hill, and Nine Barrows; and east of Egar Hill they attain a thickness of 500 feet, and are extremely rich in organic remains. They present an extended outcrop from Masbury to Stoke Lane, and Leigh upon Mendip, and in the Downhead beds near Asham Woods. The local development of these argillaceous beds of the lowest division of the Carboniferous Limestone first gave origin to the name Lower Limestone Shales. They are almost special to the west of England, and are exposed on both flanks of the Mendip range. On them rest the thick-bedded strata of the Carboniferous Limestone, which is everywhere traceable for thirty miles from Oldford, the gorge of the Vallis to Elm on the east, to the distant headland of Bleadon in the west, and everywhere abounding more or less with organisms which form the leading fossils in its beds.

Coal Measures.—On the northern flank of the Mendips, between Binegar and Wells, and resting on the Millstone Grit, highly faulted and contorted, are the well-known Coals of Vobster, Holcombe, Pitcot, &c., that portion on the west at Stratton on the Fosse, Downside, &c. being covered by Dolomitic Conglomerate, the eastern side at Newbury and Vobster being overlain by the same rock and the Inferior Oolite. There is no reason why we should not conclude that the Coals of the northern side once extended across the Mendips and now lie deeply buried along the south parts of the range. At Ebber rocks, west of Wells, we have evidence of the Millstone Grit resting on the Carboniferous Limestone; and the elevation of the Mendips being post-carboniferous, lends an additional reason for the occurrence of the Coals of the northern area to the south of the Mendips, and beneath the Lias and Peat plain of Glastonbury, Castle Carey, the Pennards, and the Poldon Hills. No Coal area in the United Kingdom is so disturbed and folded both along its strike and on the dip of the Coals as those of North Mendips; and like the Coals of the "Mons Coal-field" in Belgium, which exists under similar conditions, the seams are vertical and thrown over, so that the same seams are passed through by shafts two or three times. The Vobster and Holcombe Coal-seams are the same as those at Ashton and Kingswood near Bristol, Twerton near Bath, and probably the same as those at Yate. They underlie the whole area between the Mendips and Bristol, and are probably the same that occur at Kingswood and underlie the Pennant at Coal-pit Heath.

The Trias.—Two divisions of this group are greatly developed around and upon the Mendips, especially the inferior or Dolomitic Conglomerate, a peculiar and local condition of the base of the Keuper Sandstone of the Bristol and South Wales Coalfields, chiefly that portion of the latter which extends from Cardiff to Bridgend. The entire range of the Mendips is surrounded by Dolomitic Conglomerate; and ten or twelve patches still remain as unconformable undenuded masses of that formation resting upon the older rocks forming the massive range of the Mendips. This remarkable deposit completely covered the

[1] Proceedings of the Cotteswold Naturalists' Field Club, p. 28, 1865.

range when at a lower level, its partial removal being conclusively shown by the remnants that still cling to the steep face of the northern and southern flanks of the Mendips.

This Conglomerate is composed entirely of greater or lesser fragments of the older rocks composing the hills, and is the result of the denuding action of the sea that deposited the Keuper beds. This marine denudation took place when the entire area occupied by the Mendips and Coal-basin underwent depression, the Dolomitic Conglomerate and sandstones accumulating *pro ratâ* with the depression and consequent destruction of the rocks offered for resistance. This conglomerate, the "*overlie*" of the coal-miners of the Bristol basin, although visible only upon the Palæozoic rocks surrounding the coal-bearing area, is nevertheless entirely spread over them, and beneath the New Red Sandstone that occupy nearly the entire area from Tortworth to the southern flanks of the Mendips, its presence being marked by the marls and sandstones of the Keuper, the Lias limestones, and in other places the Oolitic rocks that lie within the Coal-basin, especially along its south-east border from Bath to Wells. We have no physical evidence more convincing of denudation, elevation, and depression over large areas of the earth's surface than what we can witness so easily and study so advantageously in the Mendip Hills; for this conglomerate rock here defines the limits between Mesozoic and Palæozoic times: the highly inclined Old Red Sandstone forms the nucleus of the chain, the Carboniferous rocks resting upon it; and the Coal Measures in conformable succession to the latter were all indurated, metamorphosed, elevated, and thrown into folds long prior to the time when, under slow depression, destruction, and denudation, the Dolomitic Conglomerate was laid down by the Triassic sea—the resultant of wave forces along a coast-line which was then the Mendip range, its shingle and boulders being slowly cemented by a magnesio-calcareous paste derived from the wasting beds of the great limestone series. For further details regarding the natural history of the Dolomitic Conglomerate I must refer to a valuable memoir on this formation by Mr. Etheridge, F.R.S.[1]

The Rhætic.—Singular beds of cherty and sandy deposits of Rhætic age occur in several parts of the Mendips, in places brecciated, or as a conglomerate, and resting either upon the Dolomitic Conglomerate or Carboniferous Limestone.

The fossils are either cherty, or they have been removed, and their moulds are formed of chert, or cavities are left where organisms existed.

These beds are exposed at East Harptree, Egar Hill, Ashwick, and Shepton-Mallet. In the Vallis they repose immediately on the upturned edges of the Carboniferous Limestone, and even fill in the numerous veins, pockets, and faults in that formation, with fossil species common to the beds.

Nowhere can the geologist read more clearly the physical history of the groups of associated rocks composing the structure of the Eastern Mendips than at Wells, the Vallis, Watley, Elm, Nunny, and Holwell, where Old Red Sandstone, Carboniferous Limestone, Coal Measures, Dolomitic Conglomerate, Rhætic beds, Lias, and Oolites are all exposed in natural sequence to each other. There can be no doubt that the Rhætic sea surrounded and covered the Mendips; for its remains are found reposing on the Old Red Sandstone, Carboniferous Limestone. Coal Measures, and Dolomitic Conglomerate, and pass upwards into the Lias beds.

The Lias.—Fragmentary portions of this formation are found resting upon the summits of the Mendips, covering respectively Old Red Sandstone, Carboniferous Limestone, Dolomitic Conglomerate, and Rhætic beds, and in the Holcombe and Barrington districts resting upon the Coal Measures, proving the former extension of the Liassic sea over the Mendips; for upon some of their highest points, as near as Castle Comfort, the cherty beds, with their characteristic fossils, are found; also at Chewton Mendip, Emberrow, Ashwick, &c.; and on the south side of the hills it is found at a considerable height, as at Dowside, Chilcott, and West Herrington. During the Lias age the Mendips must either have been an archipelago, or they were totally submerged beneath the sea which deposited the Liassic plain to the north and south. The re-elevation of the Mendip range has occasioned the removal by aqueous denudation of most of the Lias beds deposited on their summit, whilst along the southern flanks of the hills, and in the valley, a considerable thickness of this formation still remains *in situ*.

Igneous Rocks.—Mr. Charles Moore[2] has shown that there is an exposure of basaltic rocks (dioritic) along the anticlinal of the Mendips, a little west of Downhead, extending visibly nearly as far as Beacon Hill, between two and three miles in length and a quarter of a mile in width.

[1] Quart. Journ. Geol. Soc. vol. xxvi. p. 174 (1870).
[2] Ibid. vol. xxiii. p. 452 1867).

This igneous mass appears in the form of a dyke, and is coincident with the anticlinal line along the axis of the Mendips, which is here traceable for seven miles, and is again continued from near Harptree to Shipham.

There is likewise at the south end of Uphill cutting (Bristol and Exeter Railway), at the western extremity of Bleadon Hill, an extensive patch of igneous rock, discovered when that line was made, and described by Mr. W. Sanders, F.R.S.; this exposure was also in the line of the anticlinal, and ended in the fault which there crosses the line. This rock, according to Mr. Rutley's analysis, is a Pitchstone Porphyry, whilst Mr. David Forbes considers it a Dolerite.

Whether this dyke was really eruptive or overflowed the Old Red Sandstone is still a question to be solved; and whether it is co-extensive with the range is unknown; but its age must be subsequent to the Coal Measures—the whole of the Palæozoic rocks being disturbed alike, and lying at one general angle of inclination, the overlying secondary strata not being influenced or at all affected by these Palæozoic changes. The Old Devonian rocks in contact with the dyke are not altered or metamorphosed, thus establishing the facts of age and condition.

3. The Radstock District.

Among the many interesting features of the neighbourhood in which we are assembled is the Bristol Coal-field, which still offers an inexhaustible subject for scientific inquiry; extending from Cromhall in the north to Frome in the south, and from Bath in the east to Nailsea in the west, comprising an area of 238 square miles.

From a very early date it attracted the attention of geologists, and was long ago the subject of a paper by Mr. Strachey, which was published in one of the local societies. Dr. Buckland[1] contributed an able memoir on this Coal-field, in which a great quantity of important information was placed on record, which has been of the greatest possible use down to the present time.

Subsequently this area has formed the subject of able papers contributed to the North of England and South Wales Institutes of Engineers, by Mr. J. C. Greenwell, F.G.S., and Mr. Handel Cossham, F.G.S., and to other scientific societies by Mr. Robert Etheridge, F.R.S., and Mr. Charles Moore, F.G.S.

During the past twelve years Mr. J. M'Murtrie, F.G.S., of Radstock, has been continuously engaged in working out the physical geology of the district, and has contributed a series of memoirs on the Bristol Coal-field to the Bath and Somersetshire Societies, which have thrown a new and important light on these marvellous disturbances which have distorted the strata.

That part of the Report of the Royal Coal Commission bearing upon the Bristol Coal-field, and prepared by Professor Prestwich, and papers by Mr. Horace Woodward and Mr. John Anstey, have summarised our previous knowledge, and added recent facts thereto; but with all that has been done much remains to be investigated before a full history of the Bristol Coal-field can be written.

Although more or less connected throughout, the Coal-fields adjoining Bristol consist of three well-defined areas, called the Gloucestershire, Radstock, and Nailsea basins, each of which has its own distinctive features. The Gloucestershire is separated from the Radstock basin by the great Kingswood anticlinal, which intersects in a ridge-like form the entire Coal-field from east to west; and the Nailsea basin has been almost, if not entirely, cut off from the principal coal district by the elevated limestones of Broadfield Down. Of these three areas Radstock basin is the most extensive, both geographically and sectionally, a great portion of its thickness being yet entirely undeveloped. One of the features which will be remarked by visitors coming from other parts of England is the number and character of the Secondary formations by which the Radstock basin is overlain. Here and there, it is true, Mesozoic rocks have been denuded; but by far the greater portion of the Coal-field is hidden beneath a covering of New Red Sandstone, Lias, and inferior Oolite, and many of the shafts have had to pass through all these formations before the coal-seams were reached.

A very slight change in the geological circumstances of the past would have left us in entire ignorance of the existence of a Coal-field so far south as Bristol; and this reflection induces the

[1] Trans. Geol. Soc. Second Series, vol. i.

hope that in other parts of the country (at present believed to be without coal, or, if present, to lie at such a depth from the surface that it cannot be worked) it may yet be discovered at a moderate depth.

Another feature of the Radstock Coal Measures is their great thickness, which Mr. M'Murtrie estimates at 8,000 feet. From this we may infer that, however limited the area in Somersetshire of which we have at present positive knowledge, we are very far indeed from the edge of that infinitely more extensive area which the Coal Measures of the South of England originally occupied, and within which outlying basins may still be found.

It is abundantly evident that the Bristol Coal-field was originally connected with that of the Forest of Dean and South Wales, with which it has many characters in common, although it differs in other respects.

In all we find the same arrangement of the different strata, namely:—1st, an upper division of productive Coal Measures; 2nd, a central mass of Pennant Sandstone; and, 3rd, beneath, a lower division of productive Coal Measures resting upon, 4th, the Millstone Grit. Hitherto it has been found impossible to correlate the seams of coal; but they present many points of general correspondence in the districts referred to; and the information obtained leads to the conclusion that their greatest sectional development occurs between Radstock and Bristol, according to the following estimate of the thickness of the strata, number of seams, and thickness of coal-seams:—

TABLE II.—Strata and Coal-Seams.

Division of Strata.	Sectional thickness.	Number of Coal-seams.	Thickness of Coal-seams.	
			Feet.	Inches.
Upper Coal Measures.....	2,600	16	26	10
Pennant Sandstone..........	2,750	4	5	10
Lower Coal Measures.....	2,800	26	66	6
	8,150	46	97	26

This great sectional thickness is attended, however, with serious disadvantages; for although, according to the Report of the Royal Coal Commission, the Bristol Coal-field was estimated to contain 6,104 millions of tons of coal, a large portion of it lies at an unworkable depth. Another physical feature of the district is the thinness of many of the seams from which coal is at present obtained.

In many of the collieries seams of from 10 to 12 inches in thickness are extensively worked, thus setting a good example of economy of one of our most precious natural productions to other parts of England, where veins of similar thickness are left behind as worthless.

Another feature of the Radstock Coal-basin is the extreme richness of its beds in the fossil flora of the Coal Measures. The Pennant Sandstone and Lower Measures yield few plants; but the Upper divisions contain much finer specimens than I have seen elsewhere, and the fossil flora of Radstock preserved in Mr. M'Murtrie's museum is alone worth a journey to study and admire. The fossil ferns are in great variety and beautifully preserved. The *Sigillariæ*, *Lepidodendra*, and other acrogenous stems tell of the arborescent ferns that floated their plume-like foliage on the islands of the Carboniferous period, and the industry and genius of the man who has collected and preserved them for our instruction and delight. The animal remains are here very scarce; two or three species of the genus *Limulus*, and one or two *Anthracosiæ*, are all that have been found; and I have the satisfaction of adding that I am authorised to say that by previous arrangement Mr. M'Murtrie will be happy to show his museum to any members of the Association to whom the same might be interesting. As there will be, I understand, memoirs on the Radstock Coal-field, I must refer to these papers for further details on this interesting district.

4. THE BRISTOL DISTRICT.

In a radius of eight miles from the Guildhall we find exposures more or less complete of the following Palæozoic and Mesozoic formations:—1. *The Old Red Sandstone*; 2. *the Carboniferous Limestone*; 3. *Millstone Grit*; 4. *Coal Measures*; 5. *Dolomitic Conglomerate and New Red Sandstone*; 6. *Rhætic*; 7. *Lias, Lower, Middle, Upper*; 8. *Upper Lias Sands*; 9. *Inferior Oolite*; 10. *Fuller's Earth*; 11. *Great Oolite*; 12. *Alluvium*, with igneous rocks of Palæozoic age. Several of these formations I have already noticed in speaking of the Mendip Hills; therefore I shall only now add such special remarks as are required to complete their sketch in the Bristol district.

The *Old Red Sandstone* forms, as we have seen, the axis of the Mendip Hills, and here occurs as a massive rock in different regions of the Bristol Coal-field, forming ranges of hills that have been sculptured by denudation out of its anticlinal folds. The beds in general are very unfossiliferous.

In the neighbourhood of Portishead, however, the remains of some large fishes have been found in a hard conglomerate, belonging to the genus *Holoptychius*—reminding us of the fishes of the Old Red Sandstone of Scotland, which were all encased in a bony armour, and possessed some of the most remarkable forms of the ichthyic type. *Pterichthys* or wing-fish, *Holoptychius* or wrinkle-scaled fish, *Cephalaspis* or buckler-shielded fish, are all forms of the Old Red, and the earliest representatives of the class Pisces in the Palæozoic rocks.

The Carboniferous Limestone is a great marine formation, and is formed of the sediments of an extensive and wide-spreading sea; the beautiful scenery so characteristic of the Avon, Severn, and Wye is in a great measure due to the development of this rock in these regions. One of the grandest sections of all the beds of the Carboniferous Limestone is that exposed in the gorge of the Avon near Clifton, where it is seen resting on the Old Red Sandstone, and overlain by the Millstone Grit.

The various conditions of the old sea-bottom in which this mass of calcareous rock was formed may here be studied with ease. The entire thickness of the strata exposed is upwards of 4,000 feet; of this the Old Red Devonian is 768 feet, the Carboniferous Limestone 2,338, and the Millstone Grit 950 feet. This magnificent section has repeatedly been the subject of memoirs by Buckland,[1] Conybeare,[2] Bright,[3] and Williams,[4] who have given ample details of all its different beds.

The Lower Limestone Shales, 500 feet in thickness, are very fossiliferous; they consist of alternations of shales and limestone, with a bone-bed near their base; in some places beds several feet thick are formed of the ossicula of Crinoids. In the main Limestone series you have a succession of Brachiopoda; *Spirifera*, *Producta*, and *Orthis* follow each other. Of Lamellibranchs we find *Aviculopecten*, *Cardiomorpha*, &c., with Gasteropods, as *Euomphalus* and *Bellerophon*, and Cephalopods, as *Goniatites*, *Orthoceras*, *Actinoceras*, &c. To these may be added the teeth and defensive spines of large shark-like and other fishes, as *Cladodus*, *Psammodus*, *Orodus*, *Holoptychius*, &c. Some of the coral strata in the upper part of the series are very interesting, and extremely rich in very beautiful specimens of Actinozoa, belonging to the reef-building groups of the ancient sea, as *Michelinia*, *Amplexus*, *Lithostrotion*, *Syringopora*, *Lonsdaleia*, &c., reminding us of the structure of coral reefs in our present seas. Associated with the coral masses are other organisms which lived on the reefs, or in shallow lagoons. The coral beds are covered by strata formed of Oolitic limestone and other detrital materials derived from the débris of wasted reefs, and formed along the shores of the ancient coral strand; sections of these oolitic beds prepared as slides for the microscope disclose the fact that the nucleus of the oolitic granules is often the shell of Foraminifera.

Millstone Grit is well seen at Brandon Hill; it rests upon the Limestone, and attains a thickness of 1,000 feet. On this repose the Coal Measures of the Bristol Coal-field, which I have already described in connection with the Mendip and Radstock districts.

Dolomitic Conglomerate.—The Palæozoic rocks of the Bristol Coal-field are here and there covered over by patches of Dolomitic Conglomerate lying unconformably on their upturned edges, at heights varying from 20 to 300 feet above the Avon. This remarkable formation is very well seen in the new road leading from the Hot-wells to Clifton and Durdham Down. It has been

long well known to geologists, and was in former days described by Bright, Gilby, Buckland, and others.

Rhætic.—Between the uppermost beds of the grey marls of the Keuper and the lowest beds of the Lias there lies a remarkable assemblage of strata, which I formerly described,[1] as the "*Avicula contorta* beds," from that shell forming the leading fossil therein. The name Rhætic has since been given to the series, from a supposition that the beds are identical with some that occur in the Rhætian Alps, which is, however, more than doubtful. Typical sections of the *Avicula contorta* series are exposed at Garden Cliff, Aust Cliff, Penarth, and Watchet on the Severn, and at Weston, Keynsham, Willsbridge, and Saltford near Bath, and Puriton, Uphill, and Wells in Somersetshire, as well as at many other localities. Two of the most classical of the series are Garden Cliff and Aust Cliff; the latter has been long known to continental geologists as the Bristol Bone-bed. In the upper part of the section are dark grey shales, intersected by bands of limestone; *Avicula contorta*, *Cardium*, *Rhæticum*, *Pecten Valoniensis*, *Axinus*, &c. are found in these. The Bone-bed consists of a hard dark-grey siliceous grit full of the bones, spines, scales, and teeth of fishes belonging to the genera *Nemacanthus*, *Acrodus*, *Sargodon*, *Hybodus*, *Ceratodus*, &c. Beneath this thin Bone-bed, with its ichthyic débris is a bed of shale which rests upon the grey marls of the Keuper. A similar succession of strata is repeated in most of the other typical sections. I have named especially those of Garden Cliff, Penarth, Uphill, and Watchet.

Aust has been long famous for its *Ceratodus* teeth, and is, I believe, the only locality where they are collected. You will find a fine series of them in the Bristol Museum. This wonderful collection is quite unique and will well repay an attentive examination.

The only living representative of the genus *Ceratodus* now lives in the rivers of Queensland; and a fine specimen was lately purchased for and presented to the Museum by W. W. Stoddart, Esq., F.G.S., for the purpose of showing the comparative size of the recent and fossil teeth.

5. Dundry District.

The Oolitic Formations.—The Oolitic formations will long remain classical ground to English geologists, as it was whilst studying these rocks in Wilts and Somerset that Dr. William Smith first acquired that knowledge which enabled him to "identify strata by organic remains," and establish a true natural system of stratigraphical geology.

The Oolitic period admits of a subdivision into three groups—the Lower, Middle, and Upper; each group is based on a great argillaceous formation, on which rest minor beds of sands and cream-coloured Oolitic and Pisolitic limestones. The argillaceous formations form broad valleys, extending diagonally across England in a direction north-east by south-west. The limestones constitute low ranges of hills, with escarpments facing the south-west, and overlooking the valleys. The Lower Oolites rest on the Lias, the Middle Oolites on the Oxford Clay, and the Portland and Upper Oolites on the Kimmeridg Clays.

The *Lias Formation* is well developed around Bristol; and many interesting and instructive sections of the Lower beds may be studied at Horfield, Keynsham, Saltford, and Weston, whilst the Middle and Upper divisions are exposed in other localities. It has been often repeated of late years that the geological record is imperfect, and that many of the leaves, and even whole chapters of the Rock-book on which the hieroglyphics of its history were written, are wanting; yet "Time, which antiquates antiquities, and hath an art to make dust of all things, hath yet spared these minor monuments;" for it is certainly true that the Jurassic formations contain a marvellously complete record of the succession of life in time during their deposition from the dawn of the Lias until the close of the Coral Sea, amid whose islands fossil *Cycadeæ* luxuriantly flourished, and whose remains are buried in their native Dirt-beds in the Portland Oolites.

I have shown elsewhere that the three divisions of the Great Lias formations admit of several subdivisions or zones of life, each characterised by a group of species which individualise it. A careful examination of these subdivisions has further proved that there is no confusion in the rocks when carefully examined—that Nature is always true to herself, although all geologists are not true to Nature. The fossils of the Lower Lias are quite distinct from those of the Middle Lias, and both specifically different from those of the Upper.

[1] Quart. Journ. Geol. Soc. vol. xvi. p. 374.

The *Ammonites* are important leading Liassic shells, that appear to have had a limited life in time, but a wide extension in space; and they have greatly aided us in determining periods and making out the history of the Liassic sea. The great Sauropterygia, represented by the *Plesiosaurus*, and the Ichthyopterygia by the *Ichthyosaurus*, are remarkable forms of Reptilia, adapted to the waters of that epoch, whilst the Dinosauria, represented by *Scelidosaurus*, the Pterosauria by the *Pterodactylus*, lived in this area during the Lias age; magnificent specimens of these different forms of reptiles adorn the walls of the Bristol Museum.

The Jurassic Age.—Dundry Hill, 700 feet in altitude, is the most westerly outlier of the Oolitic range, from which it is nine miles distant. It is a locality of great interest to the local naturalist, as it affords capital lessons of stratigraphical geology, admirable examples of surface-rock sculpture by denudation, and a commanding point of view for surveying the same, and showing the grand panorama in the midst of which it stands. The greater portion of the hill is composed of Lower Lias strata, which are well exposed at Bedminster Down, Whitchurch, Keynsham, Queen Charlton, Norton, Malreward, Winford, and Barrow. The beds consist of alternations of limestones and shales, having a total thickness of 550 feet. The Middle Lias and Marlstone are feebly developed, and the Upper Lias represented by some thin clays, with dwarfed specimens of *Ammonites bifrons* and *A. communis*; and the Upper Lias sands, from one to two feet thick, are not fossiliferous. On these rest beds of Inferior Oolite rock which have long yielded a very fine series of organic remains, some of the best of which are now preserved in the Museum collection. The Inferior Oolite of the south of England admits of a subdivision into three zones of life: the *Lower* resting upon the Lias sands has the *Ammonites Murchisonæ* as its leading fossil; the *Middle* contains a large assemblage of Mollusca, and especially of *Ammonites*, among which *Ammonites Humphriesianus*, *Sowerbyi*, *concavus*, and *Blagdeni* are conspicuously characteristic; the *Upper* contains *Ammonites Parkinsoni*, *Martinsii*, and *subradiatus*, with many Echinoderms and a large series of reef-building chorals. These three subdivisions are rarely all developed in the same section; but the order of their sequence in nature is as stated in Dundry. The lower beds are feebly represented; and there is an immense development of the middle and upper divisions.

In the iron shot shelly beds there is a fine assemblage of Lamellibranchs; and the stratum which covers them is very rich in Ammonites, many with their shells preserved, and having their oral lobes and other appendages *in situ*.

These are succeeded by other conchiferous strata; and the whole is covered by Ragstone and Building-stone, forming the upper zone, with *Ammonites Parkinsoni*, *Echinidæ*, and Corals. The stratigraphical, lithological, and palæontological conditions seen in the Oolitic capping of Dundry Hill, are repeated in other localities in Gloucestershire, Somersetshire, and Dorsetshire; and a full development of all the zones in actual superposition may be examined in certain sections in the Cotteswold Hills, as at Leckhampton and Cleeve.

The Fuller's earth must be studied at North Stoke and Lansdown, and the Great Oolite at Coombedown, Lansdown, and other localities around Bath; the typical Bradford Clay, with Apiocrinital heads and stems, and beautiful Brachiopoda near Bradford; the Forest Marble and Cornbrash at Faulkland, Chickwell, Marston Bagot, and Cloford. The Middle Jurassic rocks are admirably exposed near Calne, and the Upper Jurassic near Swindon, Wilts.

The great importance of the Bristol district as a source of mineral wealth, added to the complicated structure of this region, led my old friend Mr. William Sanders, F.R.S., to construct an elaborate geological map of the Gloucestershire and Somersetshire Coal-fields and adjacent country, on the scale of four inches to a mile. The topographical portion of this undertaking was reduced to one scale from the Tithe-Commission Maps; and Mr. Sanders traced out all the geological boundary lines in the field, and laid them down in MS. copies of the Tithe Maps, making copious notes of the strata as he proceeded with his work. The whole was finally reduced to one scale four times the size of the Ordnance-Survey Maps, and reproduced with the most scrupulous care by Mr. Stratton, who for many years assisted Mr. Sanders with the work which he had made the chief object and occupation of his later life; and it is but simple

justice to say that, single-handed, no such exact map for any one area was ever before constructed, either as regards scale or details. This undertaking occupied its author 15 years, fills 19 separate folio maps, and is a most valuable acquisition to the estate-agent, mineral engineer, and practical geologist. Its real merits can only be fully appreciated by those who understand how much patient labour, long-sustained energy, and high mental qualities were required to complete so extended a survey over such a complicated piece of country. In doing this, however, Mr. Sanders has made his scientific reputation, enriched his native country, and achieved a success which falls to the lot of few men. Having considered the stratigraphical relation of the rocks in the Bristol district, I desire now to say a few words on a branch of the subject which falls more immediately within the range of my own special studies—I mean the organic remains found imbedded in these strata. The science of Palæontology (*palaios*, old; *onta*, beings) forms an immense field of observation, and one that widens more and more every year. It is impossible to enter upon any of its details now; but some of its principles may be satisfactorily explained, and this I shall endeavour to do.

It is now established, 1st, that the stratified rocks containing organic remains admit of a division into four great groups, representing four great periods of time:—*a*, the Palæozoic or Ancient; *b*, the Mesozoic or Middle; *c*, the Cainozoic or Tertiary; and *d*, the Quaternary or Modern periods. 2nd. That each period is distinguished by its own hieroglyphic characters, which are graven on the rocks in definite and determinable characters. 3rd. That these hieroglyphics are the fossil remains or imprints of animals that lived in the water in which the sediments were formed in successive layers on the earth's crust, and are only found in the rocks they distinguish, so that it is possible to determine the age and position of the strata from which they have been collected, or, in other words, *identify strata by organic remains;* and by this key we are enabled to read the pages of the Rock-book, study the history of extinct forms of life, and determine their distribution in time and space.

Let us apply these principles to the subject we have in hand. The Palæozoic period comprises the history of the Cambro-Silurian, Devonian, Carboniferous, and Permian ages; and if we attentively examine the fossils of this period, contained in the cases of the magnificent Geological Museum of this institution, we shall see that all the organisms belonging to one age are entirely distinct from those belonging to the others. You will find, for example, in the case of the Silurian age, some beautiful corals, crinoids, and cephalopods, with a remarkable assemblage of Crustacea, the representatives of an extinct family, the Trilobitidæ, which are so highly characteristic of this age that the rocks may be called Trilobitic.

The Devonian age succeeds the Silurian; and among the corals and shells so well seen in this collection, we observe a striking resemblance to those of the Silurian on the one side and the Carboniferous Limestone on the other; but when closely examined we find that many are generically, and all are specifically distinct from both; besides this we discover that a new group of organisms of a different and higher type of structure are now introduced for the first time, namely, those remarkable forms of the ichthyic class the fishes of the Old Red Sandstone, and whose singular forms with their bony armour and osseous scales remind us of the remarkable fishes *Lepidosteus* and *Polypterus*, from North American, African, and Australian rivers of our time. The hieroglyphics, therefore, engraven on the strata of the second age are visibly different from those on the first.

The Carboniferous succeeds the Devonian; and here we find a marvellous development of the life of this age preserved in the cases of this institution. Pray study attentively the fine specimens of Anthozoa here exhibited, all derived from the upper beds of the Carboniferous Limestone at the gorge of the Avon, and showing very clearly that this portion of the section was formed in a tropical sea, and that the limestone is the product of the living energies of those Polyps, sections of whose skeletons lie there before you. Of the family FAVOSITIDÆ we see *Favosites*, *Alveolites*, *Syringopora Michelinia;* and of the family CYATHOPHYLLIDÆ we have *Cyathophyllum*, *Lithostrotion*, *Lonsdalia*, &c. Many of the beds of limestone are almost entirely composed of the ossicula of Crinoids; and we see the stems, arms, and calyces of these sea-lilies strewed in abundance in the rocks, such as *Actinocrinus*, *Poteriocrinus*, *Platycrinus*, *Cyathocrinus*, *Pentremites*, &c., with the remarkable ancient Sea-urchin *Palæchinus* associated with them. The Mollusca were chiefly represented by the Brachiopoda, which were very common in the Carboniferous age, as you may see in the large slabs containing *Orthis*, *Spirifera*, and *Productus* in great profusion. The Lamellibranchiata were represented by *Cardiomorpha* and *Conocardium*, and the Gasteropoda by *Euomphalus*, *Pleurotomaria*, and *Natica*, and the Cephalopoda by *Goniatites*, *Orthoceras*, &c. The Trilobites which formed so remarkable a feature in the fauna of the Silurian sea are here represented by a few specimens of *Phillipsia*, a dwarfed genus of this family. The fine collection of teeth and spines of large fishes from the Carboniferous Limestone enables us to compare the forms of this age with those of the Devonian already described, and shows at a glance that the ichthyic types in the seas of these two periods were entirely distinct, and both evidently adapted to conditions of existence widely different.

The life of the Carboniferous Limestone proves that it was a great marine formation accumulated during a long lapse of time out of the exuviæ and sediments of many generations of Mollusca, Echinodermata, and Actinozoa, the reef-building corals having contributed largely to the thickness of the Coral beds, and the wasted reefs of former generations having been used up again and again in the formation of the Oolitic beds which succeeded the reef-building periods.

The Coal Measures present a remarkable contrast to the Coral sea of the Carboniferous era. The Ferns (*Sigillaria*, *Lepidodendra*) and other arborescent Acrogens of the Coal-seams grew and flourished in low islands; and their remains were accumulated under conditions very different from those in which the thick-bedded limestones of the Avon section were formed. Good typical examples of the vegetation of this remarkable time in the world's history are well preserved in the large collection, filling several cases; these specimens are all very fine, and require, and I am sure will have, a careful examination.

With the close of Palæozoic time there appears to have been a great break in stratigraphical sequence of the fossiliferous rocks; mighty changes then took place. Volcanic agency was intense and active, flexing, contorting, and upheaving the older beds. These displacements in our area were post-carboniferous and pre-triassic, and are well exemplified in the unconformable position of the Dolomitic Conglomerate and New Red Sandstone of the Bristol district.

The Dolomitic Conglomerate contains the bones of Dinosaurian reptiles discovered in Durdham Down, and preserved in this Museum; they were described by Dr. Riley and Mr. Stuchbury in 1836,[1] and were then the oldest Dinosauria in Britain. Since that date the Triassic sandstones of Cheshire, Scotland, and North America have been found to contain the foot-imprints of *Cheirotheria*, and the same formation near Warwick the bones and teeth of remarkable reptiles belonging to the family *Labyrinthodontia;* subsequently it has been discovered that the coal-field of Münster-Appel in Rhenish Bavaria, and that of Saarbrück between Strasburg and Trèves, contain the skulls and bones of several species of air-breathing reptiles which were described by Goldfuss under the generic name *Archegosaurus*. The reptilian remains of the conglomerate, though now not the oldest of their class, still retain their interest for the Palæontologist, as they prove that highly organised Dinosauria lived on Triassic land. I must refer you to the original memoir for a full account of these bones, which enabled its authors to establish two genera for them. The one, *Thecodontosaurus*, has the teeth placed closely together in the jaw-bones. They are sharp, conical, compressed, and have their anterior and posterior borders finely denticulated, and the extremity slightly bent, like the teeth of *Megalosaurus*. *Palæosaurus* has the teeth compressed and pointed likewise; but one of the borders only is denticulated, and the other trenchant. The species are distinguished by the size and form of the teeth. The vertebræ resemble those of *Teleosaurus* in being contracted in the middle, and having their articular surfaces slightly biconcave; and the rest of the bones of the skeleton resemble the forms of the Lacertian type.

We know very little of the life of the Trias in the district under consideration, beyond the reptilian remains first noticed here, until we come to the close of this age, when we find upper grey marls of the Keuper overlain by and passing into a series of black shales and limestones known as the *Avicula contorta* or Rhætic beds, which have a great interest for us, as they comprise the famous Bone-bed of Aust Cliff known to all geologists. The leading fossils are *Avicula contorta*, *Cardium Rhæticum*, *Monotis decussata*, *Pecten Valoniensis*, and the small crustacean, *Estheria minuta*. The fishes are *Nemacanthus*, *Saurichthys*, *Hybodus*,

[1] Trans. Geol. Soc. 2nd series, vol. v. p. 349 (1840).

Gyrolepis, *Sargodon*, and *Ceratodus*, with bones of *Plesiosaurus* and *Ichthyosaurus*. It is the teeth of *Ceratodus*, or horned teeth, that have made Aust Cliff famous; and more than 400 different forms have been described. Mr. C. T. Higgins made the finest collection of these remains, which has been purchased for the Museum, and forms one of its rarest treasures. When these horned teeth, so called from the prominences they exhibit, were first described by Agassiz, the living species of this genus was not known; it is now ascertained that it lives in the Mary, Dawson, and other rivers of Queensland, and is called by the natives "Barramanda." The *Ceratodus* is very nearly allied to the *Lepidosiren*, is cartilaginous, a vegetable-eater, and, like the *Lepidosiren*, lives in muddy creeks; during the hot season it buries itself in the mud, whence it is dug up by the natives, its retreat being discovered by the air-hole through which it breathes; its nostrils are placed in the inside of the roof of the mouth.

A very interesting paper on *Ceratodus Fosteri* (the specimen in the Museum) by Mr. Stoddart, F.G.S., will be found in the "Proceedings of the Bristol Naturalists' Society," vol. i. p. 145.

The Lias, which succeeds the *Avicula contorta* beds, presents a remarkable contrast to them, and shows how much the life-conditions of every age depend on the physical agents that surround it. Two groups of animals appeared in great force in the Liassic sea—Ammonites and Reptiles.

The Ammonites of the Lower Lias beds, *A. angulatus*, *A. Bucklandi*, *A. Conybeari*, and others, attained a large size; and the middle and upper divisions of the same formations were all characterised by different species that marked horizons of life in these divisions. Associated with the Ammonites a large assemblage of other Mollusca are found, as *Gryphœa*, *Lima*, *Unicardium*, *Pholadomya*, *Cardinia*, *Hippopodium*, *Pleurotomaria*, and a profusion of Belemnites and large *Nautili*.

The Reptiles were very large, as you can see by the fine specimens on the walls: *Ichthyosaurus* and *Plesiosaurus* were the dominant forms of this class; and Pterodactyles with expanded wings performed the part of birds on the dry land of that era; so that the air, the estuary, and the ocean had each separate forms of Reptile life in the Lias age. Another change of conditions introduces us to new forms in the Lower Jurassic sea. A large number of species of Conchifera and Gasteropoda crowd the shelly beds of the Inferior Oolite; and new forms of Ammonites appertaining to groups entirely different from those of the Lias are found in abundance in Dundry Hill. In addition to the Mollusca we find many beautiful forms of Echinodermata, and a large collection of reef-building corals in the upper beds of the hill. Nothing gives us a clearer insight into the fact that all fossil species had a limited life in time than the distribution of the Echinodermata of the Jurassic strata, inasmuch as these animals possess a skeleton of remarkable structure, on which generic and specific characters are well preserved; they form, therefore, an important class of the Invertebrata for the study of the life-history of species in time and space; and this Table of the stratigraphical distribution of the Jurassic Echinoderms which I now exhibit reduces these observations to a practical demonstration.

The Oolitic rocks were formed in a coral sea analogous to that which rolls its waters in the Pacific between 30° on each side of the equator. In the Lower Oolites are four or five Coral formations superimposed one above another, with intermediate beds of Mollusca. The Middle Oolite is remarkable for the number and extent of its coral reefs, and the Upper Oolite for those found in the Portlandian series.

The Jurassic rocks were accumulated as sediments or shore-deposits under many changes of condition; and the idea of a slowly subsiding bed of the coralline sea gives us, perhaps, the nearest approach to what appears to have prevailed.

The Jurassic waters were studded with coral reefs, extending over an area equal to that of Europe, as they stretch through England diagonally from Yorkshire to Dorsetshire, through France from the coast of Normandy to the shores of the Mediterranean, forming besides a chain winding obliquely through the Ardennes in the north to Charente-Inférieure in the south, including Savoy, the Hautes-Alpes and Basses-Alpes, the Jura Franche-comté, the Jura chain of Switzerland throughout its entire length from Schaffhausen on the Rhine to Cobourg in Saxony, and along the range of the Swabian Alps and Franconian Jura. Throughout all this widely extended Oolitic region, coralline strata were accumulating through countless ages by the living energies of Jurassic Polypifera, as all the Madreporic limestone beds in these formations are due to the life-energies of different species of Anthozoa; and were we to venture to estimate the lapse of time occupied in the sedimentation of the coralligenous Oolites by what we know of the life-history of some living species, we should find good reasons for concluding that the Jurassic age must have been one of long duration. It is not the mere coralline structure *per se* that is due to Polyp-life, but the entire mass of Oolitic limestones are the products of the same vital force; for there could be no doubt in the mind of any competent observer who carefully examined such a rock as that in my hand that it was a mass of coral secreted by a Jurassic polyp, and that the Oolitic limestone which surrounds the coral stem is the product of a portion of a wasted reef which had been broken up, ground into mud, and constituted the calcareous paste that had coated particles on the shore, and formed by the roll of the waves the oolitic globules which were afterwards cemented by calcareous waters, and the whole transformed into the rock we call Oolitic limestone; and thus the genesis of the Oolites was due to the vital energies of the myriads of polyps that lived in the Jurassic seas.

The reefs that remain are merely fragments of what had existed; and those that have disappeared furnished the calcareous material out of which the Oolites of subsequent formations have been built up.

I have to thank my old friend Mr. Etheridge for the valuable notes he has supplied on the Mendip Hills (which he knows so well), and to Mr. M'Murtrie for his excellent notes on the Radstock district (which he has so long explored), and to Mr. Stoddart for kindness and assistance in many ways. Without their friendly co-operation it would have been impossible for me to have given so much exact information on the structure of the interesting and complicated region in which we have again assembled.

In these remarks I have carefully avoided any allusion to the origin of species, because Geology suggests no theory of natural causes, and Palæontology affords no support to the hypothesis which seeks by a system of evolution to derive all the varied forms of organic life from pre-existing organisms of a lower type. As far as I have been able to read the records of the rocks, I confess I have failed to discover any lineal series among the vast assemblage of extinct species which might form a basis and lend reliable biological support to such a theory. Instead of a gradation upwards in certain groups and classes of fossil animals, we find, on the contrary, that their first representatives are not the lowest, but often highly organised types of the class to which they belong. This is well illustrated in the Corals, Crinoids, Asteriadæ, Mollusca, and Crustacea of the Silurian age, and which make up the beginnings of life in the Palæozoic period. The fishes of the Old Red Sandstone we have already seen occupy a respectable position among the Pisces; and the Reptiles of the Trias are not the lowest forms of their class, but highly organised Dinosauria. *Ichthyosaurus*, *Plesiosaurus*, *Pterodactylus*, *Teleosaurus*, and *Megalosaurus* stand out in bold relief from the Mesozoic strata as remarkable types of animal life that were specially organised and marvellously adapted to fulfil important conditions of existence in the Reptilian age; they afford, I submit, conclusive evidence of special work of the Great Designing Mind which pervades all creation, organic and inorganic. In a word, Palæontology brings us face to face with the Creator, and shows us plainly how in all that marvellous past there always has existed the most complete and perfect relation between external nature and the structure and duration of the organic forms which gave life and activity to each succeeding age.

Palæontology likewise discloses to our feeble understanding some of those methods by which the Infinite works through natural forces to accomplish and maintain His creative design, and thereby teaches us that there has been a glorious scheme, and a gradual accomplishment of purpose through unmeasured periods of time; but Palæontology affords no solution of the problem of creation, whether of kinds, of matter, or of species of life, beyond this, that although countless ages have rolled away since the denizens of the Silurian beach lived and moved and had their being, the same biological laws that governed their life, assigned them their position in the world's story, and limited their duration in time and space, are identical with those which are expressed in the morphology and distribution of the countless organisms which live on the earth's surface at the present ttme; and this fact realises in a material form the truth and force of those assuring words, that the Great Author of all things, in these His works, is the same yesterday, to-day, and for ever.

THE FRENCH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

THIS year's session of this Association was opened last Thursday at Nantes, under the presidency of M. d'Eichthal, who is largely connected with French railways. The income of the Association for 1874 was 37,126 francs, and its capital fund amounts to 174,731 francs. In 1874, 5,350 francs were distributed for purposes of research, and already, owing to the generosity of three of the foundation members, 7,000 francs have been allotted to other purposes without trenching on the regular resources of the Association. This year 13 foundation members and 500 annual members have been added to the Association.

The President in his opening address spoke of the intimate connection between pure science and the various methods employed to satisfy the wants of humanity. It would be almost impossible, he said, to enumerate all the branches of human activity which owe their success to the researches of pure science, —Hygiene, Medicine, Surgery, the Fine Arts, Mechanics, Industry in all its branches, Mining, Metallurgy, Textile Industries, Lighting, Warming, Ventilation, Water Supply, &c. He then referred in detail to several examples of the influence which the results of science have had upon progress in the arts, with the motive forces of water, air and steam, mentioning a multitude of names of men eminent in pure science, from Pascal and Boyle down to Faraday and Sir William Thomson, upon the results of whose researches the great advances which have been made in machinery of all kinds have depended. M. d'Eichthal then spoke of electricity in connection with the names of Oerstedt, Ampère, Faraday, Becquerel and Ruhmkorff; passing on to speak at some length of the steam-engine in its various forms, of the progress which by means of scientific research is being made in its construction and its uses, and of the great services which this powerful application of a scientific discovery renders to man. M. d'Eichthal advocated the establishment of local centres of culture as the best counterpoise to that over-centralisation to which France owes so many of its social misfortunes. "In our time," he said, "science, history, literature, have great wants. Libraries, lecture-halls, laboratories, costly materials, instruments numerous and expensive, are indispensable to pupils for learning and to teachers for carrying on their researches; it is by putting, on a large scale, these resources at their disposal, that we can attract and fix in our midst men eminent in all branches of human knowledge."

M. Ollier, the General Secretary of the Association, gave a detailed *résumé* of the work done at Lille last year.

M. d'Eichthal has been very well received in Nantes, having been greeted with a serenade on Wednesday night.

The most notable foreigner present at the meeting, Admiral Ommaney, was elected, *pro honore*, president of the Geographical Section. The Geographical Congress of Paris has evidently diminished the attendance at the Nantes meeting, although M. Dumas and M. Wurtz have displayed on its behalf a most creditable zeal. Two ladies delivered addresses, on "Female Condition," and the "Sanitary Condition of Schools;" rather a novelty in France, ladies very rarely appearing as lecturers.

The excursions, which are by far the most interesting part of the proceedings, began on Saturday. A balloon ascent is contemplated for to-day. The balloon will be exceptionally large, 4,000 metres, conducted by local aëronauts who have organised an aërial sporting club.

NOTES

AMONGST the objects which have been recently added to the galleries of the Paris Industrial Exhibition of Geography, and are attracting public notice, we may mention a collection of French birds exhibited by M. Bouvier, the collection of apes from the Gaboon, by the Marquis de Compiègne, and a number of antediluvian fossils from the Mentone Caves. The skeletons of two children which had been buried together are in a splendid state of preservation, exhibiting admirably the characteristics of prehistoric cave-life. These two young people were buried in the home of their parents, very probably because it was the only means of defending their bones against the teeth of ferocious hyænas and other large carnivorous animals which were disputing with man the empire of the future Gaul. The bones were covered with small shells, of which the loin cloth of the departed youngsters had been made. Neither of them had any ornaments in bone, jasper, or pearl, such as is generally discovered under similar circumstances when the skeleton is that of an adult. No child is buried with such objects in Polynesian islands, as none are allowed to wear them even when belonging to the regal families.

IN connection with the Exhibition and Congress, it is believed that a series of proposals will be made to the French National Assembly for the promotion of the study of geography. The principal and most effective is to have a relief map of each parish in the parish school, so that pupils may learn to understand the purpose of geographical maps.

THE large reflecting telescope at the Paris Observatory is completed, although it will not be brought into use for two or three months. The equilibrium of the tube is perfect, and it can be directed with the utmost facility on any part of the heavens, although it weighs about six tons.

THE Commission appointed by the Prefect of the Seine for deciding on the improvements to be introduced in the construction of lightning conductors have just published their report. They are of opinion that the conductors should terminate in a point of copper instead of platinum as recommended by the Academy, and propose to institute an annual inspection of lightning conductors, as recommended by M. Wilfrid de Fonvielle in his pamphlet, "Lightning Conductors and the necessity of controlling them." A series of measurements will be presented to the Municipal Council in the next session. The inspection is to take place in autumn, when the stormy season is over.

THE annual provincial meeting of the Iron and Steel Institute will commence, in Manchester, on Tuesday, September 7, under the presidency of Mr. William Menelaus. The Council of Owens College have granted the use of that building for the business meetings. On Tuesday, the Mayors of Manchester and Salford respectively will welcome the members of the Institute, and the remainder of that and Wednesday morning will be devoted to the reading and discussion of papers. On the afternoons of Tuesday and Wednesday, various works in the neighbourhood of Manchester will be open for inspection. On Tuesday evening there will be a conversazione in the Town Hall; on Wednesday evening the members will dine together in the Hulme Town Hall; and on Thursday they will visit works within easy reach of Manchester. On Friday, the whole day will be devoted to North Staffordshire.

DURING last week the British Archæological Association made frequent excursions to places around Evesham, and in the evenings a number of papers were read, mostly of strictly antiquarian interest. The Cambrian Archæological Association also held its annual meeting last week at Carmarthen, both meetings being brought to a close on Saturday. Next year the latter body meets at Abergavenny under the presidency of Mr. Freeman.

MR. HENRY WILLETT, writing with reference to the Sub-Wealden Exploration, states that the committee have "succeeded beyond their fondest anticipations in solving the original problem, and can now state with certainty that palæozoic rocks do not exist at a depth variously estimated at from 700 ft. to 1,700 ft." From 1,670 ft. to 1,750 ft.—the depth now reached—the strata are shattered and very soft, greatly retarding the work, and seriously imperilling any prospect of attaining a much greater depth. Although at any moment a change of strata may be reached, Mr. Willett is not sanguine that he ever will be able to

report more than that Kimmeridge clay has been discovered in Sussex, and that this clay is very thick.

AN interesting geological discovery has been recently made during excavations for a new tidal basin at the Surrey Commercial Docks. On penetrating some 6ft. below the surface, the workmen everywhere came across a subterranean forest bed, consisting of peat with trunks of trees, for the most part still standing erect. All are of the species still inhabiting Britain; the oak, alder, and willow are apparently most abundant. The trees are not mineralised, but retain their vegetable character, except that they are thoroughly saturated with water. In the peat are found large bones, which have been determined as those of the great fossil ox (*Bos primigenius*). Fresh-water shells are also found. No doubt is entertained that the bed thus exposed is a continuation of the old buried forest, of wide extent, which has on several recent occasions been brought to the daylight on both sides of the Thames, notably at Walthamstow in the year 1869, in excavating for the East London Waterworks; at Plumstead in 1862-3, in making the southern outfall sewer; and a few weeks since at Westminster, on the site of the new Aquarium and Winter Garden. In each instance the forest-bed is found buried beneath the marsh clay, showing that the land has sunk below the tidal level since the forest flourished.

WE have received a "Catalogue of the publication of the U.S. Geological Survey of the Territories, F. V. Hayden, Geologist in Charge." The catalogue covers twenty pages, and although the publication extends only from 1867, they already form quite a large library of reports, monographs, catalogues, &c., relating to all branches of the geology, natural history, meteorology, and other points of the extensive region which is being surveyed. The publications of the survey, we believe, Dr. Hayden is willing to send to any societies, libraries, or persons engaged in active scientific investigation who may desire them; those who do should communicate with Dr. Hayden, U.S. Geologist, Washington, D. C. (U.S.) Dr. Hayden is desirous of securing by exchange the publications of foreign countries in geology, palæontology, and natural history generally, to aid in the formation of a library of reference for the use of the Survey, and he hopes that all persons or societies who receive the publications of the Survey will aid him in this matter.

VOL. IV. of the second series of the *Mémoires* of the Royal Society of Science of Liége, contains only three papers, one of them a mere note of two pages on a new species of Lepidotus, *L. mohimonti*, by Dr. T. C. Winkler. The other papers are long treatises, one by Dr. E. Candèze, being a "Revision of the Monograph of the Elateridæ" (218 pp.), and the other a treatise "On the Calculus of Probabilities," by the late A. Meyer, published from the MSS. of the author by F. Folie (446 pp.)

MR. J. WOOD-MASON, of the India Museum, Calcutta, has lately directed attention to the presence of a chain of superorbital bones in the wood partridges (*Arboricolæ*), similar to that recorded by Mr. W. K. Parker in the tinamous.

THE fourth number of the *Bulletin de la Société Impériale de Naturalistes de Moscou* contains papers on entomology, botany, geology, &c., by M. V. Motschoulsky, M.A. Petrovsky, M. H. Trautschold, and others, in the French and German Languages.

THE Cincinnati Society of Natural History has lately received a bequest of $50,000 from Mr. Charles Bodman, of that city. The gift is absolute and without conditions.

A LARGE meteor was observed at Niort (Deux-Sevres), on August 19, at 8.20 P.M. Although the moon was quite full, it was a magnificent spectacle. It made its appearance in the zenith, lasted thirty seconds, and disappeared in the south-east at an altitude of sixty degrees above the horizon. It must have been seen from other parts of France, but no record has come under our notice.

A CHAIR of Organic Chemistry has been created in the Faculty of Sciences of Paris.

THE additions to the Zoological Gardens during the past week include two Kinkajous (*Cercoleptes caudivolvulus*) from British Honduras, presented by Mr. James Wickin; a Central American Agonti (*Dasyprocta punctata*), two Brown Gannets (*Sula fusca*) from Costa Rica, presented by Mr. J. C. Hussey; a Woodford's Owl (*Syrnium woodfordi*) from Natal, presented by Mr. W. E. Oates; a Purple-capped Lory (*Lorius domicella*) from Moluccas, presented by Mr. T. P. Medley; a Mexican Guan (*Penelope purpurascens*) from Central America, presented by Mr. A. Warrington; two Gordon's Terrapins (*Platemys gordoni*) from Trinidad, presented by Mr. Devonish; a Tiger (*Felis tigris*) from India, a White-thighed Colobus (*Colobus bicolor*) from W. Africa, a West Indian Agonti (*Dasyprocta antillensis*) from St. Vincent, deposited; a Blotched Genet (*Genetta tigrina*), and two Crested Pigeons (*Ocyphaps lophotes*) bred in the Gardens.

SCIENTIFIC SERIALS

THE *Naturforscher* for July contains the following among other papers:—On the distribution of land and water in Northern Europe during the ice-period, by K. Pettersen.—On the diffusion of gases through thin layers of liquid, by Franz Exner.—On Helmholtz's theory of vowels, by E. von Quanten.—On the influence of the surface of di-electric bodies upon their action at distances, by Romich and Fajdiga.—On electrodes which cannot be polarised, by A. Oberbeck.—On the changes of colour in an alcoholic solution of cyanine, by El. Borscow. Cyanine is the blue colouring matter of the flowers of *Ajuga reptans* and *A. pyramidalis*.—On the determination of alcohol in wine, by M. Malligand.—On the action of a weak acid upon the salts of a stronger, by H. Hübner and H. Wiesinger.—On the influence of the season upon the skin of embryos, by Herr Dönhof.—On the action of electricity of high tension upon liquids, by G. Planté—On the motion of the imbibition water in wood and in the vegetable cell, by Julius Wiesner.—On a simple means to find the poles of a rod magnet, by F. Müller.—On the analysis of Japanese bronzes, by E. J. Maumené.—On the nutrition of the animal body by peptone, by A. Gyergyai and P. Plosz.—On the conducting of electricity by flames, by F. Braun.—On the fauna of the Caspian Sea, by O. Grimm.—On the action of lime upon the germinating process of *Phaseolus multiflorus*, by J. Böhm.—The solubility of sodic nitrate and its hydrate, by A. Ditte.—The electric conduction resistance of air, by A. Oberbeck.—Influence of chlorine upon the nutrition of plants, by W. Knop.—On some experiments with disinfectants, by Herr Erismann.—Distinction between chemical and physiological ferments, by A. Müntz.—On the time of the disappearance of the ancient Fauna from the Island of Rodriguez, by A. Milne-Edwards.—Application of the tuning-fork to electric telegraphs, by P. La Cour.—On the climate at the Lower Jenissei, by W. Köppen.—Temperatures and specific gravity of the water of the German Ocean, by H. A. Meyer.—On the diffusion of moist towards dry air, by L. Dufour.—On the condensation of water in the soil, by A. Mayer.—What influences determine the sex of the hemp plants? by Fr. Haberlandt.

Transactions of the Academy of Science of St. Louis (*U.S.*), vol. iii. No. 2.—This part contains the following papers:—By Dr. C. V. Riley: "Hackberry Butterflies, Description of the early stages of *Apatura lycaon*, Fabr., and *Apatura herse*, Fabr., with remarks on their Synonymy;" "On the Oviposition of the Yucca Moth;" "Description of two new Subterranean Mites;" "Descriptions and Natural History of two Insects which brave the dangers of *Sarracenia variolaris*;" "Description of two new Moths." "Notes on the genus Yucca," by G. Engelmann; "On the Well at the Insane Asylum, St. Louis County," an account of a geological section, by G. C. Broadhead, who also contributes a paper "On the occurrence of bitumen in Missouri;" "Results of Investigations of Indian Mounds," by J. R. Gage; "Catalogue of Earthquakes in 1872-3," by R. Hayes; "On the Forms and Origin of the Lead and Zinc Deposits of S.W.

Missouri," by Dr. A. Schmidt; "On the *Terebratula mormonii*," by Jules Marcou; "On Climatic Changes in Illinois—its Causes," by A. Sawyer.

Annali di Chimica applicata alla Medicina, July.—The more important papers in this part are:—On some preparations from *Eucalyptus globulus* and *E. amygdalinus*, by G. Righini.—On soluble phosphate of lime, or hydrochloro-phosphate of lime, by G. Tarantino.—On a glycerine solution of salicylic acid, by Prof. S. Zinno.—On the hydrate of croton-chloral, by Dr. Weill.—On the aqueous solution of nitrous oxide, by Prof. Ritter.—On veratrine, by Lepage.—On the ozonisation of the air in unhealthy rooms, by Dr. Leuder.—On a green colour free from poison, by Prof. Casali.—On the function of wine in nutrition, by Bouchardat.—On diphtheria, by Dr. G. Tamborlini.—On a remedy against hydrophobia, by Jitzki.—On the reactions of cod-liver oil, by Buchheim.—On mineral waters in their relation to chronic diseases, by Durand Fardel.

SOCIETIES AND ACADEMIES

Vienna

Imperial Academy of Sciences, June 10.—On some mechanical effects of the electric spark, by E. Mach.—On the different solubility of different planes of the same crystal, and the connection of this phenomenon with some general principles of science, by Prof. Pfaundler.—On the boiling points of chloride of calcium solutions of different concentration, by the same.—On the latent melting heat of sulphuric bihydrate, by the same.—On the Pyrrhulina species of the Amazon River, and on a new Bryconops species, by Dr. F. Steindachner.—On the pretended dependence of the wave-lengths from the intensity of light, by Prof. F. Lippich.—Determination of the orbit of planet (100) Hecate, by Dr. J. E. Stark.—On the theory of the functions of three variables, by Prof. M. Allé.—On a new remedy against Phylloxera (ethylsulphocarbonate of potash), by Dr. Ph. Zoeller and Dr. E. A. Grete.—Dr. L. Löwy recommends salicylic acid for the same purpose.—Further researches on the molecular theory, by Dr. A. Handl.—On the determination of the mechanical equivalent of heat, by J. Puluj.

June 17.—Ichthyological researches, by Dr. Steindachner.—On some determined integrals, by Prof. L. Gegenbaur.—On the earthquake observed on June 12 in the vicinity of Vienna, by Prof. E. Suess.—On the conducting of heat by gases, by Prof. Stefan.—Meteorological observations made at Hohe Warte, near Vienna.

June 24.—On the determination of nitrogen in albuminates, by Dr. L. Liebermann.—On the quantities of nitrogen and albumen present in human and in cows' milk, by the same.—On the origin of the acacia gum, by Dr. J. Möller.—On alluvial territories, by Dr. A. Boué.—On a new method to use Böttger's sugar test, by Prof. Brücke.—On the action of chlorine upon solutions of sodic citraconate and sodic mesaconate, by Th. Morawski.—On the tannic acids of the oak, by Dr. J. Oser.—On the manner in which guano is formed, by A. Habel.

July 8.—On a new form of Fresnel-Arago's interference experiments with polarised light, by E. Mach and W. Rosicky.—On acoustic attraction and repulsion, by Dr. V. Dvorak.—On the elastic after-effects from torsion of steel wires, by Dr. J. Finger.—Some experiments on the magnetic effects of rotating conductors, by Dr. J. Odstrcil.—On the conversion of acids of the series $C_nH_{2n-2}O_2$ into such of the series $C_nH_{2n}O_2$, by Dr. G. Goldschmidt.—Theoretical kinematics, by F. Reuleaux.—On the influence of pressure and draught on the thermal coefficients of the expansion of bodies, and on the relative behaviour of water and caoutchouc, by C. Puschl.—On gentisine, by Herr Hlasiwetz and Dr. Habermann.—On glutaminic acid, by Dr. Habermann.—On the structure of the spinal ganglia, by Herr Holl.—On the Adriatic Annelida, by Dr. E. von Marenzeller.—Researches on artificial misformations in hens' eggs, by Dr. Szymkievicz.

Paris

Academy of Sciences, Aug. 16.—M. Frémy in the chair.—The following papers were read:—Meridian observations of the minor planets, made at Greenwich Observatory (transmitted by the Astronomer Royal) and at Paris Observatory during the second trimester of the year 1875, communicated by M. Leverrier; the planets observed were Nos. 7, 25, 8, 82, 93, 53, 54, 108, 55, 23, 110, 72, 62, 68, 74, 128, 113, 26, 45, 29, 88, and 64.—Remarks by M. Leverrier on the lately discovered planets 144 and 145.—On the structure of the ovum and of the seed of Cycadeæ, as compared with that of different fossil grains of coal deposits, by M. Ad. Brogniart.—Some remarks by M. Chevreul on a historical note relating to J. B. van Helmont, *àpropos* of the definition and of the theory of a flame by M. Melsens.—Ninth note on the electric conductibility of bodies which are only moderate conductors, and on the electric polarisation of minerals, by Th. du Moncel.—A note by M. F. Tisserand, on the observations of shooting stars on Aug. 9th, 10th, and 11th last.—On the reducing action of hydriodic acid at low temperatures upon ethers proper and on mixed ethers, by R. D. Silva.—Synthetical researches on the uric group, by M. E. Grimaux (second paper).—A note by M. Cornu, on the presence of Phylloxera galls, spontaneously developed on European vines.—M. Vinot then presented an instrument to the Academy, which he calls *sideroscope* and, which enables any person, however ignorant of astronomy, to find easily all constellations and the principal stars.—Note on a new method of giving proper signals at sea, by M. Trève.—On the action of copper and its derivatives on the animal organism, by MM. Ducom and Burg.—On an acid obtained from wine, which turns the plane of polarisation to the right, by M. Maumené.—Analysis of the gases given off by the soil on the island of St. Paul, by Ch. Velain.—On Blaen's globes, and on a discovery made by the same in 1600, of a variable star in the constellation of Cygnus, by M. Baudet.—Fourth note by M. J. M. Gaugain on the process of magnetisation.—On some new singing flames, by M. C. Decharme.—Researches on tempered glass, by MM. V. de Luynes and Ch. Feil.—On some double metallic sulphocarbonates, by M. A. Mermet.—On a proper reaction by which to recognise sulphocarbonates in solution, by the same.—On the active part in the seeds of pumpkins as employed as a remedy against tape-worms, by M. E. Heckel.—On the post-tertiary fauna of the caves of Baoussé Roussé in Italy, commonly called grottoes of Mentone, by M. E. Rivière.

BOOKS AND PAMPHLETS RECEIVED

British.—A Yachting Cruise in the South Seas: C. F. Wood (H. S. King and Co.)—Transactions of the Watford Natural History Society, Vol. i. Part 1.—Rotomahana, and the Boiling Springs of New Zealand, by D. L. Mundy and Ferd. von Hochstetter (Low and Marston).—Journal of the Anthropological Institute, Vol. iv. Part 2; Vol. v. Part 1.—Snicland, or Iceland; its Jokulls and Fjalls: W. L. Watts (Longmans).—Protection of Life and Property from Lightning: W. McGregor (Beuford, Robinson).—Game Preserves and Bird Preservers: G. F. Morant (Longmans).—Geology: James Geikie (Chambers).—Magnetism and Electricity: John Cook (Chambers).—Chemistry: A. Crum-Brown (Chambers).—Astronomy: A. Findlater. (Chambers).—On the Relation between Diabetes and Food: Dr. Donkin (Smith, Elder and Co.)—Impressions of Madeira: Wm. Longman (Longmans).—Light as a Motive Power: Lieut. R. H. Armet, Vol. i. (Trübner).—Rambles in Search of Shells: J. E. Harting (Van Voorst).—Syllabus of Plane Geometry (Macmillan and Co.)—Instructions in the Use of Meteorological Instruments: Robt. H. Scott, M.A., F.R.S. (Official).—Quarterly Weather Report of the Meteorological Office, Part 4, 1873 (Official).—Second Report on the Sanitary Condition of Oxfordshire: G. W. Child (Longmans).

THURSDAY, SEPTEMBER 2, 1875

*THE SCIENCE COMMISSION REPORT ON THE ADVANCEMENT OF SCIENCE**

WE now proceed to indicate the tenor of the evidence received by the Royal Commission on the last two heads under which they have classified that part of their inquiry which relates to the Advancement of Science.

III.—*The Assistance which it is desirable the State should give towards that object* [the promotion of Scientific Research.]

On this head the evidence is enormously voluminous, and it may be said to be practically unanimous in demanding a very great increase to the aid now given towards original scientific investigation and observation. In order to afford some idea of the general tendency of this mass of testimony, we cannot do better than summarise the extracts appended in their Eighth and Final Report to the recommendations of the Commission.

As to the general question, which must precede all others, whether the State should aid science, the Commission refers first, with great propriety, to the opinions of eminent statesmen on what is as much a problem of statescraft as a question of science.

The evidence of Lord Salisbury is emphatic :—

"Do you hold that the State may legitimately interfere in giving aid to the advancement of science?—I certainly do. It is a very orthodox doctrine to hold, and one which could be supported if necessary by quotations out of Adam Smith, the essence of the doctrine being, that the State is perfectly justified in stimulating that kind of industry which will not find its reward from the preference of individuals, but which is useful to the community at large."

"The State has already, to a considerable extent, recognised, has it not, that duty; and there are a considerable number of scientific institutions supported more or less by the State?—No doubt the State, in the money that it gives, and has given in past times, to the best Universities, has recognised that duty."

"There are the Observatory at Greenwich, the British Museum, and Kew Gardens; you would consider those as instances in which the State aids the promotion of science?—They would be all instances in point; and I do not apprehend that as to the abstract doctrine itself there has ever been any serious contest." . . .

Lord Derby's evidence in favour of State aid to science is all the more weighty from the limitations by which he guards it :—

"I think there has been a very general consent amongst a large number of men of science who have been examined before this Commission that in the present state of science there are many branches as to which there is no probability of their being advanced to the degree to which they are capable of being advanced by private effort, and without the assistance of State funds in some shape; what is your lordship's opinion upon that subject?—I am, as a general rule, very strongly in favour of private effort, and very decidedly against the application of State funds to any purpose that can be accomplished without them; but I think that if there is any exception to that which I venture to call a sound and wholesome rule, it is in the case of scientific research, because the results are not immediate, they are not popular in their character, and they bring absolutely no pecuniary advantage to the person engaged in working them out. A great mathematical or a great astronomical discovery is a benefit to the whole community, and in a certain sense to mankind in general; but it is productive of absolutely no benefit, in a pecuniary point of view, to the person who has given his labour to it."

Sir Stafford Northcote thus states his opinion on the point :—

". . . The State should do what it can both to promote scientific education and also to assist in the prosecution of scientific experiments and inquiries when they can be best prosecuted by the aid of the State."

It is a matter of congratulation that these opinions, though expressed when out of office, are held, and will doubtless be maintained, by three of the foremost members of Mr. Disraeli's Cabinet. Nor can we forget that the Premier himself some time ago forcibly descanted on the extreme value of sanitary science, or that the Home Secretary, who has laboured so zealously in many departments of social reform, reminded the House of Commons, during the late session, that the proper method of paving and cleansing our wretched London streets really involved difficult scientific problems, at present neglected, and with nobody to undertake their solution.

The Commissioners observe that "on the proposition that it is the duty of the State to encourage original research they might multiply their extracts from the evidence indefinitely," and they refer to the scientific testimony of Dr. Frankland, Sir W. Thomson, Dr. Joule, Mr. Gore, Dr. Carpenter, Prof. A. W. Williamson, Mr. Reed, Sir E. Sabine, Dr. Siemens, Dr. Sclater, Mr. Farrer, Admiral Richards, and numerous others, to show that the aid of Government to scientific research has been beneficial, so far as it has gone, but that it has been insufficient and should be increased; and as representing the opinions of public servants occupying high official positions in Government departments, they refer to the evidence of Admiral Richards, late Hydrographer of the Admiralty, and to that of Mr. Farrer, Secretary to the Board of Trade.

The broad general principle that the State should aid original research, and that it at present does so insufficiently, being established, the next question is in what direction is additional aid required? The evidence on this question is classified by the Commissioners under the heads Laboratories, Physical Observatories, Meteorology, Tidal Observations, the Government Grant administered by the Royal Society, and Payment of Scientific Workers.

Evidence relating to the Establishment of Laboratories.—Amongst the witnesses who are in favour of the erection of new laboratories for research is Colonel Strange, whose view of the national requirements in these respects is thus given :—

"Will you be so good as to enumerate the institutions which you think should be under the State?—(1) an observatory for physics of astronomy; (2) an observatory for terrestrial physics, namely, meteorology, magnetism, &c.; (3) a physical laboratory; (4) an extension of the Standards Office; (5) a metallurgical laboratory; (6) a chemical laboratory; (7) an extension of collections of natural history, and an able staff of naturalists; (8) a physiological laboratory; (9) a museum of machines, scientific instruments, &c. I believe that under one or

* Continued from p. 285.

other of these and existing institutions every requisite investigation will range itself. I have not stopped to inquire whether one or another is more or less important. My aim in the spirit of my postulate No. 2* has been *completeness*. It may be necessary for a manufacturer to prosecute only such particular investigations as promise direct and speedy profit. A great nation must not act in that commercial spirit. All the operations of nature are so intimately interwoven, that it is impossible to say beforehand that a given line of research, apparently unproductive, may not throw light in unsuspected directions, and so lead to untold and undreamt-of treasures." . . .

Sir W. Thomson's evidence is as follows :—

"Are you of opinion that any national institutions supported by the Government are required for the advancement of science?—I think that there ought to be institutions for pure research supported by the Government, and not connected with the Universities. The only suitable place at present for such institutions would be London, or the neighbourhood of London; in that situation, I believe, very great things could be done by institutions for pure research, at which work of a very great immediate money value would be produced at an extremely moderate cost, and I believe that discoveries redounding to the honour and credit and pleasure of this country would infallibly be made."

"Are you able to give any idea as to how many such institutions would be required?—There should be five. One at present exists, namely, the Royal Observatory at Greenwich. Another in my opinion is very much wanted, an observatory for astronomical physics, then again a physical laboratory, and a laboratory for chemical research, and a physiological laboratory are necessary." . . .

"Would such a physical laboratory differ in any essential respects from a physical laboratory attached to an University?—Yes; it would be adapted solely for research, with no provision for pupils except what may be called apprentices, or pupils for research; no provision for teaching the mere elements of manipulation, but provision for researches directly adapted to increase knowledge, and for making pattern researches for the sake of training research pupils who had already gained experience and proved ability in institutions of instruction."

"Would you leave the researches to be carried on at such a laboratory mainly to the discretion of the person who had charge of it, or would you place it in any degree under the control of the council of which you have been speaking?—I would leave it to the discretion of the person who has charge of it." . . .

"And that the Government should also be able to command investigation on the advice of the council?—Yes."

"Of course the director would report?—Yes, the director would report on everything, both researches undertaken at his own instigation, and investigations undertaken for the council or for the Government."

"And your view of what should be done in the chemical and physiological laboratories would, I presume, be something of the same nature?—Yes, something of the same kind, *mutatis mutandis*."

"With respect to the apparatus, and the annual supply of apparatus, it is probable, is it not, that the physical laboratories would be the most costly?—Yes, the most costly in apparatus."

"Some very fine instruments of a costly kind are now required in physiological inquiries, and large pieces of apparatus are sometimes employed, such as the respiration apparatus at Munich, which was put up on the recommendation of Prof. Pettenkofer?—Yes, it would be in my opinion necessary not to limit to a fixed endowment the expenditure of any one of those institutions, but to let it be determined (if I may use the expression once more) by natural selection; applications for money to be made to the council to be duly weighed, and the council to apply to the Treasury. That would be much more economical than giving a fixed sum which, being to be spent, might be spent without due regard to economy, or which, on the other hand, might prove to be insufficient for valuable researches, causing the institution thereby to be crippled and to lose efficiency."

"You would not think it indispensable, would you, that such institutions, if the Government thought fit to establish them, should be in the heart of London, or in any very central situation?—No; it would be much better that they should be in the country in positions conveniently accessible to London." . . .

"You would not institute any regular provision for teaching in those laboratories?—No."

"But you would allow young men or students who wished to carry out original research to avail themselves of them under the direction of the persons who were in charge of them?—Yes, under the direction, and to some degree under the instruction of the persons in charge; but the instruction should be limited to methods for advancing science. The director of such an institution must not be occupied with lecturing in any other institution, or with lecturing at all. He ought indeed to be prohibited from lecturing, except one or two occasional lectures in the course of a year."

"You think that the object for which you recommend the establishment of those laboratories could not be accomplished by any other means—not by investigations carried on in other laboratories in the country?—Certainly not by any other means."

Dr. Frankland thus refers to the double function which such laboratories might perform, and states his view in reference to their management :—

"Can you make any suggestions as to stimulating original research in this country?— . . . . We have in this country a considerable body of investigators who are not engaged in teaching at all, and I think that this is a peculiarly hopeful feature of our case. It shows that the English have not only a taste for research, but that they have a natural talent for it. We have numerous men like Mr. Gassiot, Sir W. Grove, Dr. De la Rue, Mr. Spottiswoode, Mr. Huggins, Mr. Duppa, Mr. Buckton, Mr. Joule, Mr. Lockyer, Mr. Perkin, Mr. Schunck, Col. Yorke, and others whom I could name, who are not in any way engaged in teaching, and never have been, but who have made important original researches, and have spent a good deal of their time in the working out of new discoveries. Now that method of stimulating research which I have mentioned in my former examination would not of course apply to them. Men of this class are really peculiar to England, for I have never known any such instance in Germany or in France, of men altogether disconnected with teaching taking up research in the way it is done in England. I think that for such men the establishment of national institutions such as those which are recommended by Col. Strange would be peculiarly useful. In fact, I have heard several of these gentlemen express strong opinions as to the great advantage it would be to them if they could go to some institution of that kind to conduct research, where expensive instruments, which are often required for their experiments, were provided for a

* Col. Strange opened his evidence before the Royal Commission in the following terms :—

"I can hardly do better than by stating the four postulates on which I base all my recommendations: it seems to me indispensable that I should state the basis upon which I am about to speak. Those postulates are as follows:—(1) That science is essential to the advancement of civilisation, the development of national wealth, and the maintenance of national power. (2) That all science should be cultivated, even branches of science which do not appear to promise immediate direct advantage. (3) That the State or Government, acting as trustees of the people, should provide for the cultivation of those departments of science which, by reason of costliness, either in time or money, or of remoteness of probable profit, are beyond the reach of private individuals; in order that the community may not suffer from the effect of insufficiency of isolated effort. (4) That to whatever extent science may be advanced by State agency, that agency should be systematically constituted and directed."

number of such investigators, and where appropriate rooms for carrying on these researches could be had. It is exceedingly difficult to carry on chemical research in one's own house, because of the want of proper contrivances for dealing with corrosive gases and vapours; and hence appropriate buildings ought to be provided for carrying on such investigations. I think, therefore, that it would afford a great stimulus to research of this kind if such institutions were provided, and furnished with such instruments as would be generally useful in research, leaving the more special instruments and materials adapted to the particular researches themselves, to be provided by each operator. . . . I have reason to believe that no inconsiderable number of men, more especially of those educated in some of the science schools, would undertake researches if such facilities were afforded them."

"Would you consider the chief use of such institutions as laboratories to be to enable private inquirers to carry on their researches, or would you propose that any investigations should be carried on there on behalf of the State?—I think that both things might be provided for. The State requires many important investigations to be carried on. . . . . That might well form one part of the objects of such a building, but I should think that so far as abstract research, of which we are more especially speaking now, is concerned, the other portion of those objects, namely, the encouragement of original investigation in the case of amateurs would be more important, because the investigations made for the Government are essentially practical investigations; they are not usually of that character which lead to discoveries or to the advancement of science."

"Would you place those laboratories under a permanent official?—They must of necessity be under the direct and constant superintendence of some one thoroughly conversant with the operations going on in them; and, so far as the conducting of the separate original researches is concerned, I think that it would be very desirable that the admission into such institutions should be granted through some such body as the Research Fund Committee, for instance, of the Council of the Royal Society, or some body of that kind, who would make intelligent and impartial inquiry into the qualifications of the men applying for accommodation."

"You would not throw upon the director the sole responsibility of deciding who should be admitted and who should not?—I think that would not be desirable." . . .

"And do you think it would be requisite that those institutions should be on a large scale?—I think that they ought to be on a fairly large scale even to begin with, because it is always a costly process to rebuild such institutions; and I am inclined to think that they would be rapidly filled. A tolerably large institution of that kind would probably in a very few years be filled with workers." . . .

"You would not recommend, in the first instance, at least, more than the establishment of one for each department of science?—I think not more than that."

"And should it be in London?—Yes, I suppose they must be commenced here, but eventually it would be desirable that the important centres in the provinces should also be furnished with such places."

"Col. Strange recommended the establishment of four laboratories; should you be disposed to agree with him in that view?—Yes, I think that those would be necessary; perhaps the least essential of them would be the metallurgical one, but certainly the others would be quite essential."

Mr. Warren De la Rue, whose opinion on this subject, as that of one of the most eminent private scientific workers on a large scale, must have peculiar weight, expresses himself as follows:—

"Are you of opinion that any new institutions in the way of laboratories should be established by the State?—I hold it to be so important that chemistry should be extensively cultivated in England, that I would strongly advocate that there should be a State laboratory. That State laboratory should undertake all the chemical work which the Government might require, but at the same time, according to the views which I hold, it ought to be such an establishment as could afford facilities to men who have completed their scientific education, and who might be desirous of continuing original investigations, in which space for working and instruments should be afforded them; and, moreover, if men were not in a position of fortune to continue their researches, in some cases materials and even money might be granted to them on the recommendation of the council. I may state that of my own knowledge I know that chemical science at present is not progressing in England in a satisfactory manner, that we do not make so many original researches as our continental neighbours, particularly the Germans, do. In Germany very great patronage is given to science, magnificent laboratories have been built, and the students, who, after they are sufficiently advanced, are encouraged to make original investigations, contribute at present most largely to scientific chemistry."

"Do you think that the establishment of those Government laboratories would be likely to give rise to complaints from any existing institutions?—I think not, if those Government establishments were not educational establishments. . . . What I contemplate is merely that facilities should be given to men who have already been educated, and not to interfere at all with the functions of educational establishments."

"Do you think that any other laboratories would be needed?—I attach the greatest importance to a chemical laboratory, because I believe that chemistry is destined to play a very important part in the advancement of the arts in all civilised countries, but there also ought to be a physical laboratory very much on the same footing as the chemical laboratory, and in which facilities should be afforded for conducting physical investigations."

"You would give admission to those laboratories on the same principle as to the chemical laboratories?—Yes, to men who could show that they were qualified to make a beneficial use of them."

"You think that any investigations required by the State should also be conducted there?—Yes, they should be conducted in either the chemical or physical laboratory, according to the nature of the investigations. For example, there were a great number of investigations carried on at Woolwich relating to the strength of different alloys whose chemical composition was determined by analysis. Such investigations would be very well conducted in the chemical laboratories."

"Would you transfer the work now done at Woolwich to such a laboratory?—Part of the work, but I would except such special work as could be better done at each of the Government establishments. Special investigations would fall within the duties of the central government laboratory. The testing of the purity of the products to be used in the department and routine work would be better conducted in those establishments."

"With respect to the other purpose of the laboratory, do you think that there would be a sufficient number of independent inquirers to occupy an establishment like that?—I think that there would be a great number of men who would be very glad to avail themselves of such opportunities as a laboratory of that kind would afford, and their doing so would not add materially to the cost of the establishment."

Mr. Gore, a distinguished practical chemist, also recommends the establishment of laboratories, his evidence being essentially of the same purport as that quoted above.

The great bulk of the evidence, in fact, on this part of the question is to the same effect; and it has not been neutralised, in the judgment of the Commissioners, by other views expressed by a small number of distinguished witnesses.

Amongst the latter Dr. A. W. Williamson thinks that the development of schools would be preferable to the establishment of laboratories. His views however do not seem to be fully matured; the following extract from his evidence showing that though more in favour than perhaps anyone else of equal authority, of combining school instruction with original research, he still perceives that some independent provision for the latter might be desirable. He says:—

"At the same time it is quite possible that, in exceptional cases, research might with advantage be carried on in separate places; but I should always view with regret, as a waste of resources, the separation of that higher work of research from the more humble work of teaching, which naturally belongs to it. They help one another, and I think that each would lose from being separated from the other; still, in some cases, it might possibly be advisable."

Dr. Siemens, on the other hand, apprehends that the establishment of Government laboratories, which, amongst other functions, should be accessible to private workers, might cause disappointment to some who might not be able to gain access to them, and that there might be favouritism and want of discrimination in the dispensing of the privileges in question.

Dr. Burdon Sanderson would rather see increased facilities given to the great schools of medicine for the prosecution of physiological research, than laboratories of an independent character established. He questions whether we have at present a sufficient number of trained workers to use establishments of the latter kind; whilst Lord Salisbury is doubtful whether by any moderate expenditure of funds we could provide an expensive class of scientific instruments of all kinds for all the persons who might be inclined to use them.

The Commissioners, after fairly balancing the views laid before them, sum up this question in their final conclusions, as follows:—

"More complete means are urgently required for scientific investigations in connection with certain Government departments; and physical as well as other laboratories and apparatus for such investigations ought to be provided."

IRBY'S BIRDS OF GIBRALTAR

The Ornithology of the Straits of Gibraltar. By Lieut.-Col. L. Howard L. Irby, F.Z.S., &c. (London: R. H. Porter, 6, Tenterden Street; Dulau and Co., Soho Square, 1875.)

HERCULES, as in our schooldays we used to be told, once took the trouble of cleaving asunder the isthmus which in his time, whenever that was, joined Europe and Africa. Colonel Irby has been at the pains of reuniting the two continents, not indeed actually, but for the purposes of his work; and has thus undone, so far as ornithology is concerned, the labour of the demigod. Though we certainly have no fault to find with the exploit which gave the waters of the Atlantic access to the Mediterranean basin, and fully admit the advantage which has thereby accrued to most European nations, and to our own in particular, it must be confessed that we deem more highly the feat of our modern hero than the prowess of him of antiquity.

It is now some years since all authorities have recognised the fact that, if socially Africa begins, as the satirical statesman said, at the Pyrenees, Europe does not biologically end at the Strait of Gibraltar; and the readers of NATURE do not need reminding that between the animal and vegetable products of either side of that narrow channel there is little essential difference. Thus the southern part of Andalucia and the northern part of Morocco form a very homogeneous district to come under the survey of an observant ornithologist perched upon the rocky heights of "Old Gib." Such an observant ornithologist Col. Irby has proved himself to be, as might indeed have been expected of him, when we remember that he was one of the few officers of the now ancient Crimean time who was sufficiently undisturbed by war's alarms to follow his pursuits over the steppes of the Tauric Chersonese, and again, when called not long after to India, in days yet pre-Jerdonian, did not intermit his occupations in Oudh and Kumaon for all that rebellion, if not something more, was still rife in those districts.

We have seldom had the pleasure of reviewing a more engaging and more unpretending book than that which is now before us. It is by one who shows himself in almost every page to be a thorough field-naturalist, and a field-naturalist of the best kind. Cherishing with pardonable pride, as a man should do, his own observations, he can yet believe that those of others may likewise have some merit, and thus he gives us an admirable account of the place of his choice, though, as he modestly remarks, "there is ample room for anyone with energy to work out a great deal more information on the birds of the Straits." Nearly all that he has to say about those of the Spanish side is from his own personal knowledge, acquired during a more or less prolonged stay at "the Rock," between February 1868 and May 1872, and again from February to May 1874, but including in this time only one summer. "For the first three years of my residence at Gibraltar," he says, "I was quartered with my regiment, the remaining time being passed there chiefly with a view to ornithological pursuits, from time to time making excursions, generally of about a fortnight's duration, to some part or other within the districts above mentioned, but chiefly confining my attentions to the country within a day's journey of Gibraltar." The observations on the Moorish birds are in great measure culled from the manuscript of the late François Favier, a French collector well-known to many ornithologists in England, who died in 1867 after a residence of more than thirty years at Tangier. This manuscript our author secured at a high price,* to find indeed, "amidst a mass of bad grammar, bad spelling, and worse writing, which cost many hours to decipher, that it did not contain so much information as I had reason to anticipate, a good deal of the matter having been copied from other authors;" and, we may add, not copied with much discrimination.

The remaining materials of which the Colonel has

* This manuscript, or possibly an older one of which it is a corrected copy, was seen at Tangier in 1844 by Wolley. Colonel Irby has lately presented it to the Zoological Museum of the University of Cambridge.

availed himself (would that he had discovered the lost *Fauna Calpensis* of John White !) are the various papers on Spanish Ornithology, by Lord Lilford and Mr. Howard Saunders, published in the *Ibis*, and the late Mr. C. F. Tyrwhitt Drake's notes on the birds of Tangier and Eastern Morocco, which appeared in the same journal. The list of Tangerine birds by Herr Carstensen (*Naumannia*, 1852, i. pp. 76-79) gave but little help; but our author does not seem to have been aware of the late Mr. G. W. H. Drummond Hay's observations (*Proc. Zool. Soc.* 1840, pp. 133-135), which, though brief, appear to be at least trustworthy.

Colonel Irby catalogues 335 species as unquestionably occurring within his limits, besides some twenty-five more which may be reasonably looked for, though he himself has not fallen in with them; while many others are doubtless to be found as stragglers, for "so local are birds in Southern Spain, that perhaps some may be resident and overlooked in consequence of the exact locality they frequent having been unvisited." His remarks on all these are exceedingly discriminative and to the point, furnishing a supply of information for which ornithologists will be duly grateful, but they are mostly of too special a kind to give extracts from them here. We prefer quoting what he has to say on Migration, as being a subject in which more of our readers will take interest:—

"Without doubt caused by the absence or abundance of food, which in turn is caused by difference of temperature, the passage of birds in these parts begins with most species almost to a day in spring, usually lasting for about three weeks, though some, as the Hoopoe and the Swallows, are more irregular in their first appearance; and with these the migration lasts throughout a longer period.

"Few (indeed hardly any birds) do not migrate or shift their ground to some extent. I can name very few which do not appear to move, viz., Griffon-Vulture, Imperial Eagle, Eagle-Owl, Blue Thrush, all the Woodpeckers, Treecreeper, Black-headed Warbler, Dartford Warbler, Crested Lark, Chough, Raven, Magpie, Red-legged and Barbary Partridges, and the Andalucian Quail. Generally speaking, it seems to me that in the vernal migration the males are the first to arrive, as with the Wheatears, Nightingales, Night-herons, Bee-eaters; but this is a theory which requires more confirmation. Some species, as the *Neophron* and most of the *Raptores*, pass in pairs.

"Most of the land-birds pass by day, usually crossing the Straits in the morning. The waders are, as a rule, not seen on passage; so it may be concluded they pass by night, although I have occasionally observed Peewits, Golden Plover, Terns, and Gulls passing by day.

"The autumnal or return migration is less conspicuous than the vernal: and whether the passage is performed by night, or whether the birds return by some other route, or whether they pass straight on, not lingering by the way as in spring, is an open question; but during the autumn months passed by me at Gibraltar, I failed to notice the passage as in spring, though more than once during the month of August, which I spent at Gibraltar, myself and others distinctly heard Bee-eaters passing south at night, and so conclude other birds may do the same.

". . . Both the vernal and autumnal migrations are generally executed during an easterly wind, or Levanter; at one time I thought that this was essential to the passage, but it appears not to be the case, as, whether it be an east or west wind, if it be the time for migration, birds will pass, though they linger longer on the African coast before starting if the wind be westerly; and all the very large flights of *Raptores* (Kites, Neophrons, Honey-Buzzards, &c.) which I have seen passed with a Levanter. After observing the passage for five springs, I am unable to come to any decided opinion, the truth being that, as an east wind is the prevalent one, the idea has been started that migration always takes place during that wind. Nevertheless, it is an undoubted fact that during the autumnal or southern migration of the Quail in September they collect in vast numbers on the European side if there be a west wind, and seem not to be able to pass until it changes to the east; this is so much the case that, if the wind keeps in that quarter during the migration, none are hardly to be seen.

"On some occasions the passage of the larger birds of prey is a most wonderful sight; but of all the remarkable flights of any single species, that of the Common Crane has been the most noteworthy that has come under my own observation.

"On the Andalucian side, the number of birds seen even by the ordinary traveller appears strikingly large, this being, no doubt, in a great measure caused by the quantity which are, for ten months at least out of the year, more or less on migration; that is to say, with the exception of June and July, there is no month in which the passage of birds is not noticeable, June being the only one in which there may be said to be absolutely no migration, as, during the month of July, Cuckoos and some Bee-eaters return to the south" (pp. 13-15).

For want of space we must pass over the spirited descriptions which the Colonel gives of the various localities within his limits, and his experience of several shooting excursions, the relation of which is wisely subordinated to the main object of the book. We can fully enter into his feelings when he was for two hours the unobserved observer of a vast assemblage (at the lowest computation, he says, between three and four thousand) of wild geese, for we ourselves remember watching just such a host, and under much the same circumstances, years ago on the banks of a Lapland river; but we cannot here introduce his account. Our author has added to the value of his book by giving a list of the Mammals of Southern Spain, *forty* in number without counting the Barbary Ape, whose presence on "the Rock" is the origin of so many theories facetious as well as scientific; and the volume concludes with a convenient summary of the Birds, besides a very good index. As reviewers we are of course entitled to our "growl," and this shall be that the two neat maps which illustrate the book are not drawn to the same scale, and while that of Northern Morocco, for which we are especially thankful, takes in a great deal more than Colonel Irby's district, that of Southern Spain leaves out at least as much. With this we bid him farewell.

HOFMANN'S REPORT ON THE PROGRESS OF CHEMICAL INDUSTRY

Bericht über die Entwicklung der Chemischen Industrie während des letzten Jahrzehends; im Verein mit Freunden und Fachgenossen erstattet von Dr. A. W. Hofmann. Autorisirter Abdruck aus dem Amtlichen Bericht über die Wiener Weltausstellung im Jahre 1873. (*Report on the Development of Chemical Industry during the last Ten Years;* in conjunction with friends and fellow-workers. Composed by A. W. Hofmann. Authorised reprint of the official report on the Vienna Exhibition of 1873. Vol. iii. Part I.) (Braunschweig: Fr. Vieweg und Sohn, 1875.)

THE Imperial Commission of Germany for the Vienna Exhibition of 1873 have put the report on the third group, "Chemical Industry," into the hands of Dr.

The great bulk of the evidence, in fact, on this part of the question is to the same effect; and it has not been neutralised, in the judgment of the Commissioners, by other views expressed by a small number of distinguished witnesses.

Amongst the latter Dr. A. W. Williamson thinks that the development of schools would be preferable to the establishment of laboratories. His views however do not seem to be fully matured; the following extract from his evidence showing that though more in favour than perhaps anyone else of equal authority, of combining school instruction with original research, he still perceives that some independent provision for the latter might be desirable. He says:—

"At the same time it is quite possible that, in exceptional cases, research might with advantage be carried on in separate places; but I should always view with regret, as a waste of resources, the separation of that higher work of research from the more humble work of teaching, which naturally belongs to it. They help one another, and I think that each would lose from being separated from the other; still, in some cases, it might possibly be advisable."

Dr. Siemens, on the other hand, apprehends that the establishment of Government laboratories, which, amongst other functions, should be accessible to private workers, might cause disappointment to some who might not be able to gain access to them, and that there might be favouritism and want of discrimination in the dispensing of the privileges in question.

Dr. Burdon Sanderson would rather see increased facilities given to the great schools of medicine for the prosecution of physiological research, than laboratories of an independent character established. He questions whether we have at present a sufficient number of trained workers to use establishments of the latter kind; whilst Lord Salisbury is doubtful whether by any moderate expenditure of funds we could provide an expensive class of scientific instruments of all kinds for all the persons who might be inclined to use them.

The Commissioners, after fairly balancing the views laid before them, sum up this question in their final conclusions, as follows:—

"More complete means are urgently required for scientific investigations in connection with certain Government departments; and physical as well as other laboratories and apparatus for such investigations ought to be provided."

As reviewers we are of course entitled to our "growl," and this shall be that the two neat maps which illustrate the book are not drawn to the same scale, and while that of Northern Morocco, for which we are especially thankful, takes in a great deal more than Colonel Irby's district, that of Southern Spain leaves out at least as much. With this we bid him farewell.

HOFMANN'S REPORT ON THE PROGRESS OF CHEMICAL INDUSTRY

Bericht über die Entwicklung der Chemischen Industrie während des letzten Jahrzehends; im Verein mit Freunden und Fachgenossen erstattet von Dr. A. W. Hofmann. Autorisirter Abdruck aus dem Amtlichen Bericht über die Wiener Weltausstellung im Jahre 1873. (*Report on the Development of Chemical Industry during the last Ten Years;* in conjunction with friends and fellow-workers. Composed by A. W. Hofmann. Authorised reprint of the official report on the Vienna Exhibition of 1873. Vol. iii. Part I.) (Braunschweig: Fr. Vieweg und Sohn, 1875.)

THE Imperial Commission of Germany for the Vienna Exhibition of 1873 have put the report on the third group, "Chemical Industry," into the hands of Dr.

time, is fully a ninth magnitude, and will be found even with the Berlin chart for Hour 23 of R.A., which is by no means one of the most complete of the series. Metis is another member of this group of planets, at present easily recognised.

D'ARREST'S COMET.—M. Leveau is continuing his researches on the motion of this interesting comet, and has obtained elements which represent with considerable precision the observations in 1851, 1857–58, and 1870; allowance being made for the difficulty of fixing the place of so faint and diffused an object, and for the magnitude of the perturbations due to the action of the planet Jupiter; these perturbations are found to have changed the R.A. of the comet on September 24, 1870, by $-14°\cdot6$, and the declination by $+7°\cdot6$. M. Leveau has employed Bessel's mass for Jupiter, and concludes that it is susceptible only of very small correction. He promises, in a future communication to the Paris Academy of Sciences, to furnish an ephemeris for the next return of the comet to perihelion in the spring of 1877.

ON THE OCCURRENCE IN NEW JERSEY OF SUPPOSED FLINT SCALPING-KNIVES

IN glancing over a considerable series of American stone implements, we quite naturally expect to find that ever-present feature of the modern Indian's outfit, the scalping-knife. In every collection we recognise the stone axe that preceded the iron tomahawk; the jasper arrow and spear heads, now replaced by metallic ones; while neatly edged flints of various shapes give us cutting implements adapted to all ordinary uses; but not so with the scalping-knife. However large the series, we cannot, at a glance, point out a form of knife peculiarly well adapted for such a purpose, from the several shapes before us. While all are *possible* scalping-knives, none *probably* are so. This, at least, has been my experience until very lately, although I have constantly sought out "probable scalping-knives" from thousands of implements gathered and being gathered in this neighbourhood. Among the hundreds of specimens of flint knives there occurred none that resembled the modern knife, and I supposed that the stone scalpers were similar—the later being modelled from earlier form.

Whether the above inference is correct or not, I have at last detected some specimens that more nearly approach the "ideal form," one such being the flint implement here figured. The result of my collecting labours during the past summer amounts to about five hundred specimens not including fragments, and it is among these that I found the cutting implement above mentioned, with several others like it, both perfect and fragmentary. As the illustration shows, better than any description can do, this slightly curved knife seems moderately well adapted for scalping, as described by Loskiel.* He says: "They place their foot on the neck of the victim, seizing the hair with the left hand, and twisting it very tight together, in order to separate the skin from the head; then they cut it all round with a sharp knife, and tear it off." The specimen is a neatly chipped and evenly outlined jasper "implement," having the edges still well defined and sharp. The curved, and I presume cutting edge, is formed by striking off comparatively large flakes, and is better adapted to making a "clean" cut, than the straighter side. The lower end, about one-fourth of the whole length, is somewhat narrower, and while less sharp along its edges, is thinner, and has no median ridge. This portion, very possibly, was inserted into a bone handle as modern Eskimo scrapers now are (vide "Reliquiæ Aquitan." Part ii. p. 14); and if so, we surely have, in the figured implement, one that would conveniently serve as a scalping-knife. In the interest of archæology I should like to experiment with this specimen, but have no available scalp at hand; my own, unfortunately, being quite innocent of hair.

There being no mineral found near here that gives off long thin flakes like true flint or Mexican obsidian, which latter was used for razors by the Mexican Indians, and the shells of our Delaware River unios being too thin and small to serve such a purpose, we must fall back on the jasper and quartz pebbles of the neighbourhood for the material for such knives.

The number of scalping-knives in use at all times must have been considerable, and this fact alone seems counter to my suggestion that the specimen figured may be a scalping-knife, inasmuch as so very few knives of this pattern have been found here. It must be remembered, however, that every warrior would have his knife buried with him, if not killed in battle, when the knife would be lost or stolen; and one such knife would last a lifetime, so that here may be an explanation of their comparative

NAT^L SIZE.

rarity, the great mass of them still lying in the nearly obliterated graves. Or, like smoking pipes, they may have been handed down from one generation to another, their peculiar use rendering them sacred in the eyes of the savage; and when buried with the other "personal effects" of the dead warrior, like the buried pipes, they may have been exhumed by those too lazy to make or too poor to purchase for themselves. That graves were thus robbed is certainly true.

In the graves that I have been fortunate enough to examine I have found cutting implements of jasper, quartz, and slate; and, twice, jasper specimens like the above. These graves to which I refer are now only to be detected by the presence of such imperishable relics as stone implements, pottery, and by the discoloration of the soil. Judging from appearances, the body was placed at full length *on the surface of the ground*, the weapons placed with it being grouped together on the right side, and a vase of rude pottery filled with a red powder at the

* Mission among North American Indians. London, 1794; P. 149.

feet. The body was then probably covered with bark, or skins of animals. Of course the decomposition would go on very rapidly, and soon no trace remain except the bones and stone implements; then the weapons only. My reason for believing these graves to be "surface" burials is in consideration of the fact that the inhumed weapons and discoloured dirt are only from three to six inches beneath the sod, and this accumulation of soil is that arising from the annual decay of the preceding summer's foliage, coupled with the dust that would naturally gather around any object lying on the ground. The graves such as I have described, too, are only to be found on the slopes of grassy hill-sides that as yet have not been disturbed by the plough. I have never seen such a grave in a ploughed field. Such have been long obliterated; and the relics now found in fields may or may not be those that were buried with their prehistoric owners.

In conclusion, then, seeing that the custom of scalping was not introduced with a knowledge of metals, but preceded it, it is certain that some stone implement was used; and if in a large series of cutting tools we find some that bear resemblance to the modern form, then it is fair to presume that these, and these principally if not wholly, were those formerly in use.

A few words concerning this custom of scalping: is it peculiarly North American? I should be much pleased to learn from some correspondent of NATURE what other races, if any, have the same practice among them. Inasmuch as the Indian custom required of every warrior incontestable proof of his success in battle or in single combat, and considering that a warrior would frequently attack singly some member of a hostile tribe (See Catlin's "North American Indians"), it seems quite a natural method of showing beyond doubt that the claimant had indeed killed his foe. To produce any portion of another's clothing, or his weapons, would not prove the enemy to have been killed; to produce his scalp shows that such was certainly the case, as the instances of survival after scalping are too few to be considered. Did the custom originate in North America, or was it brought from beyond our borders?

CHAS. C. ABBOTT

Trenton, New Jersey, Aug. 7

THE SLIDING SEAT FORESHADOWED

IT is a curious and suggestive fact that nearly all the most ingenious and important mechanical inventions find their representatives in the human frame; consequently, the more we investigate the wonderful mechanism of man's body, the more insight may we expect to get into the principles necessary for the most perfect adaptation of means to ends. Whether we take the lever, the pulley, the inclined plane, the spiral or the curved spring, the arch, or any other simple uncomplicated contrivance adapted with a view to securing strength, or motion, or elasticity, we find it represented in animal mechanics, and arranged sometimes simply, sometimes in a more complex form, in a manner and with a result far more wonderful than ever produced from the most ingenious conceptions, of man's brain.

Of late years the application of the sliding seat to rowing has attracted considerable attention, and although it is beyond the purpose of this paper to consider fully the advantages gained by its application, it will, I think, be necessary to make some reference to what appear to be its principles before we inquire whether it can be traced as existing in certain of the joints.

In the mechanics of rowing we may look upon the hips and spinal column as theoretically a firm, unyielding lever (Fig. 3, S), since it is knit together by the power of the muscles in a man thoroughly trained. The object of this fixedness is evidently to avoid the loss of power and time which would occur if parts had to be strung together preparatory to the pull as the oar catches the water. This spinal lever has its fulcrum at what we call the tuberosities of the ischia (t), or in other words at the points of contact of the body with the seat, and the motive power is placed in the muscles of the back and those of the thigh. The weight to be moved will be acted upon

FIG. 1.—Sitting at rest. Showing tip of shoulder behind the line from mastoid process to hip.

through the arms at the junction of the upper extremities with the spinal lever.

As the body moves forwards, the lever formed by the spine rotates round the tuberosities which constitute the fulcrum, and which slide forward at the same time. The knees are consequently slightly bent or separated. As the oar catches the water the body is brought back to the perpendicular by the action of the muscles of the back and those of the thigh, and the lower end of the lever is at the same time carried bodily back a distance of about eight inches.

The whole principle appears to be that of a sliding fulcrum, and the peculiar result seems to be that a greater reach is given with less bending forward of the body; for to obtain the same length of stroke the body must either be bent forward at a much more acute angle or carried back beyond the perpendicular. An increased bending

FIG. 2.—Forward movement in rowing, showing tip of shoulder far in front of the line from mastoid process to hip.

forwards, it must be borne in mind, must interfere with the respiration in a long-continued strain as in a race, and therefore with the staying powers of the individual.

If, on the other hand, the body be carried backwards beyond the perpendicular, the power of recovery is diminished, and far greater work is thrown upon the muscles of the trunk and lower limbs.

With a sliding seat, therefore, we seem to have a provision for greater range of movement at the distal end of the lever. In the upper extremity it seems to me we find the same principle at work, and if so it is curious that we should have adopted as a novelty or an invention what nature has provided us with in other points, that we should apply to the lower extremities in rowing the same principle that already exists in connection with the upper, and is brought into action perhaps especially in rowing, and that this should have been done unknowingly.

The bony framework of the upper limb is connected with that of the trunk at only one point, the inner or sternal end of the collar-bone, and it is round this point that movement occurs. The greatest freedom of motion, however, takes place at the shoulder-joint, and as this joint is, moreover, at the apparent junction of the free limb with the body, the movements here are generally looked into to the exclusion of those at the junction of the collar-bone and breast-bone. But the importance of the latter will at once be recognised when it is considered that the collar-bone and shoulders rotate round the upper part of the breast-bone, and according to their length and mobility will move through a larger or smaller arc.

The amount of movement between the extremes of forward and backward positions of the shoulder (Figs. 1 and 2) can be readily tested, and I have found that the average of several observations on different individuals, taken at the tip of the shoulder, the chest being absolutely fixed, is from six to seven inches; or, in other words, the tip of the shoulder moves backwards and forwards to that extent between the extremes of forward and backward movement.

Similarly in the vertical line a large extent of motion occurs, the difference between the extremes being on the average four inches. Now, when it is noticed that the arm moves at the shoulder-joint with an extraordinary amount of facility, and that its chief motions as a mechanical appendage to the trunk occur in that articulation, we are led to look upon the arm, fore-arm, and hand as a compound lever, working with its one end free and the other rotating in the socket of the shoulder-joint.

In the lower extremity we also find the compound lever working with one end somewhat similarly in a socket. In the case of the upper, however, the socket is a movable one, slipping backwards and forwards freely with the limb and strangely increasing its range of motion; still capable of being fixed firmly in position by the superficial muscles of the back. But in the lower extremity the socket is fixed, and there is no provision for sliding, since strength rather than range of motion is wanted, and where greater range of motion is needed, as in rowing, there a blind application of the principle found in the upper extremity has been only recently effected.

I have referred only to the sliding fulcrum at the shoulder as seen on both sides equally, and as is best exemplified in the position of the arms in rowing, when however the whole trunk also moves; but it must be borne in mind that a still further sliding of the fulcrum is constantly taking place when one hand alone is used, for the chest is also turned towards the object to be reached, by rotating and flexing the spine. The advantage of the vertical motion is seen in such actions as bell-ringing, weight-lifting, &c. Moreover it must be noticed that when the lever forming the arm is raised from the side to a right angle with the body it has reached its limit of motion at the shoulder-joint, and that subsequently the upward motion occurs in the collar-bone, since the top of the shoulder checks the further movement of the arm upwards. There is in connection with the lower extremity a somewhat similar mechanical arrangement, which is not however brought into play so fully as in the upper. The sockets of the hip-joints can be brought forward by a rotation of the spine. This is especially noticeable in those who are prevented from using their feet freely, where therefore the elasticity and spring which are so wonderfully provided in the foot are lost, and the length of stride is obtained by the utmost use of mechanical advantages commonly unused in connection with the hip. Ploughmen and labourers whose feet are cased in unyielding clogs walk from the hips, or in other words they slide the fulcrum forwards by rotating the spine, whereby they gain a larger stride.

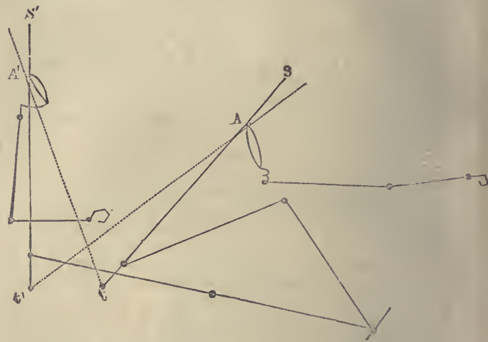

FIG. 3.—Diagram to show sliding-seat action at the shoulders. In the forward position the arm is thrown forward so that the shoulder is about three to four inches in front of the spinal line S A t. In the backward position the same point is about one to two inches behind the same line S' A' t', the whole movement occurring at the sterno clavicular articulation. The sliding of the tuberosities of the ischia backwards in this movement is equal to about eight inches (t to t'). The dotted lines show the degree of forward or backward movement of the body which would be necessary to gain the same range of arm-movement, if the tuberosities were fixed and no sliding were used.

Such then are some of the curiosities of animal mechanics seen in our wonderful framework, and the subject would repay us in interest as well as in usefulness if studied more by those who are concerned in mechanics generally.

W. W. WAGSTAFFE

St. Thomas's Hospital

THE BRITISH ASSOCIATION

BRISTOL, *Tuesday Night*

OUR meeting has nearly run its course, and may so far be pronounced a great success. Brilliant weather has been added to hospitality and to skilful direction, and has produced a generally harmonious result. We may certainly expect that the Association, not less than the Bristol people, will desire a repetition of the visit within somewhat fewer than forty years.

Partly owing to the comparative weakness of the President's voice, and partly to the deficient acoustic properties of Colston's Hall, the President's address was not quite so successful as it might otherwise have been. Even Prof. Tyndall had to strain his voice considerably in order to be well heard. Perhaps the most forcible ideas left on the mind by Sir John Hawkshaw are his patience and caution, his dislike for taking leaps in the dark, and his eager desire to take steps in advance when the way can be seen with tolerable clearness. His modesty in not referring to any of his own great achievements, when pertinent references might have been made, was very noticeable. Prof. Tyndall, in his admirable opening address, spoke as follows :—

"It is my privilege to introduce to you as your president for the coming year Sir John Hawkshaw, a name celebrated throughout the world for the practical application to works of the greatest magnitude of some of these sciences which it is the function of this Association to foster and advance. In him, I doubt not, you will have a wise and prudent head, a leader not likely to be caught

up into atmospheric vortices of speculation, about things organic or inorganic, about mind or matters beyond the reach of mind, but one who, struggling, Antæus-like, with his subject here to-night, will know how to maintain throughout a refreshing contact with his mother earth. I have looked forward for some time to the crowning act still in prospect of his professional career, to give our perturbed spirits rest in crossing the Channel in visiting our fair sister France. But pending that great achievement, it is his enviable lot to steer this British Association through calm waters to a haven of, at all events, temporary rest—rest all the more sweet and needful from the tempestuous weather which rasher navigators who preceded him thought it their duty to encounter rather than to avoid. To his strong hand I commit the helm of our noble barque, wishing him not only success, but triumph in that task he has undertaken, and which I now call upon him to fulfil."

Both papers and discussions have been of very high interest. Some of the papers mark epochs in science: such as Prof. Cayley's, on the theory of chemical combinations. The Transit of Venus, the proposed flooding of the Sahara, the Deep-sea Fauna, oceanic circulation, Murchison's classification of Palæozoic strata, the ethnography of races at the commencement of civilisation, the Channel and Severn tunnels, the coal question, and railway safety, may be mentioned among the chief subjects of wide interest. Social subjects have had a full share of attention, considering the pre-scientific stage in which most of them are.

Some of the personally interesting scenes have been rather notable—as when Sir W. Thomson, in relation to Mr. Croll's assault on Dr. Carpenter's doctrines of oceanic circulation, pronounced that Dr. Carpenter's demonstration was most conclusive and his reasons irrefragable; when Prof. Hull, criticising Prof. Hughes, said he had never before heard so many heresies in so few minutes; if it were possible for his hair to stand on end it would immediately begin to friz out from the centre to the circumference; and when Mr. John Evans, Canon Tristram, and Canon Rawlinson combined to give a wholesome exposition of sound doctrine in ethnological subjects and of the relative value of various kinds of evidence, after the reading of a paper which was destitute of scientific principles.

Dr. Carpenter was as happy as ever in his lecture to working men, on "A Piece of Limestone." He had a great audience of unmistakeable working men, with whom he placed himself in most cordial *rapport*.

Mr. Samuel Morley, M.P., after the lecture, said the subjects of the Association meeting were those in which working men were deeply interested, for the competition of manual labour must give way to the competition of intellect. Men who wanted to get on, and masters who wished to hold their own, must unite in promoting, by their own investigation, the knowledge and the philosophy which were to be found in, or connected with, their various manufactures. Mr. Bramwell's lecture was of a useful kind, but defended engineers and railway directors perhaps too much.

Mr. Spottiswoode's lecture on the Colours of Polarised Light was very successful both in exposition and in experimental illustration. The lecturer used a splendid instrument, in which two Nicol's prisms of great size, and beautifully cut, serve the purpose of polariser and analyser, with which he was able to secure the maximum of illumination with a large field of view. The meeting was made more interesting by Sir John Hawkshaw's announcement that the President of the French Association sitting at Nantes had that day telegraphed an expression of their good will and of their wishes for the success of the Bristol meeting. His call for a manifestation of their hearty reciprocation of those feelings was responded to with enthusiasm.

Since no other sectional address was delivered on Friday morning, Prof. Rolleston had a crowded audience to hear his address to the Anthropological Department of Section D. His auditors had one of the greatest treats the meeting has afforded, and the vigorous individuality, the vivacity of thought and action, the boldness and fearlessness, and the wit, scholarship, and research of the Professor must have been vividly impressed on many. At the commencement of the address, when he had to give directions for the opening of an extra door in order to allow a crowd of persons in the corridor outside to hear him, his sudden sally describing their desire to enter "for reasons inscrutable to me" was highly characteristic and appreciated; and the passages in which he spoke of the relative capacity of female crania compared to men's in former and present days, the toleration of nuisances and epidemics, the deterioration and improvement of races, and the value of missionary labours, were listened to with deep attention.

The microscopical *soirée* on Thursday evening was a very great success, and the Association owes its hearty thanks to Messrs. W. Tedder and J. W. Morris, the secretaries respectively of the Bristol and Bath Microscopical Societies, and to the members of those societies. A bold idea was well carried out, viz., that of exhibiting chiefly living objects. The 110 microscopes were arranged in classified divisions, devoted to Crustacea, Arachnidans, Insecta, marine and fresh-water fauna, ciliary action, vertebrate circulation, vegetable circulation, fertilisation of flowers, Cryptogamia, microspectroscopes, &c. The idea of practically illustrating Sir John Lubbock's "Fertilisation of Flowers by Insects" was novel, and so far carried out as to give a vivid idea of the processes to those who were previously unfamiliar with them. The geological division included an exhibition of the perennial *Eozoon canadense*, which must be exhibited again and again to live down the hostility to its animal nature. Altogether the exhibition was a great evidence of scientific enthusiasm, which had led many ardent students to make special dredging and fishing expeditions both in inland and marine waters.

The Museum of the Bristol Museum and Library Society has been a very considerable attraction. Bristol is exceptionally fortunate in its museum, to which the local Naturalists' Society, the Clifton Zoological Society, and many travellers and sea-captains have contributed. In Zoology it contains many valuable specimens, such as the large Gorilla from the River Gaboon, W. Coast of Africa, both the skeleton and stuffed skin being well preserved; the fine skeletons of *Manatus australis* and *otaria* from the Chilian coast; the ancient Peruvian human skulls from Arica and Islay; the very large Green Turtle's skeleton from Ascension Island. The fossil collection is still more notable, for it contains many unique and type-species of carboniferous fishes. The grand collection of Ceratodus teeth, rescued recently from purchase by Americans, is placed close to a specimen of *Ceratodus forsteri* from Australia, with jaws and teeth detached. The additions to the Museum buildings now in course of erection, which include the fine lecture-theatre in which Section C is accommodated, have enabled the local committee to find room for a local loan collection of natural history, in which Bristol ornithology and entomology are specially well represented.

The rich local flora is well represented by the efforts of the botanical members of the Naturalists' Society. Sixty comparatively rare species are exhibited. A convenient handbook to the local museum and temporary additions has been published. Messrs. Tawney, Stoddart, Wheeler, Derham, and many others have worked zealously to make this one of the most successful of the *et ceteras* at this meeting.

The temporary museum of objects illustrating papers

or reports read before the Sections, has been well stocked, and superintended by Mr. J. E. Taylor.

In accordance with resolutions presented at the Belfast meeting, the Council this year memorialised Government to take action in reference to several subjects connected with the advancement of science. First, in March this year, Prof. Tyndall addressed Government in the name of the Council, urging upon them the desirableness of continuing solar observations in India. In accordance with this request, Lord Salisbury urged upon the Governor-General of India the advisability of establishing at Simla a Solar Observatory to continue the work which is to be carried on at Roorkee in 1875-6. Secondly, the Council urged upon Government the importance of appointing naturalists to vessels engaged on the coasts of little-known parts of the world. The Admiralty thanked the Council for their suggestion. The third resolution was that the Council be requested to take such steps as they may think desirable with the view of promoting any application that may be made to her Majesty's Government by the Royal Society for a systematic physical and biological exploration of the seas around the British Isles. The Council have deferred the consideration of this resolution until action be taken by the Royal Society. The fourth resolution supported the equipment of an Arctic Expedition: with what success the efforts in this direction have been crowned, everybody knows.

The balance-sheet of the Association for 1874-5 shows a balance in hand, at the commencement, of 714*l.*; receipts from subscriptions, 2,324*l.*; dividends, 238*l.* Payments were—for Belfast meeting, 405*l.*; Report of Bradford meeting, 689*l.*; salaries, 470*l.*; rent, &c., 104*l.*; grants, 960*l.*; balance in hand, 624*l.* The estimate for 1875-6 was as follows:—Receipts at Bristol, 2,316*l.*; supposed additional members' subscriptions, 230*l.*; total estimated income, 3,438*l.*; probable expenses at Bristol, 430*l.*; printing Belfast Report, 720*l.* A balance of 1,713*l.* was shown, from which grants might be made. The number attending the meeting is approximately as follows:—Life members, 265; annual members, 385; associates, 860; ladies, 670; foreign members, 16; total, 2,196. Number at Belfast, 1,938.

Glasgow has been chosen as the place of meeting for next year, and Plymouth for 1877.

Sir Robert Christison has been chosen President-elect of the meeting at Glasgow. The Vice-presidents for the Glasgow meeting were elected as follows:—The Duke of Argyll, Sir W. Stirling Maxwell, Sir William Thomson, the Lord Provost of Glasgow, Dr. Allen Thomson, and Prof. A. C. Ramsay. The general secretaries and treasurer were re-appointed, and the Glasgow meeting was fixed to commence on Wednesday, Sept 6, 1876.

REPORTS

The Report of the Committee on Specific Volumes, consisting of Professors Roscoe, Balfour Stewart, and Thorpe, was presented by Dr. Thorpe.—The committee have undertaken to report on the validity of Kopp's laws concerning the specific volumes of liquids. The greater portion of the experimental part of the investigation has been finished, but the reduction and calculation of the results have still to be completed, and the committee will not be able to present their final report until the next meeting of the Association.

Report on Dredging off the Coast of Durham and North Yorkshire in 1874, by David Robertson and G. S. Brady.—The greatest number of novelties occurred among the Copepoda, twenty-eight species being new to science, and eleven others new to British records. Twenty-one species are added to the list of testaceous mollusca prepared by the late Mr. Alder; other orders afforded new species. Much interesting information was obtained about the distribution of the species. While the testaceous mollusca show distinctly boreal characters, in the Ostracoda and Foraminifera this is by no means so apparent. The reporters do not suppose that a cold arctic current is the only or even perhaps the chief agent in the continued existence of this peculiar Northumbrian molluscan fauna; consequently some more local circumstances must be looked to as the chief causes of the retention of the species in question over particular circumscribed areas. Copious particulars of the dredgings are given, with full lists of species.

Report on the Zoological Station at Naples.—At present the station possesses twenty-one working tables, of which seventeen are occupied or bespoken. Each table is in itself a condensed laboratory; it is supplied with a number of small working aquaria, with a constant stream of sea-water. The animals for study are provided by the station. The large aquarium of the station can also be used by students for suitable purposes. The library has already become a fairly extensive one, being especially rich in embryological works. Students may accompany and take part in the fishing and dredging expeditions of the station. The large aquarium is partly a popular exhibition, which helps to support the station. The staff consists of Dr. Dohrn, the general director; Dr. Eisig, his responsible assistant; two other scientific assistants, one to superintend the large aquarium and the fishing, and the other to arrange for the collection and preservation of animals; three engineers, four house servants, and four fishermen. The work facilitated by the station is of the following kinds:—1. Morphology and embryology of marine animals; this requires that students should visit the laboratory at the periods when the specimens required can be obtained. 2. Physiological investigation of marine animals, so little worked at hitherto. 3. Study of the habits of marine animals. 4. Systematic investigation of marine fauna and flora of the Mediterranean in the vicinity of Naples. Few tasks are more promising than a thoroughly systematic dredging of the Bay of Naples. Animal forms naturally occupy the chief attention at the station, but no less facilities are offered for the study of marine vegetable forms. This is significantly indicated by the fact that Prof. Cohn, of Breslau, and Prof. Reineke, are to visit the station next session to carry on algological researches. 5. Physical investigation of the sea in the neighbourhood of Naples, with the periodic appearance and disappearance of certain animals in shoals or large numbers. 6. Experiments on breeding and preserving delicate marine organisms in a healthy condition. 7. Transmission of specimens to investigators at home.

The scientific results of the station have been very considerable, and the students have included some of the most distinguished biologists. Next winter Dr. Dohrn proposes to begin a series of annual accounts of the work done at the station. When all the tables are taken up, it is calculated that with strict economy the institution will pay its working expenses. But it would be of the highest value if governments, universities, and public institutions would support the station to a much greater extent than at present.

Intestinal Secretion.—A second report was presented by the Committee on Intestinal Secretion—Dr. Brunton and Dr. Pye Smith. The report detailed a number of experiments which the committee had undertaken, and which were considered to prove the absence of influence on Intestinal Secretion through the splanchnic nerves, the pneumogastrics, the sympathetic above the diaphragm or the spinal marrow; and the probable influence of the ganglia contained in the solar plexus, though certainly not of the two semilunar ganglia exclusively. Also the independent occurrence of hæmorrhage and of paralytic secretion appeared, in the view of the committee, to point to a separate nervous influence on the blood-vessels and the secreting structures of the intestines. They also observed the occurrence of vomiting after section of both splanchnics and vagi.

SECTIONAL PROCEEDINGS

SECTION A—MATHEMATICS

The Section was well filled to hear Prof. Balfour Stewart's address, in spite of the great counter attraction offered by Mr. Froude's address and experiments which were taking place simultaneously in the room underneath, Section G. After the conclusion of the address, and after a cordial vote of thanks, moved by Col. Strange and seconded by Rev. R. Mason, had been accorded to Prof. Stewart, Prof. Everett gave in a few words the report of the Underground Temperature Committee, specially referring to the observations recently made at the St. Gothard Tunnel, at Chiswick, and at Swinderby near Lincoln. Prof. Guthrie then showed his experiments on the measure-

ment of the rate of wave progress. His apparatus consisted of three deep troughs, two circular and one rectangular, and the steadiness of the motion in each was remarkable; he compared the velocities of the waves with the times of vibrations of pendulums, and verified that in different sized troughs the rate varied inversely as the square root of the diameter. The experiments excited a good deal of interest.

The Rev. S. J. Perry, of Stonyhurst College (one of the members of the expedition to Kerguelen to observe the Transit of Venus), read a paper on that event. Father Perry illustrated his remarks by diagrams of the sun and the planet, as seen from various stations, and gave a very interesting explanation which was attentively listened to. He said that although much prominence had not been given to the idea, he believed that a very important reason why so much expense was gone into in the expedition was that the distance of the earth from the sun entered into the calculation of lunar tables. The observations were not of any striking nature; they were simply to watch a black spot pass across the sun. There was nothing exciting about it, except that when the observations had to be taken they had to be very careful about the precise time, and they had to observe the spot during the whole time of its passage. Having pointed out with reference to his diagrams the reason why the different stations were chosen, he denied the assertions that had been made that Sir George Airy neglected Halley's method of observation for Delile's; the truth was he had rightly decided in favour of Delile, but he had not neglected Halley. With regard to the (Halleyan) stations in the extreme north, they were left to the care of the Russians, and the English, French, Americans, Germans and others occupied in the southern hemisphere. As it was mid-winter, the sun was very nearly on the line of the southern tropics and nearly vertical at ingress over the eastern border of Australia. There were primarily five English Government expeditions, but as these were subdivided, there were, including private observers and those of India and the Colonies, about twenty English stations of observation. His station was Kerguelen, to the south-west of Australia, and after arriving there they found that the Americans had taken the station recommended by the members of the *Challenger* Expedition, but in spite of that they had plenty of time to look about the island (which was a very barren place, about ninety miles by forty-five), and they were fortunate enough to get a much better position than the Americans, after all, by going a little to the south-west. They had been told before they went out that there was always a mist over the island, but, though that might be the case in the north of the island, which had been chiefly visited before, it did not apply to the south while they were there, and they had not more mist than there would have been in London. On the morning of the transit, which they expected to begin at 6·30, they rose at four, and at once made preparations for the day's work. They were divided into three parties, and were so placed that, with the Americans, they formed four parties, about eight miles distant from each other. They saw the sun very well until after six o'clock, at the first (his own) station, until almost the time that Venus was coming on to the sun's disc, and they had the external contact as well as could be expected, for there never could be absolute certainty with regard to such a point. They continued very well until they had taken the bisection by the planet of the sun's disc, but then there was just one little cloud that came and placed itself right over the planet and remained till ten minutes after the commencement of the transit. At the other stations they were able to make observations of the ingress. At his station they were able to get observations of the internal and external contact at egress, and a few photographs. Father Perry added particulars of the result of observations at the other stations as far as could be ascertained, and narrated his experience of a cyclone in the Indian Ocean on the homeward passage. He added that during their stay on the island they not only made astronomical observations, but also a series of magnetic and meteorological observations; and the Rev. A. E. Eaton was sent by the Royal Society to study the botany of the island.

In answer to a gentleman, Father Perry said if they got the results of the observations in seven years' time they would be very lucky, as they had first to determine their longitude, and that occupied a very long time.

Prof. Osborne Reynolds read a paper *On the Refraction of Sound by the Atmosphere*, in which he remarked that in previous papers he had pointed out that the upward diminution of temperature in the atmosphere (known to exist under certain circumstances by Mr. Glaisher's balloon a cents) must refract and give an upward direction to the rays of sound which would otherwise proceed horizontally, and it was suggested that this might be the cause of the observed difference of the distinctness with which similar sounds were heard on different occasions, particularly of the very marked advantage that the night has over the day in this respect. On this subject he had made a series of experiments. He mentioned a case in which at sea, when leaving a yacht in a small boat, for the purpose of making experiments on sound, those in the yacht and the boat were able to call to one another, and he heard at a distance of three-and-a-half miles, and that the hiss and report of a rocket sent up from the yacht was heard at a distance of five miles. Also on the same occasion the barking of a dog on shore, which was eight miles distant, was heard, and the paddles of a steamer which must have been fifteen miles off were distinctly audible. Prof. Reynolds remarked that the distinctness with which sounds of such comparatively low intensity could be heard was perhaps beyond anything definitely on record, although remarkable instances of sounds heard a long way off were occasionally heard of. As the result of a series of experiments made by means of an electric bell, Prof. Reynolds found that when the sky was cloudy and there was no dew, the sound could invariably be heard much further with than against the wind; but when the sky was clear, and there was a heavy dew, the sound could be heard as far against a light wind as with it. On one occasion in which the wind was very light and the thermometer showed 39° at one foot above the grass, and 47° at eight feet, the sound was heard 440 yards against the wind and only 270 yards with it.

The paper by Prof. G. G. Stokes and Dr. J. Hopkinson, *On the Optical Properties of a Titano-silicic Glass*, we give *in extenso* on account of its importance. At the meeting of the Association at Edinburgh in 1871, Prof. Stokes gave a preliminary account of a long series of experiments in which the late Mr. Vernon Harcourt had been engaged, on the optical properties of glasses of a great variety of compositions, and in which since 1862 Prof. Stokes had co-operated with him.* One object of the research was to obtain, if possible, two glasses which should achromatize each other without leaving a secondary spectrum, or a glass which should form with two others a triple combination; an objective composed of which should be free from defects of irrationality without requiring undue curvature in the individual lenses. Among phosphatic glasses, the series in which Mr. Harcourt's experiments were for the most part carried on, the best solution of this problem was offered by glasses in which a portion of the phosphoric was replaced by titanic acid. It was found, in fact, that the substitution of titanic for phosphoric acid, while raising, it is true, the dispersive power, at the same time produces a separation of the colours at the blue, as compared with those at the red end of the spectrum, which ordinarily belongs only to glasses of a much higher dispersive power. A telescope made of discs of glass prepared by Mr. Harcourt, was, after his death, constructed for Mrs. Harcourt by Mr. Howard Grubb, and was exhibited to the Mathematical Section of the late meeting in Belfast; this telescope, which is briefly described in the Report,† was found fully to answer the expectations that had been formed of it as to destruction of secondary dispersion.

Several considerations seemed to make it probable that the substitution of titanic acid for a portion of the silica, in an ordinary crown glass, would have an effect similar to that which had been observed in the phosphatic series of glasses. Phosphatic glasses are too soft for convenient employment in optical instruments, but should titano-silicic glasses prove to be to silicic what titano-phosphatic glasses have been found to be to phosphatic, it would be possible, without encountering any extravagant curvatures, to construct perfectly accurate combinations out of glasses having the hardness and permanence of silicic glasses; in fact, the chief obstacle at present existing to the perfection of the achromatic telescope would be removed, though naturally not without some increase to the cost of the instrument. But it would be beyond the researches of the laboratory to work with silicic glasses on such a scale as to obtain them free from striæ, or even sufficiently free to permit of a trustworthy determination of such a delicate matter as the irrationality of dispersion.

When the subject was brought to the notice of Mr. Hopkinson, he warmly entered into the investigation, and thanks to the liberality with which the means of conducting the experiments

* Report for 1871. Transactions of the Sections, p. 38.

† Ditto for 1874. Transactions of the Sections, p. 26.

were placed at his disposal by Messrs. Chance Brothers, of Birmingham, the question may perhaps be considered as settled. After some preliminary trials, a piece of glass free from striæ was prepared of titanate of potash mixed with the ordinary ingredients of a crown glass. As the object of the experiment was merely to determine in the first instance whether titanic acid did or did not confer on the glass the universal property of separating the colours at the blue end of the spectrum materially more, and at the red end materially less, than corresponds to a similar dispersive power in ordinary glasses, it was not thought necessary to employ pure titanic acid; and rutile fused with carbonate of potash was used as titanate of potash. The glass contained about seven per cent. of rutile, and as none was lost, the percentage of titanic acid cannot have been much less. The glass was naturally greenish from iron contained in the rutile; but this did not affect the observations, and the quantity of iron would be too minute sensibly to affect the irrationality.

Out of this glass two prisms were cut. One of these was examined as to irrationality by Prof. Stokes, by his method of compensating prisms; the other by Mr. Hopkinson, by accurate measures of the refractive indices for several definite points in the spectrum. These two perfectly distinct methods led to the same result, viz., that the glass spaces out the more as compared with the less refrangible part of the spectrum no more than an ordinary glass of similar dispersive power. As in the phosphatic series, the titanium asserts its presence by a considerable increase of dispersive power; but, unlike what was observed in that series, it produces no sensible effect on the irrationality. The hopes therefore that had been entertained of its utility in silicic glasses prepared for optical purposes appear doomed to disappointment.

A paper was read by Mr. J. A. Fleming, *On the Decomposition of an Electrolyte by Magneto-electric Induction.* When a solid conductor is moved in a magnetic field induced currents are created in it. In a solid these expend themselves partly or wholly in producing heat in the conductor. The paper was occupied with an examination of the effect produced on electrolytes under the same circumstances, viz., when made to flow or move in a magnetic field: experiments were described to show first that induced currents are produced under these conditions in electrolytes, and then that the electrolyte is to some extent decomposed by these currents.

Dr. Moffat, in his paper *On the apparent connection between Sunspots, Atmospheric Ozone, Rain, and Force of Wind,* stated that in discussing ozone observations from 1850 to 1869, he had observed that the maxima and minima of atmospheric ozone occurred in cycles of years, and that he had compared the number of new groups of sunspots in each year of these cycles with the quantity of ozone, and the results showed that in each cycle of maxima of ozone there is an increase in the number of new groups of sunspots, and in each cycle of minima a decrease. He also gave a table to show that the years of maximum ozone and number of sunspots were generally distinguished by an increase in the quantity of rain and the force of the wind.

Sir W. Thomson's paper *On the effects of Stress upon the Magnetism of Soft Iron* was a continuation of two that had been read before the Royal Society. In the physical laboratory at Glasgow University he had stretched steel and soft iron wire about twenty feet long from the roof. An electro-magnetic helix was placed round a few inches of the wire, so that the latter could be magnetised when an electric current was passed through the former; the induced current thus produced in a second helix outside the first being indicated by a reflecting galvanometer. When steel wire was used, the magnetism diminished when weights were attached to the wire, and increased when they were taken off; but when specially made soft iron wire (wire almost as soft as lead), the magnetism was increased when weights were put on, and diminished when they were taken off. Afterwards he discarded the electrical apparatus, and by suspending a piece of soft iron wire near a magnetometer consisting of a needle, a small fraction of a grain in weight, with a reflecting mirror attached, the wire was magnetissed inductively simply by the magnetism of the earth, and changes in its magnetism were made by applying weights and strains, the changes being then indicated by the magnetometer.

Prof. W. F. Barrett read a paper *On effects of Heat on the molecular Structure of Stee Wires and Rods,* in the course of which he said he found that if steel of any thickness be heated by any means, at a certain temperature the wire ceases to expand, although the heat be continuously poured in. During this period also the wire does not increase in temperature. The length of time during which this abnormal condition lasts varies with the thickness of the wire and the rapidity with which it can be heated through. It ceases to expand, and no further change takes place till the heat is cut off. When this is done the wire begins to cool down regularly till it has reached the critical point at which the change took place on heating. Here a second and reverse change occurs. At the moment that the expansion occurs, an actual increase in temperature takes place sufficiently large to cause the wire to glow again with a red-hot heat. It is curious that this after-glow had not been noticed long ago, for it is a very conspicuous object in steel wires that have been raised to a white heat and allowed to cool.

Mr. Braham exhibited some experiments on magnetised rings, plates, and discs of hardened steel, and also experiments on air, hydrogen and oxygen.

SECTION D.

Biology.

Opening Address by Dr. P. L. Sclater, M.A., F.R.S., F.L.S., President.

On the Present State of our Knowledge of Geographical Zoology.

In the office, which I have now held for more than sixteen years, of Secretary to the Zoological Society of London, I have been not unfrequently requested by our members and correspondents in various parts of the world to furnish them with information as to the best works to be consulted on the zoology of the countries in which they are respectively resident, or which they are about to visit. With the well-furnished library of the Zoological Society at my command this is not usually a very difficult task, so far as publications are actually in existence to supply the desired information. I am also frequently asked to point out the principal deficiencies in our knowledge of the animals of particular countries. This is also a not very difficult request to reply to, although it is somewhat embarrassing on account of the very imperfect information which we still possess of geographical zoology generally, and the largeness of the claims I am therefore constrained to put forward for the attention of those who make such inquiries. Great, however, has been the progress made of late years towards a more complete knowledge of the faunas of the various parts of the world's surface. Expeditions have been sent out into countries not previously explored; collections have been formed in districts hitherto little known; and many general works have been published, combining the results of previous fragmentary knowledge on this class of subjects. Under these circumstances I have thought that such an account as I might be able to give of the general progress that has been recently made towards a better knowledge of the zoology of the various parts of the earth's surface, accompanied by a series of remarks upon the best available authorities to be consulted upon such subjects, might supply a want which, as above mentioned, I know by personal experience is often felt, and at the same time would form a not inappropriate address from the chair which I have now the honour to occupy.

I must premise, however, that my observations must be restricted mainly to the terrestrial members of the sub-kingdom Vertebrata. To review the recent progress of our knowledge of the various sections of invertebrate animals in different countries would be beyond my powers, and would inordinately enlarge my subject. Besides, it is certain that the higher classes of animals have occupied the principal attention of recent writers on geographical zoology, and it is with their distribution that we are best acquainted.

Taking, therefore, the seven great regions into which the earth's surface may be most conveniently divided for zoological purposes one after another, I will endeavour to point out our leading authorities on the Mammals, Birds, Reptiles, Batrachians, and Fishes of each of them, and their main constituent parts. At the same time, I will endeavour to indicate the principal deficiencies in our knowledge of these subjects, and may perhaps be able to add a few suggestions as to how some of these deficiencies might be best overcome.

In these remarks I will take the divisions of the earth's surface

in the same order as I have generally used in my lectures on zoological geography, namely :—

I.—Palæarctic Region II.—Ethiopian Region IIa.—Lemurian Sub-region III.—Indian Region IV.—Neartic Region	*Arctogæa.*
V.—Neotropical Region Va.—Antillean Sub-region	*Dendrogæa.*
VI.—Australian Region . . .	*Antarctogæa.*
VII.—Pacific Region	*Ornithogæa.*

I.—THE PALÆARCTIC REGION.

The Palæarctic Region I shall consider for convenience sake in the following seven sub-regions :—

1. The *Cisatlantean Sub-region*, embracing all that part of the Palæarctic Region lying south of the Mediterranean Sea.

1*a*. The Atlantic Islands.

2. The *European Sub-region*.

3. The *Siberian Sub-region*, embracing the whole of Northern Asia.

4. The *Mantchurian Sub-region*, containing Northern China and the adjoining part of Mongolia.

5. The *Japanese Sub-region*, embracing the Japanese Islands.

6. The *Tartarian Sub region*, containing the great desert-region of Central Asia.

7. The *Persian Sub-region*, embracing Persia, Asia Minor, and Syria.

1. The Cisatlantean Sub-region.

As regards the zoology of the main western portion of this district (Tunis and Algeria) our knowledge may be now said to be pretty far advanced. The standard work on the subject is the "Exploration Scientifique de l'Algerie" published by the French Government, in which are treatises on the Mammals and Birds of Algeria by Loche, and on the Reptiles and Fishes by Guichenot. This work was commenced in parts in 1840, and the portions relating to the Mammals and Birds were, I believe, intended to have been written by M. Vaillant, the artist of the Commission ; but only the plates were issued, and the text by Captain Loche was not completed until 1867. A smaller and more convenient work for travellers is the last-named author's catalogue of the Mammals and Birds of Algeria, published in 1858.

As regards the herpetology of Algeria, an excellent memoir on this subject by Dr. Alexander Strauch will be found in the fourth volume of the new memoir of the Academy of St. Petersburg. Those who penetrate beyond the Atlas will find the lists of the vertebrated animals appended to Canon Tristram's "Great Sahara" very useful. Many interesting details about the birds of Tunis and Algeria will likewise be found in the papers communicated to the "Ibis," by Messrs. Salvin, Tristram, and J. H. Gurney, jun.

Of Morocco and the extreme western portion of the Atlas, our knowledge is as yet by no means so perfect. As regards the birds of Tangier and its vicinity, we have Colonel Irby's lately published volume on the Ornithology of the Straits of Gibraltar, in which the "observations on the Moorish birds are in a great measure culled from the MSS. of the late M. Favier—a collector long resident in Tangier." But in the south of Morocco, in the Western Atlas and surrounding district, there is certainly a considerable *terra incognita* within easy reach of England, which has hitherto been almost inaccessible to naturalists, though the short expedition of Dr. Hooker, Mr. Maw, and Mr. Ball in 1871 (of which a notice only has been published, but a complete scientific account is, I believe, in preparation), shows that it *may* be penetrated if proper precautions are taken.

1*a*. *The Atlantic Islands.*

The Atlantean island-groups of the Canaries, Madeira, and the Azores, may perhaps be most naturally appended to this division of the Palæarctic Region. Our knowledge of the fauna of each of these three groups is tolerable, although there is of course much to be done in working up details. As regards the Canaries, the standard work is Webb and Berthelot's "Histoire Naturelle des Iles Canaries," published at Paris under the auspices of the Minister of Public Instruction. Dr. Carl Bolle has visited the group more recently, and written several excellent articles in Cabanis's Journal on their ornithology.

Madeira has had the advantage of the residence of several first-class English naturalists—I need only mention the names of Lowe, Vernon, Wollaston, and Johnson, to establish this point. More than twenty years ago Mr. E. W. Harcourt, in his "Sketch of Madeira," and in contributions to the "Proceedings of the Zoological Society," and "Annals of Natural History," gave us a good account of the ornithology of Madeira. Mr. F. Godman has recently published an excellent article on the Birds of Madeira and the Canaries in the "Ibis" for 1872, in which a complete *résumé* is given of the whole of our previous knowledge of this subject, together with the information obtained by the author himself during his expedition to these islands in 1871.

As regards the fishes of Madeira, they have formed a subject of study of several excellent ichthyologists. The Rev. R. T. Lowe made numerous communications to the Zoological Society of London upon them in the early days of the Society, and published in their "Transactions" a Synopsis of Madeiran Fishes, to which divers supplements were afterwards added. Subsequently Mr. J. Y. Johnson took up the subject and made numerous additions to Mr. Lowe's experiences, which were mostly published by the same Society. Dr. Günther has likewise contributed to our knowledge of Madeiran fishes, so that on the whole there is, perhaps, hardly any locality out of Europe with the ichthyology of which we have a better general acquaintance.

For our knowledge of the higher animals of the third island-groups above spoken of, that of the Azores, we are mainly indebted to the energy of Mr. F. D. Godman, who made a special expedition to those islands in 1865, with the object of studying their fauna. The results are embodied in his volume on the Azores, published by Van Voorst in 1870. Morelet's work on the Azores, previously published, is mainly devoted to the Land-shell. Mr. Godman is almost the only authority upon the Mammals, Birds, and other Vertebrates.

2. The European Sub-region.

To discuss, or even to give the titles of, all the works that have been published on the Vertebrates of Europe would extend this address to far beyond its proper limits. I must content myself with a few words on the principal works which have appeared of late years—first, upon the Zoology of Europe generally, and secondly, upon the Faunas of its chief political divisions.

A. *Mammals of Europe.*

To begin with the Mammals, our standard authority upon the European members of this class is Blasius's "Naturgeschichte der Saugethiere Deutschlands und der angrenzenden Länder," and an excellent work it is. Unfortunately, however, it does not extend into Southern Europe, where alone many of the more interesting forms of European Mammal-life make their appearance. A work founded on Blasius's volume and embracing the additional species of Mammals to be met with in Spain, Italy, and Turkey is very desirable, and it is with great pleasure that I have been informed that an energetic member of this Association has already set some such undertaking before him. The only work of reference of this extent that I am at present acquainted with is Lord Clermont's useful "Guide to the Quadrupeds and Reptiles of Europe," published in 1859. As regards the constituent countries of the European Sub-region, there are but few recommendable works devoted to the illustration of their Mammal-faunas. In England we have Bell's "British Quadrupeds," belonging to Mr. Van Voorst's excellent series. This remained long out of print, until its recent re-issue in 1874 by the author, with the assistance of Mr. R. F. Tomes and Mr. Alston. For France, M. Gervais's "Zoologie et Paléontologie Française" enumerates both recent and fossil Mammals, though most regard is paid to the extinct fauna. As regards Spanish Mammals, almost the only authority I am acquainted with is Rosenhauer's "Thiere Andalusiens" which is, however, very defective, the author having devoted himself principally to the study of the Invertebrates. Captain Cork (afterwards Widdrington) was the original discoverer of several of the rarer Mammals of Spain ; but the account of them in his "Sketches" is very meagre. A bare list of the Mammals of Portugal is given by Prof. Barboza de Bocage in the "Revue Zoologique" for 1863. Passing over to Italy, Bonaparte's "Fauna Italica" and Costa's "Fauna del Regno di Napoli" must be mentioned, though both are somewhat out of date. But the former work is still the only authority on certain of the rarer Italian species and local forms.

A recent summary of Italian Mammals has been given by Prof. Cornalia in "Italia;" but on the whole it must be allowed that a good work upon the Mammals of the Italian peninsula is still a desideratum. Of the Mammals of Switzerland, on the other hand, we have an excellent recent work by Dr. Fatio, forming the first volume of his "Faune des Vertébrées de la Suisse," in which special attention is devoted to the difficult groups of Rodents and Insectivores. No student of the European Mammal-fauna should omit to consult it.

Passing to Eastern Europe, we find our state of exact knowledge as to the Mammals very defective. As regards Greece, we may refer to the French "Expedition Scientifique en Morée," in which there is a memoir on the Mammals by Geoffroy St. Hilaire, and Erhard's "Fauna der Cycladeen," which gives some details on the Mammals of the Greek Archipelago. Of Turkey we find very little information, and there is certainly still much to be done as regards the smaller Mammals of this part of Europe. In Russia we have Ménétriés's "Catalogue of the Animals of the Caucasus," and P. Demidoff's "Voyage dans la Russie Méridionale," and perhaps other works in the language of the country, which I am not acquainted with. But there can be no doubt that it is in South-eastern Europe that our knowledge of the Mammal-fauna of this continent is exceedingly defective, and that much remains to be done in order to complete our acquaintance with this branch of European Zoology.

In Northern Europe, which we now turn to, the case is quite different. The highly cultivated and laborious naturalists of Scandinavia have for many years paid great attention to this as to every other part of their fauna. The first volume of Nilsson's "Scandinavian Fauna," published at Lund in 1874, has long been a standard book of reference on this branch of zoology. Much, however, has been done since that period; and in Prof. Lilljeborg's lately issued work on the Mammals of Sweden and Norway, we have an exhaustive account of the present state of our knowledge of this subject.

As regards the few Mammals of Spitzbergen, reference should be made to the second volume of Heuglin's "Reisen nach dem Nordpolarmeer," where that energetic naturalist has put together an account of the nineteen species of Mammals that penetrate so far north.

B. *Birds of Europe.*

(a.) *Europe generally.*—There can be no question, I suppose, that the attractive class of Birds has received much more attention than its sister-classes of Vertebrates in Europe as generally elsewhere. Of late years especially a considerable number of naturalists in almost every part of this continent have devoted their principal attention to ornithology. Two journals are devoted solely to this science—in which the larger number of articles treat of the birds of some portion or other of Europe. The mass of literature on the subject is large, and I must therefore be rather concise in my notices of the principal modern authorities that should be referred to by an inquirer on the subject of European Ornithology.

First, as to the avifauna of the whole continent, Temminck's "Manual"—long the acknowledged authority on this subject—was superseded in 1849 by the issue of Degland's "Ornithologie Européenne." The new edition of this work, issued by the author and Gerbe jointly in 1867, is perhaps now the most complete book of its kind. But it has great faults and imperfections, particularly as regards its indications of the distribution of the species. This branch of the subject had never been properly worked until the recent issue of Mr. Dresser's (formerly Sharpe and Dresser's) "Birds of Europe," which contains, so far as it has hitherto progressed, by far the most exhaustive account of the European birds yet attempted. Its large size and numerous illustrations, however, render it rather cumbersome as a manual; but a handbook based on it when completed, and containing a judicious abridgment of its information (which I hope Mr. Dresser will not fail to prepare), will, I am sure, form a most valuable work.

Fritsch's "Naturgeschichte der Vögel Europas," lately published at Prague, is a cheap and useful manual for those who understand German; while Gould's "Birds of Europe," though out of date, will be always referred to for its illustrations.

(b.) *Birds of Great Britain.*—For many years the standard book of reference on the ornithology of these islands has been Yarrell's "British Birds," and its several Supplements. The new edition of this work, commenced in June 1871 by Prof. Newton, is familiar, no doubt, to most of the members of Section D. As to its merits there can be no question; I think it is seldom indeed that a task is entrusted to one so thoroughly competent to perform it, or so careful in the execution of what he undertakes. But the slow progress of the work is appalling. After four years only one of the promised four volumes has been completed. As amongst the best of numerous local works on the birds of this country recently issued should also be mentioned Gray's "Birds of the West of Scotland," and Hancock's memoir on those of Northumberland and Durham. A very useful work of reference for ornithologists is also Mr. Harting's "Hand-book of British Birds," in which the exact dates and places of occurrence of all the rarer visitants are recorded. Those who love life-sized illustrations, and have full purses, will not fail to acquire (provided a copy is left) Mr. Gould's splendid work on the "Birds of Great Britain," now complete in five volumes. After this enumeration it will be almost needless to remark that Ornithology has no reason to complain of want of support in this country.

(c.) *Birds of France.*—In France less attention has been devoted to the native birds of late years; and besides the new edition of Degland's "Ornithologie Européenne" already spoken of, I have only to mention Bailly's "Ornithologie de la Savrie," and Jaubert and Barthélemy-Lapommeraye's "Richesse Ornithologique de la Midi de la France," in each of which will be found much information about the rarer birds of the districts respectively treated of.

(d.) *Birds of Spain and Portugal.*—Much attention has been paid to the avifauna of Southern Spain of late years, but rather by visitors from the north than by native naturalists. Lord Lilford and Mr. Howard Saunders have both given us some excellent articles in the "Ibis" on this subject, and have made a variety of interesting discoveries, amongst which are actually several new species,* or at all events well-marked local forms. Dr. A. E. Brehm, long resident at Madrid, has also devoted much attention to Spanish ornithology, and written a complete list of Spanish Birds, which should be consulted. To Colonel Irby's work on the Straits of Gibraltar I have already alluded; as regards the southern extremity of the peninsula he is our best and most recent authority. For information on the birds of Portugal we must again go to an English source—Mr. Alfred Charles Smith, "Narrative of his Spring Tour" being the best authority which I am acquainted with on this subject.

(e.) *Birds of Italy.*—Savi's "Ornithologia Toscana," published as long ago as 1827, was for long almost our only authority on Italian ornithology. Bonaparte's "Iconographia," already alluded to, gave some additional information as to rarer species. Salvadori's memoir on the birds, forming the second volume of the recently published "Fauna d'Italia," is the best and most recent authority on this subject, and contains an excellent "Bibliografia Ornithologica Italiana." A large illustrated work on the birds of Lombardy has been recently published at Milan by Bettoni. We must also call attention to the persevering way in which Mr. C. A. Wright has worked up the Avifauna of Malta, and to Mr. A. B. Brooke's recently published notes on the Ornithology of Sardinia.

(f.) *Birds of Turkey and Greece.*—Dr. Krüper, a well-known German naturalist, has been long resident in various parts of the Levant, and has contributed numerous articles upon the birds met with to various periodicals. These have been recently put together and edited by Dr. Hartlaub, and published as a number of Mommsen's "Griechische Jahrezeiten," which thus contains a summary of all our principal information on the birds of Greece and its islands. Before that our best authority on Grecian birds was Lindermayer's "Vögel Griechenlands." As regards European Turkey, Messrs. Elwes and Buckley have lately published a good paper in the "Ibis" on its birds; and MM. Alléon and Vian have written several articles in the "Revue Zoologique" on the ornithology of the neighbourhood of Constantinople. But there is certainly still much to be done as regards birds in this part of the continent, as likewise amongst the islands of the Greek Archipelago, many of which are almost unexplored by the naturalist.

(g.) *Birds of Southern Russia and the Caucasus.*—Though many notices of the birds of Southern Russia have appeared in the "Bulletin" of the Society of Nuturalists of Moscow, I am not aware of any complete account of them having been issued. Demidoff, in the third volume of his "Voyage dans la Russie Méridionale," gives a list of the birds of what he calls the

* *Gecinus Sharpii*, P.Z.S. 1872, p. 153, and *Calendrella bætica*, Dresser, "Birds of Europe," pt. 21.

"Faune Pontique," but his original observations are somewhat meagre. Eichwald's "Fauna Caspio-Caucasica" and Ménétriés's Catalogue of the Zoology of the Caucasus, should also be consulted, although both are rather out of date. An excellent zoologist, Hr. Gustav Radde, is now resident at Tiflis; but I do not think he has yet prepared any general account of the birds of the Caucasus, where there must be certainly much of interest, as is proved by the discovery of the remarkable Grouse, allied to our Black Grouse, which has just been described by M. Taczanowski.*

(h.) *Birds of Germany and Central Europe.*—Local lists of the birds of the various States of Central Europe, and their principal divisions, are very numerous; and there are also many manuals and memoirs on the same subject. But J. A. Naumann's excellent "Vögel Deutschlands," commenced in 1822, with its supplements, is still, I believe, quite unsuperseded as a standard book of reference on Central European Ornithology. It was generally understood that Prof. Blasius, at the time of his lamented death, had a work on the birds of his native country in preparation; but unfortunately this was never finished, or it would have proved to be, no doubt, of first-rate excellence. In no other country, however, except our own, is ornithology so much cultivated as in Germany. Two societies emulate each other in their pursuit of this science, and a special journal is devoted to its progress. There is no lack, therefore, of recent information upon the birds of every part of Germany, although this has to be fished out of journals and periodicals of different sorts, instead of being put together, as we should rather wish to see it, in some general work.

(i.) *Birds of Scandinavia and North Europe.*—In Scandinavia also there is no dearth of diligent observers of birds as of every other class of animals. The bird-volume of Nilsson's Scandinavian Fauna was published in 1858, and is still worthy of careful study. But the more recent works of Collett upon the Birds of Norway, in German and in English, should be consulted, as also Sundevall's "Svenska Foglarna," unfortunately not quite finished at the time of his decease, and Von Wright and Palmén's "Finland's Foglar." Many memoirs have also recently appeared upon the birds of the extreme north, which have always attracted great interest among ornithologists. Amongst these special attention may be called to v. Heuglin's account of the birds of Nova Zembla, first published in Cabanis's Journal for 1872, and afterwards enlarged and revised in the second volume of his "Reisen in dem Nordpolarmeer;" to Prof. Newton s essay on the birds of Iceland in Mr. Baring-Gould's "Iceland, its Scenes and Sagas;" and lastly, to Messrs. Alston and Brown's narrative of their adventures among the birds of Archangel—a little explored district, and one of much promise, to which one of these active explorers has returned this year.

C. *European Herpetology.*

In this field of research there is not so much of recent work to record as among the birds; but Dr. E. Schrieber's "Herpetologia Europæa," which has just appeared, marks an important epoch in this branch of science, since there was previously no good work of reference upon the Reptiles and Batrachians of Europe. Dr. Schrieber's work is drawn up upon the same plan as Blasius's well-known "Säugethiere Europas," and forms a most convenient handbook. The list of published works and memoirs on the same subject prefaced to it renders it unnecessary for me to refer to the previous authorities on European herpetology in detail. I observe, however, that Lord Clermont's very useful "Guide to the Quadrupeds and Reptiles of Europe" is not referred to in the list, and it would appear that Dr. Schrieber is not acquainted with it. I must also call special attention to Dr. Strauch's excellent memoir on the Serpents of the Russian Empire, recently published in the Memoirs of the Imperial Academy of St. Petersburg, which is as important for the European as for the Asiatic part of the Russian dominion. As regards our native Herpetological Fauna also, I may point out that the last edition of Bell's "British Reptiles," published in 1839, requires considerable revision to bring it up to our present standard of knowledge, and that it is much to be desired that a new edition should be undertaken. Let me venture to suggest that Mr. Van Voorst should communicate with Dr. Günther upon this subject.

D. *European Ichthyology.*

I am not aware of the existence of any special work on European Ichthyology, but C. Th. v. Siebold published in 1863 a volume on the Fresh-water Fishes of Central Europe, which forms a useful guide to the Pisci-fauna of the principal European river-basins. For the fishes of the Atlantic which visit the British coasts we have the third edition of Yarrell's "British Fishes," edited by the late Sir John Richardson, which was published in 1859. Now that Dr. Günther's great general work on Fishes has been completed, this portion of Mr. Van Voorst's excellent series would be also much benefited by revision and rearrangement according to Dr. Günther's modern system and nomenclature. As a cheaper and more popular work we may also refer to Conch's "British Fishes" in four volumes, in which the figures are coloured.

Prof. Blanchard issued in 1866 a volume of the Freshwater Fishes of France, which, however, does not bear so high a character as Siebold's work above referred to. For our knowledge of the fishes of Spain and Portugal we are chiefly indebted to Steindachner's memoirs in the Sitzungsberichte of the Vienna Academy, and to F. de Brito Capello's papers in the *Journal of Sciences of Lisbon.* Of those of Italy, Prof. Canestrini has lately published a revised list with short specific characters, as a portion of the work called "Italia" already referred to. Those interested in the fishes of the Black Sea and adjoining river-basins should consult the ichthyological portion of Demidoff's "Voyage dans la Russie Méridionale," entitled "Pisces Faunæ Ponticæ." I am not acquainted with any other important recent memoirs on the ichthyological faunas of the different European States which it is necessary to refer to until we come to Scandinavia, where Malmgren published in 1863 an excellent essay upon the Fishes of Finland, which was subsequently translated into German. As regards the fishes of Spitzbergen and Nova Zembla, Heuglin's Synopsis of them in the second volume of his already quoted "Reisen nach dem Nordpolarmeer" is the most recent authority, though it is principally founded upon the labours of Lovén and Thorell, and of the naturalists of the Swedish expeditions of 1861 and 1864.

3. The Siberian Sub-region.

When I call to mind the numerous scientific expeditions sent by the Russians into different parts of their recent acquisition in Northern Asia, and turn over the pages of the excellent and instructive work in which the results of these expeditions have been given to the world, I must own to a feeling of indignation at the manner in which such matters are usually dealt with by the Government of this country. In the first place, in order to get such an expedition sent out at all, great exertions and special influence is necessary. The Treasury must be memorialised, the Chancellor of the Exchequer besought, and the Admiralty petitioned, before any grant of money can be sanctioned for the purpose, and even then it is too often bestowed in a niggardly and grudging way. When the expedition returns, similar applications have to be made in order to get the results worked out and properly published, and these are in some cases altogether rejected, so that the money already spent upon collecting becomes virtually thrown away. In Russia, although the nation may be less awake to the claims of science than in this country, the Government is certainly more so; and it is to the scientific men attached to the Government expeditions that we are indebted for nearly all the knowledge we possess of the fauna of Northern Asia. Of the more important reports of the more recent of these expeditions I will say a few words.

Middendorff's "Sibirische Reise," published in 1851, gives an account of the fauna of the extreme north and east of Siberia. The second volume of the zoological portion is entirely devoted to the Mammals, Birds, and Reptiles, and gives full details concerning the structure and habits of the species met with. Of Von Schrenck's "Amur-reise," a volume published in 1859, contains a complete memoir on the Mammals and Birds of the newly acquired district traversed by the Amoor, lying to the south of that investigated by Hr. v. Middendorff. Lastly, two volumes of Radde's "Reisen in dem Suden v. Ost-Sibirien," published in 1862 and 1863, render more perfect our knowledge of the Mammals and Birds of South-eastern Siberia. Hr. Radde's chief observations were made in Transbaikalia, but he incorporates the knowledge accumulated by his predecessors in the surrounding districts, and goes deeply into general results.

Dr. A. v. Middendorff's "Isepiptesen Russlands" should also be consulted by those who wish to understand the migration of birds in Siberia, or indeed throughout the Russian dominions.

* *Tetrao mlokosiewiczi*, Tacz., P.Z.S., 1875.

4. THE MANTCHURIAN SUB-REGION.

Of this district, which embraces the country lying south of the Amoor and the greater part of Northern China, down perhaps to the great river Yang-tze, we have, besides the Russian works lastly spoken of, two principal sources of information. The first of these consists in the researches of Mr. Robert Swinhoe, of H.M. Chinese Consular Service, one of the most industrious and successful exploring naturalists that have ever lived, as is well known to many of my brother members here present. Mr. Swinhoe's memoirs and papers on Chinese Zoology are very numerous, but his last revised list of the birds of China will be found in the Zoological Society's "Proceedings" for 1871. Père Armand David, a worthy rival of our Consul, has likewise contributed in no small degree to our knowledge of the fauna of Northern China. His journals, containing numerous remarks full of interest, have lately been published in the "Nouvelle Archives du Muséum d'Histoire Naturelle de Paris;" and M. Alphonse Milne-Edwards's recently completed "Recherches sur les Mammifères" contains a section specially devoted to the Mammals of Northern China, which is mainly based on Père David's researches. I shall, however, have again occasion to mention the discoveries of both Mr. Swinhoe and M. David in a subsequent portion of this address.

5. THE JAPANESE SUB-REGION.

Temminck and Schlegel's "Fauna Japonica" have long been our standard authority upon the zoology of Japan, and not much has been done of late years to perfect it, except as regards the birds. On this branch of our subject some very good articles have been published in the "Ibis" by Capt. Blakiston, based upon his researches in Hakodadi; by Mr. Whitely, who was for some time resident along with Capt. Blackiston at the same port; and by Mr. Swinhoe. Reference should also be made to the second volume of Commodore Perry's "Narrative of the U.S. Expedition to Japan in 1852–54," wherein will be found articles on the birds collected by Cassin, and on the fishes by Brevoort.

6. THE TARTARIAN SUB-REGION.

Into the great desert-region of Central Asia, hitherto almost unknown, except from Eversmann's "Reise nach Buchara," which contains a short natural-history appendix, excursions have recently been made from two opposite quarters. The advancing tide of Russian conquest from the north, accompanied, as usual, by its scientific corps, has already made us well acquainted with the zoology of Turkestan. Mr. Severtzoff has unfortunately yielded to the unphilosophical spirit of nationality, which has of late years attained such a monstrous development, and published his "Turkestanskie Jevotnie," or review of the distribution of animal life in Turkestan, in his native Russian. But a translation and reproduction of the portion relating to the birds has already appeared in German, and an abstract of it in English is now being given to the world by Mr. Dresser in the "Ibis."

From the south, the peaceful embassies of this country to Yarkand have led naturalists into the fringe of the same zoological district. Of the first of these expeditions we have an excellent account as regards the birds by Mr. A. O. Hume, forming the second part of Henderson's "Lahore to Yarkand." Sir D. Forsyth's second expedition to Yarkand and Kashgar was accompanied by Dr. Ferdinand Stolitzska, one of the most accomplished and energetic members of the staff of the Indian Geological Survey, whose life was miserably sacrificed to the hardships encountered on the return. Of this last expedition we have as yet only incomplete accounts,* but may, I trust, look forward to the publication of an equally interesting volume on the zoological results. The ichthyological part of the collections has, I believe, been entrusted to Dr. F. Day to work out in this country.

7. THE PERSIAN SUB-REGION.

Of the Persian or "Mediterraneo-persic" Sub-region, as Mr. Elwes prefers to call it,† which may be held to embrace European Turkey, Palestine, and Persia, our knowledge was until recently very limited, and even up to the present day remains very imperfect, considering the proximity of the district to Europe, and the many interesting features which it presents. As regards Palestine, Canon Tristram's energetic researches have done much to remove what has long been a scandal to biblical scholars as well as to naturalists. His long-promised "Synopsis of the Flora and Fauna of Palestine" is, however, not yet issued by the Ray Society, and we must be consequently content with Mr. Tristram's papers on the Birds of the Holy Land in the "Ibis" and Dr. Günther's article upon the Reptiles and Fishes in the Zoological Society's "Proceedings," until the finished work appears. Of Asia Minor and Armenia it may be said that we are miserably ignorant, Tchihatcheff's desultory account of its natural history in his "Asie Mineure" being almost the only authority we have to refer to. Thirty years ago the Zoological Society had two excellent correspondents at Erzeroum —Messrs. Dickson and Ross; and it is a great misfortune that no continuous account was ever prepared of the fine collection which they sent home.*

As regards Persia, we may hope very shortly to be much more favourably situated. Mr. W. T. Blanford and Major St. John have recently made large zoological collections in various parts of that country, particularly of birds, and it is generally understood that the report of the Persian Boundary Expedition will contain a complete account of the zoology of Persia from Mr. Blanford's accomplished pen. Hitherto we have had to rely on De Filippi's "Viaggio in Persie," and other fragmentary sources of information.

II.—ÆTHIOPIAN REGION.

This region I shall speak of, for convenience sake, under the following six sub-divisions :—

1. *Western Africa*, from the Senegal to the Congo.
2. *South-western Africa*, or Angola and Benguela.
3. *South Africa*.
4. *South-eastern Africa*, from the Portuguese possessions up to the Somali coast.
5. *North-eastern Africa*, including Abyssinia, Nubia, and Egypt.
6. *Arabia*.

1. WESTERN AFRICA.

The Mammals of Western Africa are certainly not so well known as they should be; and there is no one work which gives an account of them except Temminck's "Esquisses Zoologiques sur la côte de Guinée," which is devoted to the collections transmitted to Leyden by Pel, a most energetic and successful Dutch explorer. On the Mammals of Gaboon, Pucheran's article in the French "Archives du Muséum," and Du Chaillu's travels and the literature connected therewith, should be consulted.

The birds of Western Africa, on the contrary, have attracted much attention from European naturalists since the time when Swainson published his "Birds of West Africa." This work, however, has been quite superseded by Hartlaub's classical "System der Ornithologique West-Afrikas," published in 1857. Since that period many memoirs and papers have appeared on the birds of various parts of this district, principally by Cassin, of Philadelphia, Dr. Finsch, of Bremen, and Mr. R. B. Sharpe, of the British Museum, who has paid special attention to the African Ornis, and is understood to be preparing a general work on the subject.

For information on the Reptiles and Fishes of West Africa we must refer to Aug. Duméril's memoir in the tenth volume of the "Archives du Muséum et Histoire Naturelle," founded on the collections in the Paris Museum.

2. SOUTH-WESTERN AFRICA.

The Portuguese colonies of Angola and Benguela, which seem to belong to a zoological sub-region, distinct from both that of West Africa and that of the Cape, were until recently almost unexplored. Within these last few years, however, Prof. Barboza du Bocage has acquired extensive series of specimens in nearly every department of natural history from these countries for the Lisbon Museum, and has published several important memoirs on the subject, which he will probably ultimately incorporate into a general work. Mr. J. J. Monteiro has also sent to this country collections of Mammals and Birds which have formed the subject of several papers in the Zoological Society's "Proceedings."

3. SOUTHERN AFRICA.

Sir Andrew Smith's "Illustrations of the Zoology of South Africa" constitute four solid octavo volumes, devoted to the new and rare vertebrates met with during that energetic traveller's many explorations of the Cape Colony and the

* See Hume, "Stray Feathers," ii. p. 513 and iii. p. 215.
† *Cf.* P.Z.S. 1873, p. 647.

* See notices, P.Z.S. 1839, 1842, and 1844.

adjoining districts. But there is no perfect list of the Cape fauna given in Sir Andrew Smith's work, and Mr. Layard's "Birds of South Africa," though not very completely elaborated, was, therefore, a most acceptable and convenient work to the ornithologist. Still more agreeable will it be to witness the completion of the new and enlarged edition of Mr. Layard's little volume, which Mr. Sharpe has undertaken, and of which he has just issued the first part. Mr. Sharpe will however, I trust, pardon me for remarking that he has cut the synonymy of the species rather short in his pages. It is hard to expect every South-African colonist to have at his side the British Museum Catalogue of Birds, to which he always refers us. Another modern and much-to-be-recommended bird-book belonging to this sub-region is Mr. J. H. Gurney's "Birds of Damara-land" founded on the extensive collection of the late C. J. Anderson. No less than 428 species of birds were obtained by this indefatigable collector, and the task of editing his field-notes has been well performed by Mr. Gurney.

4. South-eastern Africa.

Our knowledge of the fauna of Mozambique is chiefly due to the scientific visit made to that country by Dr. W. Peters, of Berlin, in 1842 and the following years. The volume of this distinguished naturalist, "Naturwissenschaftliche Reise nach Mozambique," on the Mammals was published in 1852, that on the Fishes in 1864. The delay in the issue of the portions relating to the Reptiles and Birds is much to be regretted, more especially when we consider the high standard of the work, although diagnoses of the new species discovered in these groups have been long since published; and I am sure I am expressing the sentiments of naturalists in general when I say that I hope to see the series shortly completed. Proceeding further north along the African coast, we come to Zanzibar, where an excellent ichthyologist, Consul Playfair, was lately resident. The "Fishes of Zanzibar," by Günther and Playfair, founded on the extensive collections here made, was published in 1866, and gives an account of above 500 species, and many excellent figures.

The ornithology of the whole East-African coast, from Cape Gardafin to Mozambique, has been elaborately worked out by Drs. Finsch and Hartlaub. The results are contained in these authors' "Vogel Ost-Afrikans," forming the fourth volume of the unfortunate Baron Carl Claus von der Decken's "Reisen in Ost-Afrika." Full details as to older authorities on the subject are given in this excellent work, so that it is not necessary to refer to them.

As regards the Mammals of this part of Africa, however, it is necessary to say a few words. Our knowledge of this class of animals is, as regards the coast opposite Zanzibar and the country surrounding the great lakes of the interior, mainly comprised in the fragmentary collections of Speke and Grant (of which an account has been published in the Zoological Society's "Proceedings," and in the few specimens transmitted by Dr. Kirk from Zanzibar. There is no doubt, however, that much remains to be done here, and I believe there is at the present moment no finer field for zoological discovery available than this district, where we know that animal life in every variety is still abundant, and excellent sport can be obtained to add a zest to scientific investigation. The fishes of the great lake of Tanganyika and the Victoria and Albert Nyanza are likewise utterly unknown, and their investigation would be a subject of the greatest interest. Of those of the more southern Nyassa Lake, a few specimens have been obtained by Dr. Kirk.

5. North-east Africa.

For many years Rüppell's "Atlas" and "Neue Wirbelthiere," and, as regards birds, his "Systematische Uebersicht," remained our standard works of reference upon the zoology of North-eastern Africa. The recent completion of Th. von Heuglin's "Ornithologie Nordost-Afrikas" has superseded Rüppell's volumes for general use; and no more valuable piece of work for ornithologists has been accomplished of late years than the reduction of the multitudinous observations and records of this well-known traveller and naturalist into a uniform series. V. Heuglin's work, however, concerns mainly Upper Nubia, Abyssinia, and the wide territory drained by the confluents of the Upper Nile. For Egypt and the Lower Nile a more handy volume is Capt. Shelley's "Birds of Egypt," published in 1872, which will be found specially acceptable to the tourist on the Nile. Nor must I forget to mention Mr. Blanford's interesting volume on the Geology and Zoology of Abyssinia, which contains an account of the specimens of Vertebrates collected and observed during his companionship with the Abyssinian Expedition. Mr. Jesse's birds, collected on the same occasion, were examined by Dr. Finsch, and the result given to the world in a memoir published in the Zoological Society's "Transactions."

A good revision of the Mammal-fauna of North-east Africa is much to be desired. Meanwhile Fitzinger's list of v. Heuglin's collection, and the latter author's own account of them in his Travels on the White Nile may be consulted.

6. Arabia.

Of Arabia, as might have been expected, we know but little, zoologically or otherwise. But little, it may be said, can be expected to be found there, looking to the general aspect of the country. Still it would be of interest to know what that little is. At present the only district that has been visited by naturalists is the peninsula of Sinai, and of this our knowledge is by no means complete. Hemprich and Ehrenberg's unfinished "Symbolæ Physicæ" was for many years our sole authority. More recently Mr. Wyatt has published an article in the "Ibis" upon the birds of the Sinaitic peninsula. Let me suggest to some of the officers who are stationed idle at Aden that an account of the animals to be met with in that part of Arabia would be of great value, and would give them much useful and interesting occupation. I have been more than once told that there is nothing whatever to be found there. But this I am slow to believe. Anyone with a good pair of eyes and a taste for collecting might certainly do much good to science by passing a few months at Aden, and making excursions into that part of "Arabia Felix."

II*a*.—LEMURIAN SUB-REGION.

This aberrant appendage of the Ethiopian Fauna I will speak of under two heads, namely :—

1. *Madagascar.*
2. *Mascarene Islands.*

1. Madagascar.

To our knowledge of the extraordinary fauna of "Lemuria," as I have elsewhere proposed to call Madagascar and its islands,* great additions have been recently made, but it is manifest that Madagascar is by no means yet worked out.† Dr. Hartlaub's "Ornithologischer Beitrag zur Fauna Madagascars" was the first attempt at a *résumé* of the remarkable avifauna of this part of the world. Since its issue two Dutch naturalists, Pollen and Van Dam, have visited Madagascar, and forwarded rich collections to the Leyden Museum. Of these the Mammals and Birds have been worked out by Professor Schlegel and Mr. Pollen, and the results published in a well-illustrated volume entitled "Recherches sur la Faune de Madagascar." This has been since followed by an accompanying account of the Fishes, and treatise on the Fisheries, by Messrs. Bleeker and Pollen. Following upon the footsteps of these naturalists, a French explorer, Alfred Grandidier, has since visited the interior of Madagascar, and in his turn has reaped a grand harvest, of which some of the results have already been given to the public. But we are promised to have these discoveries in a much more extended and complete form, in a work now in progress, in which M. Grandidier has obtained the efficient assistance of M. Alphonse Milne-Edwards. There still remain to be spoken of the discoveries recently made by an English collector in Madagascar, Mr. A. Crossley. Mr. Crossley's birds have been worked out by Mr. Sharpe in several papers published from time to time by the Zoological Society, while Dr. Günther has described several new and remarkable Mammals from the same source.

2. The Mascarene Islands.

The fauna of the islands of Bourbon, Mauritius, and Rodriguez forms an appendage to that of Madagascar, and merits careful study. Our knowledge of these islands, since the recent investigation of Rodriguez by the naturalists sent out with the Venus Expedition, is tolerably complete, but requires to be put together, as it consists of fragments dispersed over various

* Quart. Journ. of Science, 1864, p. 213.

† Witness the Mammal-forms, *Brachytarsomys* and *Mixocebus*, lately described by Dr. Günther and Dr. Peters, and the new genus of birds, *Neodrepanis*, recently characterised by Mr. Sharpe.

journals and periodicals. I trust that Mr. Edward Newton, who has had so many opportunities of acquiring information on this subject during his Colonial Secretaryship at Mauritius, and has so well used these opportunities, may shortly have leisure to devote to this task. His labours to recover the skeleton of *Pezophaps*, in which, I am pleased to think, he was aided by a grant from this Association, are well known, as is likewise the excellent memoir by himself and Prof. Newton, in which the result of his labours was given to the world. Nor must I omit to mention Prof. Owen's dissertations on the extinct fellow-bird of Mauritius, recently published by the Zoological Society.

As regards the recent ornithology of these islands, we have nothing later to refer to than Hartlaub's little work on Madagascar, noticed above, which includes what was then known of the avifauna of the Mascarenes.

The neighbouring group of the Seychelles was visited by Mr. Edward Newton in 1867, and several new and most interesting species of birds obtained there. A complete account of the ornithology of these islands was given by Mr. Newton in the "Ibis" for 1867. Since that period Dr. E. P. Wright, formerly an active member of this Association, has made a scientific excursion to the Seychelles, with a view, as was generally understood, of preparing a complete monograph of the fauna and flora of these interesting islands. It is much to be regretted that this very desirable plan has not yet been accomplished.

III.—INDIAN REGION.

Of the extensive and varied Indian Region I will now proceed to say something under the subjoined heads :—

1. *British India.*
2. *Central* and *Southern China.*
3. *Burmah, Siam,* and *Cochin.*
4. *Malay Peninsula.*

4*a*. *Andaman* and *Nicobar Islands.*

5. *East-Indian Islands.*
6. *Philippine Archipelago.*

1. British India.

For British India Dr. Jerdon's well-known series of zoological handbooks was intended to supply a long-standing want; and it is a great misfortune that his untimely death has interfered with their completion. The three volumes on Birds were finished in 1866, and one on Mammals in 1867. Of the volume on the Reptiles and Batrachians a portion, I believe, was actually in type at the time of his decease; but of the Fishes no part, as far as I know, was so much advanced. For the Reptiles, therefore, we must for the present refer to Dr. Günther's "Reptiles of British India," published by the Ray Society in 1864. Indeed, as regards India, any future account of these animals must, in any case, be founded upon the basis of that excellent and conscientious work. For the Indian fishes generally there is at present no one authority, though Dr. Day, author of the "Fishes of Malabar" and of numerous other papers, is understood to have in preparation a general work on this subject, which his office of Inspector-General of Indian Fisheries has given him excellent opportunities of studying. Complete lists of both the freshwater and marine species of India are given in the appendices to Dr. Day's two "Reports on the Fisheries of India and Burmah," published in India in 1873.

But although our wants as regards the Indian Vertebrates will probably be supplied in this way, it would be much more satisfactory if the Indian Government would select a successor to Dr. Jerdon, and place under his control the necessary means for the preparation of a series of zoological handbooks for India. There is no reason why botany should be more favoured than zoology in this matter; and I believe it is only the greater energy of the botanist that in this, as in other cases, has given them the start. New editions of Dr. Jerdon's Mammals and Birds are both necessary to bring our knowledge up to date, and the original editions are long out of print. There can be no question as to the great impetus to the study of natural history in India that has already followed on the publication of these handbooks; and it will be a great misfortune to science if our Indian rulers fail to continue the good work. They have only to select a competent editor for the series, and to place the necessary funds temporarily at his disposal. The sale of the works would in the end recoup all the necessary expenses.

Amongst more recent contributions to our knowledge of Indian ornithology, which, under the influence above referred to, have been especially numerous, I can now only stop to call attention to a few. Mr. Allan Hume, C.B., has been specially active, and has published numerous papers in his queerly-titled periodical "Stray Feathers," which is exclusively devoted to Indian Ornithology. Amongst them the articles on the birds of Scinde and those of Upper Pegu are of special interest. Mr. Holdsworth's most useful "Synopsis of the Birds of Ceylon," lately published in the "Proceedings of the Zoological Society," is also of great value, more especially as Ceylon was omitted from the scope of Dr. Jerdon's work. Nor must I omit to mention Major Godwin-Austen's series of papers on the ornithology of the newly-explored districts on the north-eastern frontier, which contains so much of novelty and instruction.

As regards the Testudinata of India, we may shortly expect a complete account of them from Dr. John Anderson, who has devoted much time and toil to their study. His magnificent series of drawings of these animals, from living specimens, I have had the pleasure of inspecting; and I trust sincerely that some means may be found of reproducing them for publication. Such a work would vastly increase our knowledge of this very difficult group of animals.

2. Central and Southern China.

In speaking of Northern China I have introduced the names of the two great modern zoological discoverers in China, Mr. Robert Swinhoe and M. le Père David. Mr. Swinhoe's article on the "Mammals of China," recently published in the Zoological Society's "Proceedings" gives a complete list of the species known to him to occur south of the Yang-tze. It includes those of the great island of Formosa, which is essentially part of China, although it possesses some endemic species, and which was a complete *terra incognita* to naturalists before Mr. Swinhoe's happy selection as the first British Vice-Consul in 1861. Mr. Swinhoe's last revised catalogue of the Birds of China, published in 1871, has been already referred to. He is now at home, unfortunately in ill health, but is by no means idle on his bed of sickness, and has in contemplation, and, I may say, in actual preparation, a complete work on Chinese Ornithology, for which he has secured the co-operation of one of our most competent naturalists.

The still more remarkable discoveries of Père David have revealed to us the existence on the western outskirts of China, or on the border-lands between China and Tibet, of a fauna hitherto quite unknown to us, and apparently a pendant of the Sub-Himalayan Hill-fauna first investigated by Hodgson. In his recently completed "Recherches sur les Mammifères," already referred to, M. Alphonse Milne-Edwards has given us a complete account of M. David's wonderful discoveries among the Mammals of this district. M. David's birds were worked out by the late Jules Verreaux, and the novelties described in the "Nouvelle Archives," but no complete list of them has yet been issued. In herpetology, I believe, M. David has also made some remarkable discoveries, amongst which, not the least assuredly, is the discovery of a second species of gigantic Salamander * in the mountain-streams of Moupin.

3. Burmah, Siam, and Cochin.

I speak of these ancient kingdoms, which occupy the main part of the great peninsula of South-eastern Asia, principally to express my surprise at how little we yet know of them. There are several good correspondents of the Jardin des Plantes in the French colony of Saigon, who have, I believe, transmitted a considerable number of specimens to the Muséum d'Histoire Naturelle, but beyond the descriptions of a certain number of novelties we have as yet received no account of them. The two philosophic Kings of Siam appear not yet to have turned their attention to biological discovery, although there is certainly much to be done in the interior of that State, with which the late M. Mouhot, had his life been spared, would certainly have made us better acquainted. As it happens we have only one or two published memoirs upon the results which this unfortunate naturalist achieved.

Lower Burmah now forms part of British India, and will be doubtless well explored. As regards Burmah proper and the Shan-States, our Indian legislators appointed a most efficient naturalist to accompany the Yucan Expedition of 1868; but when he returned, refused or neglected to provide him with the facilities to work out and publish his results. I rejoice, however, to learn that this error has been to a certain extent remedied,

* *Sieboldia Davidiana*, Blanchard.

and that Dr. Anderson has now in preparation a connected account of his Yucan discoveries, which is to be issued by the Linnean Society in their "Transactions." A separate publication of these results would not have involved much additional expense, and would have been more worthy of the Government which sent out the expedition.

4. MALAY PENINSULA.

The Malay peninsula belongs unquestionably to the same Sub-fauna as Sumatra. Its zoology is tolerably well known to us from numerous collections that have reached this country, but a modern revision of all the classes of Vertebrates is much to be desired. About twenty years ago, Dr. Cantor, of the East Indian Medical Service, published catalogues of the Mammals, Reptiles, and Fishes of Malacca in the Journal of the Asiatic Society of Bengal. To obtain a knowledge of its birds we must refer to the papers of Eyton, Wallace, and various other ornithological writers.

4*a*. ANDAMAN AND NICOBAR ISLANDS.

The two groups of islands in the Bay of Bengal have of late years attracted considerable attention from naturalists. Port Blair, in the Andaman Islands, having become the seat of an Indian penal settlement, has received visits from several excellent Indian workers who have made extensive collections, especially in ornithology. The most recent authorities upon the birds of the Andaman Islands are Lord Walden, who has worked out the series forwarded to him by Lieut. Wardlaw Ramsay, and Mr. Vincent Ball, who has published in "Stray Feathers" a complete list of all the birds known to occur in the Andaman and Nicobar groups.

5. EAST INDIAN ISLANDS.

Up to a recent period the standard authority on the fauna of the East Indian Islands was the great Dutch work on the Zoology of the foreign possessions of the Netherlands Government, based upon the vast collections formed by Macklot, Müller, and other naturalists, and transmitted to the Leyden Museum. This has been supplemented of late years by several works and memoirs of Dr. Schlegel, the eminent director of that establishment, and in particular by his "Musée des Pays Bas," which contains an account of that magnificent collection drawn up in a series of monographic catalogues. Up to this time, however, Dr. Schlegel has only treated of the class of birds, though at the present moment, I believe, he is engaged on a revision of Quadrumana. To the class of fishes, and especially to the fishes of the Dutch Islands and Seas in the East Indies, another naturalist, Dr. P. P. Bleeker, has for many years devoted great attention. His memoirs and papers on the Ichthyology and Herpetology of the various islands and settlements are far too numerous to mention. But his "Atlas Ichthyologique," his principal work on the Fishes of the Indian Seas, is one of great importance, and claims a special record as embracing the results of the life-work of one of the most energetic and laborious of living naturalists.

The travels of our countryman, Mr. Wallace, in the Malay Archipelago are well known to the general public from his instructive and entertaining narrative, and to zoologists from the large collections which he made in every branch of natural history. It is a misfortune that no general account of them has ever been prepared. But special articles on the birds of the Sula group to the east of Celebes or those of Bourou, and on those of the islands of Timor, Flores, and Lombock, will be found in the Zoological Society's "Proceedings," besides other ornithological papers referring more or less to this district.

Of the island of Celebes we have acquired more intimate knowledge from the researches of Dr. A. B. Meyer, and from two excellent memoirs on its Ornithology, prepared by Lord Walden. The adjacent territory of Borneo has likewise not escaped the attention of recent writers, an accomplished Italian author, Dr. Salvadori, having made it the subject of a special ornithological essay. For the animals of Java and Sumatra, we have unfortunately no such recent authority, but must refer primarily in the one case to Horsfield's Zoological Researches, and in the other to Sir Stamford Raffles' Catalogue, supplementing in each case the deficiency by reference to various more recent books and memoirs. The fact is that before we can attain precise notions as to the real zoological relations of these great islands, we require a much more complete acquaintance with their different faunas, and special monographic essays upon them. So there is certainly no lack of work remaining for the zoologist in this quarter.

6. PHILIPPINE ARCHIPELAGO.

In spite of the visits of Cuming, and more recently of Semper and Jagor, there has been until very lately great lack of a work for reference on the Vertebrates of the Philippine Archipelago. This deficiency has been partly supplied by the excellent essay published by Lord Walden in the "Transactions" of the Zoological Society, upon the Birds of the Philippines. Although based upon the collections of Dr. A. B. Meyer, this memoir contains a *résumé* of all that is yet known upon the subject. It likewise points out the deficencies in our present information, which, I need hardly add, are many and numerous.

That the knowledge of our Mammal-fauna of the Philippines is also by no means perfect, will be sufficiently manifest when I recall to my hearers the fact that there is now living in the Zoological Society's Gardens a very distinct species of Deer,* quite unknown to all our Museums, which is undoubtedly endemic in one of the Philippine Islands. There is much want of more information on this subject, as also on the Reptiles and Fishes, although Dr. Peters has lately made us acquainted with many novelties from Jagor's researches in these branches.

IV.—NEARCTIC REGION.

This part of my subject will be most conveniently treated of under two heads:—

1. *North America down to Mexico*,
2. *Greenland*,

leaving Mexico to be spoken of as a whole under the Neotropical Region, although part of it undoubtedly belongs to the Nearctic.

1. NORTH AMERICA.

(a.) *Mammals*.—The latest revision of the Mammals of North America is still that of Prof. Baird, contained in the Reports on the Zoology of the Pacific Railway Routes, published by the War Department of the U.S. in 1857. I understand, however, that Dr. Coues is now engaged on a more perfect work on the same subject, which will embrace the results of the large additions since made to our knowledge of this subject. The marine Mammals are not included in Prof. Baird's revision; and under this head I may notice two important works recently issued, Mr. Allen's memoir on the Eared Seals, which specially treats of the North-Pacific species, and Capt. Scammon's volume on the marine Mammals of the North-western coasts of North America, which contains a mass of information relative to the little-known Cetaceans of the North Pacific.

Prior to them Audubon and Bachman's Quadrupeds of North America, published at New York in 1852, was the best book of reference.

(b.) *Birds of North America*.—The American ornithologists have been specially active of late years. Up to about twenty years ago, the recognised authorities upon the Birds of the United States were Wilson, Audubon, Bonaparte, and Nuttall. In 1856 Cassin's "Illustrations," chiefly devoted to the species then recently discovered in Texas, California, and Oregon, appeared. In 1858 the joint work of Messrs. Baird, Cassin, and Lawrence, on the Birds of North America, forming part of the "Pacific Railway Routes," was issued. This was republished with additions as a separate work in 1860 in two volumes, and still forms an excellent work of reference on American ornithology. The List of Authorities given at the end of the letterpress will be found extremely useful for those who require a guide to the literature of American ornithology. But even this bids fair to be superseded by the more recent publications of our energetic fellow naturalists. In the first place, three volumes of a "History of North-American Birds," illustrated by plates and numerous woodcuts, by Messrs. Baird, Brewer, and Ridgway (were issued last year, and two more volumes to complete the work will soon be ready. Then for those who require a handy book for reference nothing can be more convenient than Dr. Coues' "Key," in one volume, published in 1872. The same energetic naturalist has also lately issued a "Handbook of the Ornithology of the North-west," containing an account of the birds met with in the region drained by the Missouri and its tributaries, amongst which he has had such long personal experience. Nor must I conclude the list without mentioning Mr. D. G. Elliot's "Birds of North America," which contains life-sized illustrations of many rare

* *Cervus Alfredi*, Sclater, P.Z.S. 1870, p. 381, pl. xxviii.

and previously unfigured species, and Cooper's "Birds of California," devoted to an account of the birds of the Pacific coast-region, which has been edited by Prof. Baird from the late Mr. Cooper's MSS. Of the last-named work, however, only the first volume is yet published. It will be thus seen that we have ample means of acquiring the most recent information on the birds of the Nearctic Region, and in fact in no part of the world, except Europe itself, is our knowledge of the endemic avifauna so nearly approaching towards completion.

(c.) *Reptiles and Batrachians of North America.*—Holbrook's "North American," in five quarto volumes, published at Philadelphia in 1843-4, contains coloured figures of all the North American Reptiles and Batrachians known to the author, and is a reliable work. A large amount of information has been acquired since that period and published in the various "Railway Reports" and periodicals by Hallowell, Baird, Cope, and others. In 1853 Messrs. Baird and Girard published a catalogue of North American Serpents, and Prof. Agassiz devoted the first volume of his "Contributions" mainly to the Testudinata of North America. Prof. Baird tells me that Prof. Cope is now engaged in printing a new catalogue of the Reptiles and Batrachians of North America, which will contain an enumeration of all the species and an account of their geographical distribution.

(d.) *Fishes of North America.*—Of the fishes of North America there is up to the present time no one authority, and the inquirer must refer to the various works of De Kay, Agassiz, and Girard for information. This, aided by the copious references in Dr. Günther's masterly Catalogue, he will have little difficulty in obtaining, so far as it is available. But the "History of American Fishes" is still to be written, and I have no doubt that our energetic brethren of the United States will before long bring it to pass.

2. Greenland.

Of Greenland, which is undoubtedly part of the Nearctic Region, I have made a separate section in order to call special attention to the "Manual" for the use of the Arctic Expedition of 1875, prepared under the direction of the Arctic Committee of the Royal Society. A *résumé* of all that is yet known of the biology of Greenland is included in this volume. I may call special attention to the article on the Birds by Prof. Newton, and on the Fishes by Dr. Lütken, both prepared specially for this work. I am sure you will all join with me in thanking the present Government for sending out this new expedition so fully prepared in every way, and in hoping that large additions may be made to the store of information already accumulated in the "Manual."

(*To be continued.*)

Department of Anthropology.

Address by George Rolleston, M.D., F.R.S., F.S.A., President of the Department.

Dr. Rolleston began his address by referring to a few of the principal papers which were to be brought before the department. He referred in congratulatory terms to the work in the Pacific Islands brought out this year by Dr. Carl E. Meinicke, and to an article by the Rev. S. J. Whitmee in the *Contemporary Review* for February as the most important recent contribution to the ethnology of Polynesia. He then spoke in high terms of the services rendered to the native Polynesians by the missionaries, quoting to the same effect from Gerland's continuation of Wurtz's "Anthropologie." He also referred critically to Mr. Bagehot's statement that savages did not formerly waste away before the classical nations, as they do now before the modern civilised nations. He then went on to say:—

I come now to the consideration of the subject of craniology and craniography. Of the value of the entirety of the physical history of a race there is no question; but two very widely opposed views exist as to the value of skull-measuring to the ethnographer. According to the views of one school, craniography and ethnography are all but convertible terms; another set of teachers insist upon the great width of the limits within which normal human crania from one and the same race may oscillate, and upon the small value which, under such circumstances, we can attach to differences expressed in tenths of inches or even of centimetres. As usual, the truth will not be found to be in either extreme view. For the proper performance of a craniographic estimation, two very different processes are necessary: one is the carrying out and recording a number of measurements; the other is the artistic appreciation of the general impressions as to contour and type which the survey of a series of skulls produce upon one. I have often thought that the work of conducting an examination for a scholarship or fellowship is very similarly dependent, when it is properly carried out, upon the employment of two methods—one being the system of marking, the other that of getting a general impression as to the power of the several candidates; and I would wish to be understood to mean by this illustration not only that the two lines of inquiry are both dependent upon the combination and counterchecking of two different methods, but also that their results, like the results of some other human investigations, must not be always, even though they may be sometimes, considered to be free from all and any need for qualification. Persons like M. Broca and Prof. Aeby, who have carried out the most extensive series of measurements, are not the persons who express themselves in the strongest language as to craniography being the universal solvent in ethnography or anthropology. Aeby, for example, in his "Schädelformen der Menschen und der Affen," 1867, p. 61, says:—"Aus dem gesagten geht hervor dass die Stellung der Anthropologie gegenüber den Schädelformen eine ausserordentlich schwierige ist;" and the perpetual contradiction of the results of the skull-measurements carried out by others, which his paper (published in last year's "Archiv für Anthropologie," pp. 12, 14, 20) abounds in, furnishes a practical commentary upon the just quoted words. And Broca's words are especially worth quoting, from the "Bulletin de la Société d'Anthropologie de Paris," Nov. 6, 1873, p. 824:—"Dans l'état actuel de nos connaissances la craniologie ne peut avoir la pretention de voler de ses propres ailes, et de substituer ses diagnostics aux notions fournies par l'ethnologie et par l'archæologie."

I would venture to say that the way in which a person with the command of a considerable number of skulls procured from some one district in modern times, or from some one kind of tumulus or sepulchre in prehistoric times, would naturally address himself to the work of arranging them in a museum, furnishes us with a concrete illustration of the true limits of craniography. I say, "a person with the command of a considerable number of skulls;" for, valuable as a single skull may be, and often is, as furnishing the missing link in a gradational series, one or two skulls by themselves do not justify us (except in rare instances, which I will hereinafter specify) in predicating anything as to their nationality. Greater rashness has never been shown, even in a realm of science from which rashness has only recently been proceeded against under an Alien Act, than in certain speculations as to the immigration of races into various corners of the world, based upon the casual discovery in such places of single skulls, which skulls were identified on the ground of their individual characters as having belonged to races shown on no other evidence to have ever set foot there.

It is, of course, possible enough for a skilled craniographer to be right in referring even a single skull to some particular nationality; an Australian or an Eskimo, or an Andamanese might be so referred with some confidence; but all such successes should be recorded with the reservation suggested by the words, *ubi eorum qui perierunt?* and by the English line, "The many fail, the one succeeds." They are the shots which have hit and have been recorded. But if it is unsafe to base any ethnographic conclusions upon the examination of one or two skulls, it is not so when we can examine about ten times as many—ten, that is to say, or twenty, the locality and the dates of which are known as certain quantities. A craniographer thus fortunate casts his eye over the entire series, and selects from it one or more which correspond to one of the great types based by Retzius not merely upon consideration of proportionate lengths and breadths, but also upon the artistic considerations of type, curve, and contour. He measures the skulls thus selected, and so furnishes himself with a check which even the most practised eye cannot safely dispense with. He then proceeds to satisfy himself as to whether the entire series is referable to one alone of the two great typical forms of Brachycephaly or Dolichocephaly, or whether both types are represented in it, and if so, in what proportions and with what admixture of intermediate forms. With a number of Peruvian, or, indeed, of Western American skulls generally, of Australian, of Tasmanian, of Eskimo, of Veddah, of Andamanese crania before him, the craniographer would nearly always, setting aside a few abnormally aberrant (which are frequently morbid) specimens, refer them all to one single type.*

* It is not by any means entirely correct to say that there is no variety observable among races living in isolated savage urity. The good people of

Matters would be very different when the craniographer came to deal with a mixed race like our own, or like the population of Switzerland, the investigation into the craniology of which has resulted in the production of the invaluable "Crania Helvetica" of His and Rütimeyer. At once, upon the first inspection of a series of crania, or, indeed, of heads, from such a race, it is evident some are referable to one, some to another, of one, two, or three typical forms, and that a residue remains whose existence and character is perhaps explained and expressed by calling them "Mischformen." Then arises a most interesting question —Has the result of intercrossing been such as to give a preponderance to these "Mischformen?" or has it not rather been such as in the ultimate resort, whilst still testified to by the presence of intermediating and interconnecting links, to have left the originally distinct forms still in something like their original independence, and in the possession of an overwhelmed numerical representation? The latter of these two alternative possibilities is certainly often to be seen realised within the limits of a modern so-called "English" or so-called "British" family; and His has laid this down as being the result of the investigations above mentioned into the ethnology of Switzerland. At the same time it is of cardinal importance to note that His has recorded, though only in a footnote, that the skulls which combine the characters of his two best-defined types, the "Sion-Typus" to wit, and the "Disentis-Typus," in the "Mischform," which he calls "Sion-Disentis Mischlinge," are the most capacious of the entire series of the "Crania Helvetica," exceeding, not by their maximum only, but by their average capacity also, the corresponding capacities of every one of the pure Swiss types.* Intercrossing, therefore, is an agency which in one set of cases may operate in the way of enhancing individual evolution, whilst in another it so divides its influence as to allow of the maintenance of two types in their distinctness. Both these results are of equal biological, the latter is of pre-eminent archæological, interest. Retzius † was of opinion, and with a few qualifications I think more recent Swedish ethnologists would agree, that the modern dolichocephalic Swedish cranium was very closely affined to, if not an exact reproduction of the Swedish cranium of the Stone period; and Virchow ‡ holds that the modern brachycephalic Danish skull is similarly related to the Danish skull of the same period. There can be no doubt that the Swedish cranium is very closely similar indeed to the Anglo-Saxon; and the skulls which still conform to that type amongst us will be by most men supposed to be the legitimate representatives of the followers of Hengest and Horsa, just as the modern Swedes, whose country has been less subjected to disturbing agencies, must be held to be the lineal descendants of the original occupiers of their soil. I am inclined to think that the permanence of the brachycephalic stock and type in Denmark has also its bearing upon the ethnography of this country. In the Round-Barrow or Bronze period in this country, sub-spheroidal crania (that is to say, crania of a totally different shape and type from those which are found in exclusive possession of the older and longer barrows) are found in great abundance, sometimes, as in the south, in exclusive possession of the sepulchre, sometimes in company, as in the north, with skulls of the older type. The skulls are often strikingly like those of the same type from the Danish tumuli. On this coincidence I should not stake much, were it not confirmed by other indications. And foremost amongst these indications I should place the fact of the "Tree-interments," as they have been called—interments, that is, in coffins made out of the trunk of a tree of this country, and of Denmark, being so closely alike. The well-known monoxylic coffin from Gristhorpe contained, together with other relics closely similar to the relics found at Treenhoi, in South Jutland, in a similar coffin, a skull which, as I can testify from a cast given me by my friend Mr. H. S. Harland, might very well pass for that of a brachycephalic Dane of the Neolithic period. Canon Greenwell discovered a similar monoxylic coffin at Skipton, in Yorkshire; and two others have been recorded from the same county, one from the neighbourhood of Driffield, the other from that of Thornborough.

Col. Lane Fox is of opinion that the earthworks which form such striking objects for inquiry here and there on the East Riding Wolds must, considering that the art of war has been the same in its broad features in all ages, have been thrown up by an invading force advancing from the east coast. Now, we do know that England was not only made England by immigration from that corner or angle where the Cimbric Peninsula joins the main land, but that long after that change of her name this country was successfully invaded from that peninsula itself. And what Swegen and Cnut did some four hundred and fifty years after the time of Hengest and Horsa, it is not unreasonable to suppose other warriors and other tribes from the same locality may have done perhaps twice or thrice as many centuries further back in time than the Saxon Conquest. The huge proportions of the Cimbri, Teutones, and Ambrones, are just what the skeletons of the British Round-Barrow folk enable us now to reproduce for ourselves. It is much to be regretted that from the vast slaughters of Aquæ Sextiæ and Vercellæ no relics have been preserved which might have enabled us to say whether Boiorix and his companions had the cephalic proportions of Neolithic Danes, or those very different contours which we are familiar with from Saxon graves throughout England, and from the so-called "Danes' graves" of Yorkshire. Whatever might be the result of such a discovery and such a comparison, I think it would in neither event justify the application of the term "Kymric" to the particular form of skull to which Retzius and Broca have assigned it.

Some years ago I noticed the absence of the brachycephalic British type of skull from an extensive series of Romano-British skulls which had come into my hands; and subsequently to my doing this, Canon Greenwell pointed out to me that such skulls as we had from late Celtic cemeteries, belonging to the comparatively short period which elapsed between the end of the Bronze period and the establishment of Roman rule in Great Britain, seemed to have reverted mostly to the præ-Bronze dolichocephalic type. This latter type, the "kumbecephalic type" of Prof. Daniel Wilson, manifests a singular vitality, as the late and much lamented Prof. Phillips pointed out long ago at a meeting of this Association held at Swansea—the dark-haired variety, which is very ordinarily the longer-headed and the shorter-statured variety of our countrymen being represented in very great abundance in those regions of England which can be shown, by irrefragable and multifold evidence, to have been most thoroughly permeated, imbibed, and metamorphosed by the infusion of Saxons and Danes in the districts, to wit, of Derby, Leicester, Stamford, and Loughborough. How and in what way this type of man, one to which some of the most valuable men now bearing the name of Englishmen, which they once abhorred, belong, has contrived to reassert itself, we may, if I am rightly informed, hear some discussion in this department. Before leaving this part of my subject I would say that the Danish type of head still survives amongst us; but it is to my thinking not by any means so common, at least in the midland counties, as the dark-haired type of which we have just been speaking. And I would add that I hope I may find that the views which I have here hinted at will be found to be in accord with the extensive researches of Dr. Beddoe, a gentleman who worthily represents and upholds the interests of anthropology in this city, the city of Prichard, and who is considered to be more or less disqualified for occupying the post which I now hold, mainly from the fact that he has occupied it before, and that the rules of the British Association, like the laws of England, have more or less of an abhorrence of perpetuities.

The largest result which craniometry and cubage of skulls have attained is, to my thinking, the demonstration of the following facts, viz.:—first, that the cubical contents of many skulls from the earliest sepultures from which we have any skulls at all, are larger considerably than the average cubical contents of modern European skulls; and secondly, that the female skulls of those times did not contrast to that disadvantage with the skulls of their male contemporaries which the average female skulls of modern days do, when subjected to a similar comparison.* Dr. Thurnam demonstrated the former of these facts, as regards the skulls from the Long and the Round Barrows of

Baden who, when they first saw them, said all the Baskhirs in a regiment brought up to the Rhine in 1813 by the Russians were as like to each other as twins, found, in the course of a few weeks, that they could distinguish them readily and sharply enough (Crania Germaniæ Occid. p. 2; Archiv für Anthrop. v. p. 485, 1872). And real naturalists, such as Mr. Bates, practised in the discrimination of zoological differences, express themselves as struck rather with the amount of unlikeness than with that of likeness which prevails amongst savage tribes of the greatest simplicity of life and the most entire freedom from crossing with other races. But these observations relate to the *living heads*, not to the skulls.

* See Dr. Beddoe, Mem. Soc. Anth. Lond. iii. p. 552; Huth, p. 308, 1875; D. Wilson, cit. Brace, "Races of the Old World," p. 380.

† "Ethnologische Schriften," p. 7.

‡ "Archiv für Anthropologie," iv. pp. 71 and 80.

* The subequality of the male and female skulls in the less civilised of modern races was pointed out as long ago as 1845 by Retzius, in Müller's "Archiv," p. 89, and was commented upon by Huschke, of Jena, in his "Schädel, Hirn, und Seele," pp. 48–51, in 1854.

Wiltshire, in the Memoirs of the London Anthropological Society for 1865; and the names of Les Eyzies and Cro-Magnon, and of the Caverne de l'Homme Mort, to which we may add that of Solutré, remind us that the first of these facts has been confirmed, and the second both indicated and abundantly commented upon by M. Broca.

The impression which these facts make upon one, when one first comes to realise them, is closely similar to that which is made by the first realisation to the mind of the existence of a subtropical flora in Greenland in Miocene times. All our anticipations are precisely reversed, and in each case by a weight of demonstration equivalent to such a work; there is no possibility in either case of any mistake; and we acknowledge that all that we had expected is absent, and that where we had looked for poverty and pinching there we come upon luxurious and exuberant growth. The comparisons we draw in either case between the past and the present are not wholly to the advantage of the latter: still such are the facts. Philologists will thank me for reminding them of Mr. Chauncy Wright's brilliant suggestions that the large relative size of brain to body which distinguishes, and always, so far as we know, has distinguished the human species as compared with the species most nearly related to it, may be explained by the psychological tenet that the smallest proficiency in the faculty of language may "require more brain power than the greatest in any other direction," and that "we do not know and have no means of knowing what is the quantity of intellectual power as measured by brains which even the simplest use of language requires.*

And for the explanation of the pre-eminently large size of the brains of these particular representatives of our species, the tenants of prehistoric sepulchres, we have to bear in mind, first, that they were, as the smallness of their numbers and the largeness of the tumuli lodging them may be taken to prove, the chiefs of their tribes; and, secondly, that modern savages have been known, and prehistoric savages may therefore be supposed, to have occasionally elected their chiefs to their chieftainships upon grounds furnished by their superior fitness for such posts—that is to say, for their superior energy and ability. Some persons may find it difficult to believe this, though such facts are deposed to by most thoroughly trustworthy travellers, such as Baron Osten Sacken, referred to by Von Baer, in the Report of the famous Anthropological Congress at Göttingen, in 1861, p. 22. And they may object to accepting it, for, among other reasons, this reason—to wit, that Mr. Galton has shown us in his "Men of Science, their Nature and Nurture," p. 98, that men of great energy and activity (that is to say just the very men fitted to act as leaders of and to commend themselves to savages)† have ordinarily smaller-sized heads than men possessed of intellectual power dissociated from those qualities.

The objection I specify, as well as those which I allude to, may have too much weight assigned to them; but we can waive this discussion and put our feet on firm ground when we say that in all savage communities the chiefs have a larger share of food and other comforts, such as there are in savage life, and have consequently better and larger frames—or, as the Rev. S. Whitmee puts it (*l.c.*), when observing on the fact as noticed by him in Polynesia, a more "portly bearing." This (which, as the size of the brain increases within certain proportions with the increase of the size of the body, is a material fact in every sense) has been testified to by a multitude of other observers, and is, to my mind, one of the most distinctive marks of savagery as opposed to civilisation. It is only in times of civilisation that men of the puny stature of Ulysses or Agesilaus are allowed their proper place in the management of affairs. And men of such physical size, coupled with such mental calibre, may take comfort, if they need it, from the purely quantitative consideration, that large as are the individual skulls from prehistoric graves, and high, too, as is the average obtained from a number of them, it has nevertheless not been shown that the largest individual skulls of those days were larger than, or, indeed, as large as the best skulls of our own days; whilst the high average capacity which the former series shows is readily explicable by the very obvious consideration that the poorer specimens of humanity, if allowed to live at all in those days, were, at any rate, when dead not allowed sepulture in the "tombs of the kings," from which nearly exclusively we obtain our prehistoric crania. M. Broca* has given us yet further ground for retaining our self-complacency by showing, from his extensive series of measurements of the crania from successive epochs in Parisian burial-places, that the average capacity has gone on steadily increasing.

It may be suggested that a large brain, as calculated by the cubage of the skull, may nevertheless have been a comparatively lowly organised one, from having its molecular constitution qualitatively inferior from the neuroglia being developed to the disadvantage of the neurine, or from having its convolutions few and simple, and being thus poorer in the aggregate mass of its grey ossicular matter. It is perhaps impossible to dispose absolutely of either of these suggestions. But, as regards the first, it seems to me to be exceedingly improbable that such could have been the case. For in cases where an overgrowth of neuroglia has given the brain increase of bulk without giving it increase of its true nervous elements, the Scotch proverb, "Muckle brain, mickle wit," applies; and the relatively inferior intelligence of the owners of such brains as seen nowadays may, on the principle of continuity, be supposed to have attached to the owners of such brains in former times. But those times were times of a severer struggle for existence than even the present; and inferior intelligences, and specially the inferior quickness and readiness observable in such cases, it may well be supposed, would have fared worse then than now. There is, however, no need for this supposition, for, as a matter of fact, the brain-case of brains so hypertrophied† has a very recognisable shape of its own, and this shape is not the shape of the Cro-Magnon skull, nor indeed of any of the prehistoric skulls with which I am acquainted.

As regards the second suggestion to the effect that a large braincase may have contained a brain the convolutions of which were simple, broad, and coarse, and which made up by consequence a sheet of grey matter of less square area than that made up in a brain of similar size, but of more complex and slenderer convolutions, I have to say that it is possible this may have been the case, but that it seems to me by no means likely. Very large skulls are sometimes found amongst collections purporting to have come from very savage or degraded races; such a skull may be seen in the London College of Surgeons with a label, "5357 D. Bushman, G. Williams. Presented by Sir John Lubbock;" and, from what Prof. Marshall and Gratiolet have taught us as to other Bushman brains, smaller, it is true, in size, we may be inclined to think that the brain which this large skull once contained may nevertheless have been much simpler in its convolutions than a European brain of similar size would be. This skull, however, is an isolated instance of such proportions amongst Bushman skulls, so far, at least, as I have been able to discover; whilst the skulls of prehistoric times, though not invariably, are yet most ordinarily large skulls. A large brain with coarse convolutions puts its possessor at a disadvantage in the struggle for existence, as its greater size is not compensated by greater dynamical activity; and hence I should be slow to explain the large size of ancient skulls by suggesting that they contained brains of this negative character. And I am glad to see that M. Broca is emphatically of this opinion, and that, after a judicious statement of the whole case, he expresses himself thus (*Revue d'Anthropologie*, ii. 1, 38):—"Rien ne permet donc de supposer que les rapports de la masse encéphalique avec l'intelligence fussent autres chez eux que chez nous."

It is by a reference to the greater severity of the struggle for existence and to the lesser degree to which the principle of division of labour was carried out in olden days, that M. Broca, in his paper on the "Caverne de l'Homme Mort," just quoted from, explains the fact of the subequality of the skulls in the two sexes. This is an adequate explanation of the facts; but to the facts as already stated, I can add from my own experience the fact that though the female skulls of prehistoric times are often they are not always equal, or nearly, to those of the male sex of those times; and, secondly, that whatever the relative size of the head, the limbs and trunk of the female portion of those tribes were, as is still the case with modern savages, very usually disproportionately smaller than those of the male. This is

* The bibliographer will thank me also for pointing out to him that the important paper in the *North American Review* for October 1870, p. 295, from which I have just quoted, has actually escaped the wonderfully exhaustive research of Dr. Seidlitz (see his "Darwin'sche Theorie," 1875).

† An interesting and instructive story in illustration of the kind of qualis which do recommend a man to savages, is told us by Sir Bartle Frere his pamphlet, "Christianity suited to all forms of Civilisation," pp. 12-14.

* See his paper "Bull. Soc. Anthrop. de Paris," t. iii. ser. i. 1862, p. 102; or his collected "Mémoires," vol. i. p. 348, 1871.

† I may, perhaps, be allowed to express here my surprise at the statement made by Messrs. Wilks and Moxon, in their very valuable "Pathological Anatomy," pp. 217, 218, to the effect that they have not met with such cases of cerebral hypertrophy. They were common enough at the Children's Hospital in Great Ormond Street when I was attached to it.

readily enough explicable by a reference to the operations of causes exemplifications of the working of which are unhappily not far to seek now, and may be found in any detail you please in those anthropologically interesting (however otherwise unpleasant) documents, the Police Reports.

Having before my mind the liability we are all under fallaciously to content ourselves with recording the shots which hit, I must not omit to say that one at least of the more recently propounded doctrines in craniology does not seem to me to be firmly established. This is the doctrine of "occipital dolichocephaly" being a characteristic of the lower races of modern days and of prehistoric races as compared with modern civilised races. I have not been able to convince myself by my own measurements of the tenability of this position; and I observe that Ihering has expressed himself to the same effect, appending his measurements in proof of his statements in his paper, "Zur Reform der Craniometrie," published in the "Zeitschrift für Ethnologie" for 1873. The careful and colossal measurements of Aeby * and Weisbach † have shown that the occipital region enjoys wider limits of oscillation than either of the other divisions of the cranial vault. I have some regret in saying this, partly because writers on such subjects as "Literature and Dogma" have already made use of the phrase "occipitally dolichocephalic," as if it represented one of the permanent acquisitions of science; and I say it with even more regret, as it concerns the deservedly honoured names of Gratiolet and of Broca, to whom anthropology owes so much. What is true in the doctrine relates, among other things, to what is matter of common observation as to the fore part of the head rather than to anything which is really constant in the back part of the skull. This matter of common observation is to the effect that when the ear is "well forward" in the head we do ill to augur well of the intelligence of its owner. Now, the fore part of the brain is irrigated by the carotid arteries, which, though smaller in calibre during the first years of life, during which the brain so nearly attains its full size, than they are in the adult, are nevertheless relatively large even in those early days, and are both absolutely, and relatively to the brain which they have to nourish, much larger than the vertebral arteries, which feed its posterior lobes. It is easy therefore to see that a brain in which the fore part supplied by the carotids has been stinted of due supplies of food, or however stunted in growth, is a brain the entire length and breadth of which is likely to be ill-nourished. As I have never seen reason to believe in any cerebral localisation which was not explicable by a reference to vascular irrigation, it was with much pleasure that I read the remarks of Messrs. Wilks and Moxon in their recently published "Pathological Anatomy," pp. 207, 208, as to the indications furnished by the distribution of the Tacchionian bodies as to differences existing in the blood-currents on the back and those on the fore part of the brain. These remarks are the more valuable, as mere hydraulics, Professor Clifton assures me, would not have so clearly pointed out what the physiological upgrowths seem to indicate. Any increase, again, in the length of the posterior cerebral arteries is *pro tanto* a disadvantage to the parts they feed. If the blood-current, as these facts seem to show, is slower in the posterior lobes of the brain, it is, upon purely physical principles of endosmosis and exosmosis, plain that these segments of the brain are less efficient organs for the mind to work with; and here again, "occipital dolichocephaly" would have a justification, though one founded on the facts of the nutrition of the brain-cells, not on the proportions of the braincase. In many (but not in all) parts of Continental Europe, again, the epithet "long-headed" would not have the laudatory connotation which, thanks to our Saxon blood, and in spite of the existence amongst us of other varieties of dolichocephaly, it still retains here. Now, the brachycephalic head which, abroad ‡ at least, is ordinarily a more capacious one, and carried on more vigorous shoulders and by more vigorous owners altogether, than the dolichocephalic, strikes a man who has been used to live amongst dolichocephali by nothing more forcibly, when he first comes to take notice of it, than by the nearness of its external ear to the back of the head; and this may be said to constitute an artistic occipital brachycephalism. But this does not imply that the converse condition is to be found conversely correlated, nor does it justify the use of the phrase "occipital dolichocephaly" in any etymological, nor even in any ethnographical, sense.

I shall now content myself, as far as craniology is concerned, by an enumeration of some at least of the various recent memoirs upon the subject which appear to me to be of pre-eminent value. And foremost amongst these I will mention Professor Cleland's long and elaborate scientific and artistic paper on the Variations of the Human Skull, which appear in the "Philosophical Transactions" for 1869. Next I will name Ecker's admirable, though shorter, memoir on Cranial Curvature, which appeared in the "Archiv für Anthropologie," a journal already owing much to his labours, in the year 1871. Aeby's writings I have already referred to, and Ihering's, to be found in recent numbers of the "Archiv für Anthropologie" and the "Zeitschrift für Ethnologie," deserve your notice. Professor Bischoff's paper on the Mutual Relations of the horizontal circumference of the Skull and of its contents to each other and to the weight of the Brain, has not, as I think, obtained the notice which it deserves. It is to be found in the "Proceedings" of the Royal Society of Munich for 1864, the same year which witnessed the publication of the now constantly quoted "Crania Helvetica," of Professors His and Rütimeyer. Some of the most important results contained in this work, and much important matters besides, was made advailable to the exclusively English reader by Professor Huxley two years later, in the "Pre-historic Remains of Caithness." I have made a list, perhaps not an exhaustive one, but containing some dozen memoirs by Dr. Beddoe, and having read them or nearly all of them, I can with a very safe conscience recommend you all to do the like. I can say nearly the same as regards Broca and Virchow, adding that the former of these two *savans* has set the other two with whom I have coupled him an excellent example, by collecting and publishing his papers in consecutive volumes.

But I should forget not only what is due to the place in which I am speaking, but what is due to the subject I am here concerned with, if, in speaking of its literature, I omitted the name of your own townsman, Prichard. He has been called, and, I think, justly, the "father of modern anthropology." I am but putting the same thing in other words, and adding something more specific to it, when I compare his works to those of Gibbon and Thirlwall, and say that they have attained and seem likely to maintain permanently a position and importance commensurate with that of the "stately and undecaying" productions of those great English historians. Subsequently to the first appearance of those histories other works have appeared by other authors, who have dealt in them with the same periods of time. I have no wish to depreciate those works; their authors have not rarely rectified a slip and corrected an error into which their great predecessors had fallen. Nay, more, the later comers have by no means neglected to avail themselves of the advantages which the increase of knowledge and the vast political experience of the last thirty years have put at their disposal, and they have thus occasionally had opportunities of showing more of the true proportions and relations of even great events and catastrophes. Still the older works retain a lasting value, and will remain as solid testimonies to English intellect and English capacity for large undertakings as long as our now rapidly extending language and literature live. The same may be most truthfully said of Prichard's "Researches into the Physical History of Mankind." An increase of knowledge may supply us with fresh and with stronger arguments than he could command for some of the great conclusions for which he contended; such, notably, has been the case in the question (though question it can no longer be called) of the Unity of the human species; and by the employment of the philosophy of continuity and the doctrine of evolution, with which the world was not made acquainted till more than ten years after Prichard's death, many a weaker man than he has been enabled to bind into more readily manageable burdens the vast collections of facts with which he had to deal. Still his works remain, massive, impressive, enduring—much as the headlands along our southern coast stand out in the distance in their own grand outlines, whilst a close and minute inspection is necessary for the discernment of the forts and fosses added to them, indeed dug out of their substance in recent times. If we consider what the condition of the subject was when Prichard addressed himself to it, we shall be the better qualified to take and make an estimate of his merits. This Prichard has himself described to us, in a passage to be found in the preface to the third volume of the third edition of the "Physical History," published in the year 1841, and reminding one forcibly of a similar utterance of Aristotle's

* Aeby, "Schädelform des Menschen und der Affen," pp. 11, 12, and 128.

† Weisbach, "Die Schädelform der Roumanen," p. 32, 1869.

‡ See upon this point:—Broca, Bull. Soc. Anth. Paris, ii. p. 648, 1861; *ibid.* Dec. 5, 1872; Virchow, Archiv für Anth. v. p. 535; Zeitschrift für Ethnol. iv. 2, p. 36; Sammlungen, ix. 193, p. 45, 1874; Beddoe, Mem. Anth. Soc. Lond. ii. p. 350.

at the end of one of his logical treatises (Soph. Elench. cap. xxxiv. 6). These are his words:—

"No other writer has surveyed the same field, or any great part of it, from a similar point of view. . . . The lucubrations of Herder and other diffuse writers of the same description, while some of them possess a merit of their own, are not concerned in the same design, or directed towards the same scope. Their object is to portray national character as resulting from combined influences—physical, moral, and political. They abound in generalisations, often in the speculative flights of a discursive fancy, and afford little or no aid for the close induction from facts, which is the aim of the present work. Nor have these inquiries often come within the view of writers on geography, though the history of the globe is very incomplete without that of its human inhabitants." A generation has scarcely passed away since these words were published in 1841; we are living in 1875; yet what a change has been effected in the condition of anthropological literature! The existence of such a dignified quarterly as the "Archiv für Anthropologie," bearing on its title-page in alphabetical order the honoured names of V. Baer, of Desor, of Ecker, of Hellwald, of His, of Lindenschmidt, of Lucæ, of Rütimeyer, of Schaafhausen, of Semper, of Virchow, of Vogt, and of Welcker, is in itself perhaps the most striking evidence of the advance made in this time, as being the most distinctly ponderable and in every sense the largest anthropological publication of the day.

Archæology, which but a short time back was studied in a way which admirably qualified its devotees for being called "connoisseurs," but which scarcely qualified them for being called men of science, has by its alliance with natural history and its adoption of natural history methods, and its availing itself of the light afforded by the great natural history principles just alluded to, entered on a new career. There is, as regards natural history, anatomy, and pathology, nothing left to be desired for the conjoint scheme represented by the periodical just mentioned, where we have V. Baer for the first and Virchow for the last, and the other names specified for the rest of these subjects; whilst archæology, the other party in the alliance, is very adequately represented by Lindenschmidt alone. But when I recollect that Prichard published a work "On the Eastern Origin of the Celtic Nations" ten years before the volume of "Researches," from which I have just quoted, and that this work has been spoken of as the work "which has made the greatest advance in Comparative Philology during the present century," I cannot but feel that the Redaction of the "Archiv für Anthropologie" have not as yet learnt all that may be learnt from the Bristol Ethnologist; and they would do well to add to the very strong staff represented on their title-page the name of some one, or the names of more than one comparative philologist. This the Berlin "Zeitschrift" has done.

Prof. Rolleston concluded by a few words on the possible curative application of some of the leading principles of modern Anthropology to some of the prevalent errors of the day.

MEETING OF THE ASTRONOMISCHE GESELLSCHAFT AT LEYDEN, AUGUST 13-16.

The sixth biennial meeting of the Astronomische Gesellschaft, founded in the year 1863, at Heidelberg took place this year at Leyden, according to the international character of the Society, and in conformity with the resolution of the last meeting at Hamburg. The first session was opened by the President, O. Struve, in the rooms of the magnificent Observatory at Leyden. Besides him were present the following members: Auerbach, Bruhns, Engelmann, Scheibner, and Zöllner from Leipzig; Winnecke, and Hartwig from Strassburg; H. G. Bakhuyzen, E.F. Bakhuyzen, Kaiser, Schlegel and Valentiner, from Leyden; Gyldèn from Stockholm, Repsold from Hamburg, v. d. Willigen from Harlem, Förster and Tietjen from Berlin, Seeliger from Bonn, Bruns from Dorpat, Kortazzi from Nikolajew, Palisa from Pola, Bosscha from the Hague, Block from Odesa.

After an address from the Curator of the Leyden University, Baron Gevers van Endegeest, in which he spoke of the great merits of the late Director of the Leyden Observatory, the eminent Kaiser, and his exertions in promoting astronomical studies in Netherland, the usual statistical notices were read.

The President stated that after the conclusion of the Hamburg meeting the number of members was 231, that 28 new members had been admitted, while the loss by death or otherwise had been 24, so that the actual number of members was 235. He gave biographical notices of some of the deceased members, Hoek, Mödler, Argelander, Winlock, and d'Arrest. The treasurer, Auerbach, read the balance of the two last years' income and expenses; the secretary, Prof. Winnecke, reported that the publications of the Gesellschaft published were: Publication No. xiii.; Spörer, "Beobachtungen der Sonnenflecken zu Anelam mit 23 Tafeln," and "Vierteljahrsschrift der Astron. Gesellschaft," (vol. viii., 3, 4, vol. ix., vol. x., 1, 2, 3). Prof. Scheibner reported on the library and mentioned, amongst others, the very valuable gift of all the manuscripts of the great astronomer of Gotha, Hansen, made by his widow to the society.

Prof. Bruhns gave an account of the progress of work on comets, undertaken by the Society. Of especial interest was the communication and discussion on Encke's comet.

Prof. Scheibner presented the first copy of a posthumous memoir of Hansen on the Pertubations of Jupiter, and explained the present state of the undertaking.

Prof. Bruhns exhibited an apparatus for the graphical solution of Kepler's problem, and explained its use. The same communicated a description of a new photometer, the execution of which was in progress. Prof. Zöllner explained then, by a model, some improvements of his well-known photometer, through which it becomes more easily adapted to all kinds of telescopes. Some observations of Mars, made by Kononewitsch, appear to indicate a real diminution in the brightness of Mars.

Prof. Bakhuyzen laid before the Society two manuscript volumes, bought lately by the Leyden Observatory, "the Areographischen Fragmente by Schröter" long reputed to be lost. Besides these, he exhibited the very interesting diagrams of Mars made two centuries ago by the celebrated Huyghens.

Dr. Engelmann of Leipzig announced that he is preparing for press an edition of Bessel's various smaller papers.

At the second meeting, August 14, the members Astrand (Bergen), Gelmuyden (Christiania), Hohwü (Amsterdam), Neumayer (Berlin) were present, and six new members were admitted.

The Council gave the Report on the progress of the Meridional Zone work by which all stars down to the 9th inclination between 80° north and 2 south declination are catalogued. The following observatories partake in this great work: Kasan, Dorpat, Christiania, Helsingfors, Cambridge (U.S.), Bonn, Chicago, Leyden, Cambridge (England), Berlin, Leipzig, Neuenburg, Nikolajew.

It was then to be decided where the Gesellshaft would meet the next time. After an invitation by Prof. Gyldèn from Stockholm, the Gesellshaft decided on Stockholm for the seventh biennial meeting.

Prof. Förster of Berlin made a detailed communication on the situation of different Astronomical Institutions of Berlin, including those which are in the course of construction. The erection of the Astro-physical Observatory near Potsdam is in good progress. It has not yet been possible to appoint a Director for this extensive institution; meanwhile the services of Prof. Spörer, Dr. Vogel, and Dr. Lohse are secured for it. This new institution is intended to promote science principally in the higher optics, and their application to astronomy, while the Observatory at Berlin and the Institution for exact Numerical Computation under the direction of Prof. Tietjen will pursue their given ways.

Prof. Bakhuyzen exhibited a new wire micrometer, sent by Merz, and explained its pecularities. Prof. Gyldèn gave a new solution of Kepler's problem with the aid of elliptical functions, and distributed some copies of a memoir on the use of elliptical integrals in the theory of the motion of the heavenly bodies. Dr. Palisa explained the construction of the new meridian circle at Pola by many large plates. Different papers sent to the meeting by Astrand, Covarrubias, Lockyer, and Struve were laid on the table.

The Observatory at Brussels appears, after the loss of its founder and genial director, Professor Quetelet, to be in a critical position. The Astronomische Gesellsshaft resolved unanimously, that it is to be wished that the distinguished activity exhibited by the Brussels Observatory in the determination of the places of stars with sensible proper motion, may be maintained, and if possible, improved by completing its instrumental means. It is in the interest of science to reduce and print the results of the measures in question as soon as possible.

At the third meeting, August 16, Covarrubias from Mexico, and Metzger from Java were present.

After the discussion of various business matters, the Zone observations, the computations on minor planets, and the reduction of the observations made during the transit of Venus 1874, December 8, Engineer Metzger made from Java different communications on the astronomical and geodetical proceedings at Java. Professor Scheibner spoke on the use of the theory of elliptical functions in the theory of perturbations, and communicated a prize-question concerning this matter by the Tablonowski Society at Leipzig. He also communicated very interesting results of his researches in dioptrics.—Professor Neumayer gave a statement on the regulations and field of labour of the Hydrographical Office at Berlin, and of the Scientific Institutions under its direction, the Observatory at Wilhelmshaven and the Deutsche Seewarte at Hamburg. Professor Winnecke described the new orbit-sweeper of the Strasburg Observatory, and announced the beginning of a review of the nebula. The equipment of the new Observatory at Strasburg is made with the direct intention of activity in this branch of astronomy.—Professor Bruhns remarked, that at the Leipzig Observatory charts for the nebula are made, which are visible in a comet-seeker.—Professor Bakhuyzen communicated his researches on the latitude of Greenwich, and its diminution in the later years.

The election of the New Council concluded the meeting: President, Professor Struve; Vice-President, Professor Bruhns; Secretaries, Professors Schönfeld and Winnecke.

NOTES

THE *Valorous*, which accompanied the two Arctic ships, the *Alert* and the *Discovery*, as far as Disco, with coals and provisions, arrived at Plymouth on Sunday. She has really nothing remarkable to tell, which is so far satisfactory. Severe storms were met with in crossing the Atlantic, but all three vessels seem to have borne themselves well, though the *Alert* and *Discovery* each lost a whale boat, a loss which was made up to them by the *Valorous* before leaving Disco. The *Valorous* was the first to reach Disco, which she did on July 4, the other two not coming up till the 6th. The ships remained together at Disco till the 15th, the two exploring vessels filling up from their consort as much coals and provisions as they could stow away. During their stay at Disco, officers and men seem to have enjoyed themselves and to have been treated with the greatest courtesy and kindness by the Danish officials and the natives. Mr. Kraup Smith, the Inspector of North Greenland, had orders from his Government to pay every attention to the Expedition, and he carried out his instructions most liberally. He provided the Expedition with sixty-four dogs and an Esquimaux. While at Disco the naturalists of the three ships were employed collecting botanical and geological specimens on shore and dredging in and outside the harbour. A very large number of plants were found, some believed to have been previously unknown in this part of Greenland. The *Alert* and *Discovery* having been put into complete trim, the Expedition left Godhavn on July 15, and on the 16th the *Valorous* took leave of her consort ships, after seeing them fairly on their way to their work in the high north. The Danish officials' reports as to the weather are favourable, leading to the belief that the navigation of Melville Bay and northwards will be comparatively easy. It is hoped that suitable winter quarters will be found for the *Discovery* on the north shore of Lady Franklin's Strait, from whence hunting parties will issue. The *Alert* will then press onwards alone to the north, landing depots, building cairns with records at intervals of about sixty miles. The surest way of reaching the Pole, in Captain Nares's opinion, is not to risk failure by pushing forward away from the land. The *Alert* will probably winter in 84° and begin sledge travelling so as to get information of the country, and then in the summer of 1876 will push boldly northwards. The grand achievement will be done by a system of depots and auxiliary sledges, enabling the foremost to be absent about 112 days, and to advance upwards of 500 miles from the ship. The *Discovery*, in the meantime, will go on exploring and advancing slowly. At the British Association on Tuesday, a paper by Mr. C. H. Markham, who accompanied his cousin to Disco in the *Alert*, was read; and Mr. Carpenter, who with Dr. Gwyn Jeffreys sailed in the *Valorous* for dredging purposes, added a few words. He said, when they parted with the *Alert* and *Discovery* they had every reason to believe from the state of the wind and weather that the Expedition would go on favourably. He thought it was more than probable that the *Discovery* was now in her winter quarters, and the *Alert* was somewhere further north. The letters which the ships would deposit would probably reach England before Christmas, and after that it is not likely they would hear anything of them until next summer, or perhaps later. On its way home the *Valorous* struck on a sunken rock to the north of Holsteinberg, but happily came off without serious damage. Temperature, soundings, and dredgings were made by the *Valorous* in its homeward journey, many interesting forms having been obtained. In a series of temperature soundings taken, 33° and a decimal was found to be the lowest. When the *Valorous* parted with the Expedition everybody on board the two ships was in perfect health.

THE annual meeting of the Ray Society was held at Bristol on Friday; Sir Philip Egerton presided. The Report of the Council stated that the arrears in the issue of volumes were at last overcome. The volumes for 1873 and 1874 had been distributed, and much advance had been made in the "Memoir on the Aphides," by Mr. G. B. Buckton, proposed as the volume for 1875. The very beautiful plates drawn and presented to the Society by Mr. Buckton are now with the colourer, and the whole will be sent to the binder probably in November. In addition to Mr. Mivart's monograph on the Tailed Amphibia, and Prof. Westwood's on the Mantidæ, Mr. G. Brady has promised a work on the Copepoda, and it is found that the MSS. and sketches of the late Mr. Hancock are sufficient to complete the long-promised monograph on the British Tunicata. The balance-sheet showed over 214*l*. in hand. The names of Prof. Bentley, Mr. Hudson, Dr. Gwyn Jeffreys, and Mr. Mennell were withdrawn from the Council, and those of Dr. A. Carpenter, Mr. Collinson, Mr. Currey, and Dr. Millar were substituted for them. Sir Philip Egerton was re-elected president, Mr. S. J. A. Salter treasurer, and the Rev. Thomas Wiltshire secretary; and cordial votes of thanks were given to them for their services.

THE Nantes Meeting of the French Association for the Advancement of Science was brought to a close last Thursday. It has been decided with much propriety that next year's meeting will be held at Clermont Ferrand, where the new Observatory of Puy de Dome is sure to prove a great attraction. The Observatory will be then in working order, and everything will be ready for the inspection of visitors. Havre has been chosen as the meeting-place for 1877. This meeting is sure to be a success, Havre being almost to Paris what Brighton is to London. M. Dumas has been appointed a vice-president of the permanent council in room of M. Faye, who has resigned. The accession of M. Dumas in the governing body is sure to infuse new life into the Association. Most of the foreigners present belonged to Oriental nations, being Greeks, Ottomans, or Persians. We hope to give an abstract of the proceedings next week.

THE twelfth congress of the Italian Scientific Associations was opened at Palermo on Aug. 29 by Count Mamiani, in presence of an audience exceeding two thousand persons. Count Mamiani began by thanking the Municipality of Palermo for the hospitable reception it had given brother Italians as well as strangers, and explained that the future Congress will assemble under the new name of the Italian Association for the Promotion of Science. No longer representing a little aristocracy of *savants*,

it would embrace all Italy. Nothing nowadays can flourish which has not its root in the people. Great individuals have given place to the co-operating multitude, and the sole thing left for the people to reverence is science—the one surviving deity on the deserts of Olympus. In Palermo, the city of the chivalric Normans and the knightly Suabian Frederic, chivalry survives, but its tournaments are philosophical discussions, and its mistress is science, which is the immortal poetry of nature and truth. Count Mamiani then signalised Sicily's services to science, and spoke of what she will yet do for meteorology.

PETERMANN'S *Mittheilungen* for September will contain the following among other papers:—On the Linguistic Divisions of Elsass-Lothringen, with a map coloured to show the districts in which Dutch, German, and mixed Dutch and French are spoken.—Travels in the Republic of Guatemala in 1870, by Dr. G. Bernouilli, concluded from previous numbers.—Remarks on a Map of Western Australia, which will accompany the number.—Under the title of "Bilder aus dem hohen Norden," Lieut. Weyprecht will commence a series of Sketches of Phenomena in the Arctic Regions; the article in the September number dealing with the Aurora and the Ice.

M. BRAZZA, an ensign in the French navy, and M. Marche, a traveller, who has already made important discoveries on the banks of the Ogové, left Paris last week for Toulon, in order to resume the exploration of Tropical Africa, and to discover the sources of the river just named. They will stay for some time Saint Louis, the chief town of the Senegal settlements, and recruit a number of Laptots chosen from among the negroes engaged under the French colours. The expedition is supported by the Society of Geography, private subscriptions, and a small grant given by the French Government. The principal resource is the sale of objects of natural history, which are so numerous in a country rich in plants, birds, and animals of every description. They are to be sent to M. Bouvier, the well-known naturalist of Paris, and catalogues will from time to time be circulated. The exploration will last for five years.

M. LEVERRIER has published in the Paris papers a notice intimating that the Observatory will be opened for observations three times a week, from half-past seven, weather permitting. Two large telescopes are placed at the disposal of visitors, who may procure a letter of admission by writing to the Secretary of the Observatory.

THE reforms which the French Minister of Public Instruction is preparing for the next University term are so numerous that no holidays will be granted to the *employés* of the Ministry of Public Instruction this year.

THE French Government have published in the *Journal Officiel* of August 24 a decree notifying the precautions to be observed by manufacturers of explosives in which dynamite is the base. The precautions, which are numerous, have been most carefully drawn up by a special commission, and are worthy of general attention.

IN the Paris International Maritime Exhibition there is a small object deserving of notice. It is a platinum wire placed in a bottle and ignited by electricity from a bichromate battery. It is intended to be immersed in the sea, and the light emanating from it is said to attract an immense number of fishes. Experiments have been tried lately on the coast of the Côtes du Nord department with a fishing-boat, and have proved very satisfactory, on a bank of sardines. The glass must be green or black, otherwise the fish are frightened by the glare and do not follow the submarine light.

THE *Civilian* states that Major-Gen. Cameron, R.E., C.B., has been appointed Director of the Ordnance Survey of Great Britain and Ireland.

THE Russian expedition to Hissar has resulted in a complete elucidation, from a scientific point of view, of the questions connected with the Hissar and Kuliaba rivers. All the important towns in the country have been visited, astronomical observations have been taken at fourteen places, and the members of the expedition are in a position to draw up a complete map of the country. Moreover, a map of military routes has been draughted and an entomological collection has been made. The Expedition has discovered that the Turkham river, whose very existence was so long doubted by geographers, is one of the most important tributaries to the Amu, and that the Drongate Pass, now called Busgol Kham, fully bears out the formidable accounts of Asiatic travellers.

THE additions to the Zoological Society's Gardens during the past week include five Bonnet Monkeys (*Macacus radiatus*) from India; a Yellow Baboon (*Cynocephalus babouin*), and a Sykes's Monkey (*Cercopithecus albigularis*), from W. Africa, presented by Mr. J. B. Tunnard; a Common Marmoset (*Hapale jacchus*) from S. E. Brazil, presented by Mrs. Puente; a Darwin's Pucras (*Pucrasia darwini*) from China; an Indian Cobra (*Naja tripudians*) from India, deposited; and an Axis Deer (*Cervus axis*) born in the Gardens.

SOCIETIES AND ACADEMIES

PARIS

Academy of Sciences, August 23.—M. Frémy in the chair. The following papers were read:—Comparison of the theory of Saturn with the observations; Tables of Saturn's motion; by M. Leverrier.—Theorems into which a condition of equality of two rectilinear segments enters, by M. Chasles.—MM. Ch. Galbruner, F. Crôtte, and Lesthevenson, made several communications with regard to Phylloxera.—A note by M. Declat on the pathological use of phenylic acid, and of phenylate of ammonia.—A note by M. de Fonvielle on a new method to determine the path described by a balloon.—On the integration of a system of equations with partial differentials, by M. N. Nicolaïdes.—On the trisection of an angle by aid of the compass, by M. Ed. Lucas.—On the properties of the diameters of wave-surfaces and the physical interpretation of these properties, by M. A. Mannheim.—On a compound of platinum, tin, and oxygen, analogous to Cassius' gold purple (platinostannic oxide of M. Dumas), by MM. B. Delachanal and A. Mermet.—On bankoul oil, by M. E. Heckel.—A reply to M. Gauthier's objections regarding the rôle of carbonic acid in the spontaneous coagulation of blood, by MM. E. Mathieu and V. Urbain.—Note on the last elements at which it is possible to arrive by histological analysis of striated muscles; by M. A. Ronjon.—On the shooting stars of August, 1875, by M. Chapelas.

THURSDAY, SEPTEMBER 9, 1875

*THE SCIENCE COMMISSION REPORT ON THE ADVANCEMENT OF SCIENCE**

UNDER head III. is brought forward the "Evidence relating to the Establishment of Physical Observatories."

On the general question of the establishment and maintenance of Physical Observatories, Lord Salisbury agrees that—

". . . Some of these institutions which have been alluded to in your grace's question, especially observatories, clearly fall within the duties of the Government; and certainly, from all that one hears, it is probable that their duty in that respect is inadequately performed, and that observatories for a much larger range of observations might with great advantage be multiplied." . . . .

Sir George Airy, Astronomer Royal, thus states his view on the subject:—

"When I began to be an astronomer, such questions as those of the constitution of the sun and the like were not entertained." . . . .

"Are you prepared to express an opinion as to whether it is an object which would be a proper one for the Government to take up as a State Establishment?—The Government are already pushed very hard in their estimates. The screw is always put upon them, 'Cannot you reduce the estimates a little more?' And then it would always come to a question of extensive feeling in the House of Commons, and of popular feeling out of the House of Commons; and I am confident from what I have seen that those two bodies would not in every case support an extension." . . . .

"Should you say that it is an object which is not very likely to be prosecuted with sufficient vigour unless taken up by the Government?—I do not see how it could go on except it were taken up by the Government. I do not believe that it could go on in any other way."

"It is not likely, you think, to be prosecuted by private individuals, or by other public bodies such as the Universities?—No, I think that their funds are almost all required for other objects, and the difficulty even of getting the business into shape is extremely great." . . . .

"Then such observations, in all probability, will either not be made at all or must be taken up by the Government?—That is my view." . . . .

Mr. De la Rue's opinion is thus given in reply to question 13,066:—

"I think that the time for the State providing means for reducing observations has now come: when the State should take up, besides mathematical astronomy (which deals with the places of the stars and planets, and the moon especially), physical observations, more particularly observations of the sun, which appear to me to bear directly upon meteorological phenomena." . . . .

Sir W. Thomson points out the importance of multiplying such Observatories:—

". . . In respect to the observatories, it might be necessary to have several observatories for astronomical physics in this country, if it were only to secure observations of interesting conjunctures, notwithstanding the varieties of the weather, that there may be in different parts of the country; and, again, observatories for astronomical physics ought most certainly to be founded in other parts of the British dominions than England, Ireland, and Scotland; in other latitudes and on the other side of the world."

* Continued from p. 364.

Dr. Siemens expresses the same view in the following evidence:—

". . . An observatory or several observatories should be established for carrying on physical research, research to obtain information on general subjects, such as solar observations, magnetic observations, and other subjects that might be thought desirable to obtain continually information upon." . . .

"I think that almost the only new establishments which you recommend are certain physical observatories?—Yes."

"What would be the principal object of such observatories?—For the purpose of magnetic observations, solar observations, and other general inquiries into physical phenomena."

"Do you contemplate the establishment of more than one such observatory?—Probably more than one would be desirable."

"Do you contemplate the establishment of any such observatories in any of the colonial possessions of the country?—Yes, I think so."

"Speaking generally, would they be costly establishments to found?—Not very costly, not so costly as astronomical observatories."

Dr. Frankland has also given evidence on the importance of promoting the study of Astronomical Physics, pointing out that "it would be necessary, in connection with the Physico-Astronomical Observatory, to have the means of performing various chemical experiments and making physical observations. Of course the chemical operations would be quite subsidiary to the cosmical observations there."

Mr. De la Rue, in reference to locality and organisation, in answer to the question whether provision for carrying out observations of this character should be in connection with the Greenwich Observatory, says:—

"In connection with the Greenwich Observatory, yes, but at the Greenwich Observatory, I should say not. I do not think, in the first place, that there is space enough at Greenwich, and the duties of the staff are already so very onerous that it would require a separate establishment for such special work; besides other new buildings it would entail a chemical laboratory, and there is hardly space for those at Greenwich. I believe also that it would cause too divided attention on the part of the Astronomer Royal, if he were called upon to personally superintend investigations in the physics of astronomy, although I think it would be very desirable that any new establishments, if they are to exist, should be affiliated to Greenwich."

Admiral Richards, late Hydrographer to the Admiralty, and a Visitor of the Royal Observatory, Greenwich, says:—

"If you are going permanently to establish physical observatories, I should prefer to see separate ones. I think that the physical work probably would be better separated from the Royal Observatory."

"You think that the two classes of observations are so distinct in character as to render that desirable?—Of course there is a certain amount of meteorology that must be observed at the astronomical observatory; but it need not be of any extended character."

A resolution in general accordance with the views expressed by Sir George Airy was transmitted to the Commission in July 1872, by the President and Council of the Royal Astronomical Society. This resolution is in favour of the extension of the Royal Observatory at Greenwich and other existing Astronomical Observatories, and does

not recommend the establishment of an independent Government observatory for the cultivation of astronomical physics in England.

In connection with some points on which differences of opinion have been expressed in this evidence, a paper was handed in by Col. Strange, consisting of questions addressed by him to Prof. Sir W. Thomson, Prof. Hilgard, the Secretary of the American National Academy of Sciences, and Prof. Balfour Stewart, and to M. Faye, the President of the French Academy of Science.

Col. Strange's questions were as follows :—

"1. Is the systematic study of the solar constitution likely to throw light on subjects of terrestrial physics, such as meteorology and magnetism?

"2. What means, at present known to science, are available for studying the sun?

"3. Do you consider that photography (one of the assumed means) will suffice for the purpose?

"4. Do you consider that the class of observations (defined in your answer to my question 2) are such as can be efficiently made in an observatory maintained by the State, or that any of them would be better left to the zeal of volunteer astronomers?

"5. Do you consider that it would be advantageous to carry on physico-astronomical researches on an extensive scale, and meridional observations, in one and the same observatory, under a single director?"

We regret that our space will not permit us to give the replies of these eminent men to Col. Strange's questions. They were, however, strongly in favour of the establishment of physical observatories on a footing quite distinct from existing meridional observatories, and equipped with the laboratories and workshops without which such institutions would be useless. We commend to all who are interested in this question the perusal of this correspondence, which is to be found as Appendix vii. to vol. ii. pp. 27-31. Its value is enhanced by the fact that two of the writers, Prof. Hilgard and M. Faye, are distinguished foreign men of science.

Evidence relating to Meteorology.

Under this head a considerable amount of evidence was taken, particularly as to the constitution, objects, and results of the Meteorological Office.

This Office is under the management of the Meteorological Committee of the Royal Society, the functions of which are thus described in the report annually presented to Parliament :—

"The Meteorological Committee consists of Fellows of the Royal Society who were nominated by its President and Council, at the request of the Board of Trade, for the purpose of superintending the meteorological duties formerly undertaken by a Government Department, under the charge of Admiral Fitzroy.

"The Committee are credited with a sum of 10,000*l.* voted annually in the Estimates, for the administration of which they are wholly responsible, and over which they are given the entire control.

"The meetings of the Committee are held once a fortnight, or oftener when necessary, when every subject on which action has to be taken by their executive officers receives their careful consideration. The duties of the Committee are onerous and *entirely gratuitous*; they were accepted and are very willingly performed by the members, on account of the earnest desire they severally feel for the improvement of meteorological science."

The position of the Committee is anomalous. In the words of the director of the Meteorological Office—

"The Government distinctly disclaims all connection with us, whilst the Royal Society equally disclaims all control over us, except merely the nomination of the members of the Committee."

"As a matter of fact, all that the Royal Society does is to nominate the members of the Committee?—That is all."

"Having so done, it ceases to have any control whatever, does it not?—Entirely."

"What is the precise relation between the Office and the Government?—That the Government gives a vote of 10,000*l.* every year, and that it calls for no account of this money excepting the account annually presented to Parliament."

"Who audits the accounts?—The members of the Committee. There is no formal audit, because, as the Government would not recognise any audit excepting its own, the Committee considered that it was not worth while paying an auditor if such audit would not be recognised, and, as a matter of fact, two of the members take the trouble of auditing the accounts every year."

"What, in your opinion, are the chief advantages and disadvantages of such an arrangement as compared with those of the direct management of the Office by the Government?—The chief advantage is the perfect freedom from political management. The risk in being connected with the Government is that if a new President of the Board of Trade comes, he may reverse the action of the preceding one. The existence of a scientific supervision for the Office is exceedingly important; it acts as an intermediate party between the public and the Office. I may mention a decided disadvantage which results from the Office not being connected with the Government, namely, the loss of prestige. The difficulty is, that if we are sending instruments by sea or by railroad, if we do not call them Government instruments we cannot get as much attention paid to them; and it is my opinion that we should get more co-operation from the merchant navy if we were an office of the Board of Trade. We should have more prestige as acting directly from the Government."

A very clear account of the objects which the Meteorological Committee propose to themselves is given in the evidence of Major-General Strachey, one of the members :—

The Commissioners remark that it is admitted that the objects thus described do not exhaust the whole of meteorology, and that the Committee in their selection of these objects have been, to a great extent, guided by the proceedings of the Meteorological Department of the Board of Trade, which existed prior to, and which has been superseded by the Committee. Thus Major-General Strachey says :—

"The Committee is now in reality doing no more than continuing the exercise of certain functions which had, in the course of time, been thrown upon the Board of Trade by the position which that department occupies in connection with the public administration."

"Has the consequence been that the action of the Committee has been from the outset rather in a practical direction than in one of original research or scientific observation, properly so called?—I think distinctly that such is the case, and that it has necessarily followed from the position in which the Committee was placed. If a reference is made to the earlier papers, and to the report of the gentlemen on whose suggestions the present arrangements originated, there perhaps is an indication that they anticipated something more in the way of scientific research than has actually occurred; but the turn that things have taken seems to me the necessary result of the sort of duties that were put upon the Com-

mittee under the essential condition that it had but a limited sum of money to spend."

"Have any results of scientific importance in your opinion been obtained by the action of the Committee?—In the direction of what one may call investigation of an absolutely scientific character, I should say none at all. Of course the observations that are made at the special observatories are valuable scientific information, and so far one has no right to say that scientific results have not been produced; but I do not think that these can properly be referred to as specific results of anything that the Committee has done. To the best of my belief there has been nothing undertaken in the way of original investigation into the specific physical causes of any of the phenomena which are recorded, nor any original research, properly so called, in relation to any of the several branches of meteorology. The Committee hardly has appliances at its command for any such investigations, and, the funds at its disposal being limited, it was hardly possible that it should attempt them. It is also no doubt quite true that the observations which are made at the seven observatories do not include any matters which are of great importance in physical science, and which would properly come within the range of meteorology."

"Are the funds at the disposal of the Committee in your opinion insufficient for doing anything more than has been actually done at present?—I should say distinctly that this is the case. The Committee has always considered that it is bound to attend primarily to the special objects before referred to, which were in a specific manner made over to it, and it finds that after this has been done there is no money left for other things."

Again, the same witness expressed a decided opinion that the State should do more for the promotion of meteorological science than it does at present, but entertains some doubt whether any increased duties could advantageously be allowed to devolve upon a body such as the Meteorological Committee.

The same view is expressed by Professor Balfour Stewart:—

"Would you organise the Meteorological Committee in any really different form to that which at present obtains?—I should be inclined to dispense with the Meteorological Committee altogether, and substitute a Meteorologist Royal, or whatever his appellation might be, a single official who should be responsible to the Government in the same way as the Astronomer Royal is responsible for his department. I do not see why the one department should be on one footing and the other department on a different footing. I think that there are grave disadvantages with a department administered by an unpaid committee."

"Would you appoint a Meteorologist Royal corresponding with the Astronomer Royal?—Yes, whatever the name might be; I should appoint an official very much corresponding to the Astronomer Royal, and responsible to the same extent. A board of visitors would not be objectionable, but the direction of an unpaid committee appears to me to be very objectionable."*

Evidence relating to Tidal Observations.

Evidence in reference to tidal observations has been placed before the Commission by Dr. Joule and Prof. Sir W. Thomson.

Dr. Joule is of opinion that—

"With regard to the sea level and the tides, although the laws with regard to the tides are pretty well known, they ought to be continuously observed, if only for the purpose of registering the changes arising from the alteration of banks, depth of channels, &c. Also with regard to the sea level, there have been reports from time to time with regard to the inroads of the sea on our coasts, but sufficient steps do not appear to have been taken to ascertain the facts in those cases. It seems to me very important to be acquainted with any alterations in the configuration of the earth which may be taking place, however minute those alterations may be."

Sir W. Thomson gives the following evidence on this point:—

"In addition to those institutions which you have recommended, you consider, do you not, that it would be advisable that the Government should undertake secular observations of the tides?—Yes, certainly, secular observations of the tides with accurate self-registering tide gauges, with the triple object of investigating the science of the tides, of perfecting our knowledge of the actual phenomena of the tides, both in respect to navigation and as a branch of natural history, and, thirdly, with a view to ascertaining the changes of the sea level from century to century."

"Is anything of the kind done at present?—There are several tide gauges, some of which have been carried on with great care, others with not sufficient care, and none with any security of permanence."

"Was not it in connection with the Ordnance Survey of Great Britain?—No sufficient steps have been taken to ascertain whether the sea level is changing relatively to the land in any part of this country."

The Commissioners state that the accurate reduction of tidal observations, without which, of course, they are useless, has not hitherto been undertaken by any department of the State, and we are indebted to the zeal of individuals for the results which have been obtained. The reductions are laborious, and require the employment of paid computers. A memorial from the British Association for the Advancement of Science to the Lords Commissioners of the Treasury, put in evidence by Sir William Thomson, shows the difficulty that has been felt in procuring the moderate sum required for the reductions, the amount asked for being only 150*l*.

The Lords Commissioners of the Treasury did not accede to the prayer of the memorial, so that at present there is no guarantee that the observations which have already been accumulated, and those which are still in progress, will ever be adequately discussed and utilised.

Evidence relating to the Extension of the Government Grant administered by the Royal Society.

The Commissioners remark: "The strong and concurrent evidence which we have received as to the usefulness of the Government grant, as at present administered by a Committee of the Royal Society, has led us to inquire whether this grant might not be advantageously extended; and the witnesses whom we have examined on this point are unanimous in expressing the opinion that great benefits might be expected from such an extension."

Prof. Owen, Mr. Spottiswoode, Prof. Grant, Mr. De la Rue, and Col. Strange are amongst those who gave evidence to the above effect. Lord Salisbury is also of opinion that the Government grant might be increased, in order to afford liberal assistance to "first-rate workers."

Evidence as to the Payment of Scientific Workers.

The Commissioners remark:—

"On this branch of our inquiry the evidence laid before

* The whole of the evidence, of which the above are curtailed extracts, coincides with the trenchant remark of the Astronomer Royal in his last Report to the Board of Visitors that "The subject of Meteorology hardly deserves the name of a science."

us, both by statesmen and men of science, is to the same effect, and in favour of increased State aid. It has also especially been urged upon us, that to afford, by direct pecuniary aid, the means of livelihood to men of distinction in pure investigation would be a great advantage to science, as competent investigators would thus be enabled and encouraged to pursue a strictly scientific career."

Lord Salisbury is of opinion that the cause of science is hindered by the want of a sufficient career for scientific men, giving the following statement of his reasons :—

"I am induced to think so, by noticing how very much more rapid the progress of research is where there is a commercial value attached to the results of it, than in other cases. The peculiar stimulus which has been given to electrical research, in the particular direction of those parts of it which concern the telegraph, is a very good instance in point, and the extent to which researches into organic chemistry have almost clustered themselves round the production of coal tar colours is another instance in point. And therefore it is difficult to avoid the conclusion that research is really hindered by the necessity under which those who are most competent to conduct it feel themselves, of providing for their own support by means of the talent and the knowledge which they possess."

With regard to the scale on which such remuneration or payments for maintenance should be made, Lord Salisbury observes :—

"I should say, taking the parallel [that of certain offices in the Church], to which I have already alluded, that an income of about 1,000*l.* or 1,500*l.* a year would be the kind of income which would suffice for the purpose that I have in view."

And he would also add provision for retirement.

With reference to the safeguards against abuse which would be necessary, Lord Salisbury continues :—

". . . It would, for their [the investigators'] own interest, and to save them from invidious comments, be desirable to impose upon them the necessity of publishing, either in the form of books or in the form of lectures (but not sufficient in number really to impede their work), an account of the result of their labours during each successive year. Perhaps one or two stated lectures in the course of a year, to be delivered to University students, would be the best means of imposing upon them that test of industry."

Lord Derby takes the same view :—

"I think that, in one way or another, where you have a man of very great eminence as a scientific discoverer, it is unquestionably the duty of the State to provide him with means and leisure to carry on his work. Whether that is to be done by giving him an office under the British Museum, or in any similar institution, or whether it is to be done by simply granting him a pension in recognition of eminent scientific service, or in whatever other way it is done, it seems to me to be immaterial, but I certainly consider that it is a very important part of the public duty, to relieve men who have shown an eminent capacity for original discovery and research from the necessity of engaging in a lower kind of work as a means of livelihood." . . .

Sir W. Thomson, in a reply to which we have already referred, stated his opinion on this point as follows :—

"That men should be enabled to live on scientific research is a matter of most immediate consequence to the honour and welfare of this country. At present a man cannot live on scientific research. If he aspires to devote himself to it he must cast about for a means of supporting himself, and the only generally accepted possibility of being able to support himself is by teaching, and to secure even a very small income, barely sufficient to live upon, by teaching, involves the expenditure of almost his whole time upon it in most situations, so that at present it is really only in intervals of hard work in professions that men not of independent means in this country can apply themselves at all to scientific research." . . .

Prof. Henry, the distinguished director of the Smithsonian Institution in the United States, who was good enough to appear before the Commission when he was in this country, gave the following emphatic evidence in the same direction :—

"My idea would be that if the funds were sufficient, and men could be found capable of advancing science, they should be consecrated to science, and be provided with the means of living above all care for physical wants, and supplied with all the implements necessary to investigation."

Prof. Balfour Stewart, after referring to the instances of wealthy persons who undertake scientific research in this country, points out that the number of those so circumstanced is very small in comparison with the number of able men who are willing to give their time and capacities to observations and research. He goes on to say that able men, and men competent to conduct research, suffer in this country from not having sufficient means at their disposal to proceed as they would like to do.

"Do you anticipate, then, that if there were any intelligent centre for the distribution of a sufficient fund to persons having the requisite capacities for observation and research, but not having the means, the distribution of such a fund would have any benumbing influence upon original observation and research?—No, I should think quite the contrary ; it would encourage it very much."

Mr. Gore also advocates the enlargement of the present system.

". . . . I should strongly advocate that the present system should be enlarged, so that the investigators should not merely be reimbursed for all that they have expended, but also paid in some measure for their time and labour, because each investigator has to give up a profitable employment in order to find the time."

He then gives his own personal experience, which probably resembles that of many of those who, without private fortune, engage in pure research.

"I refuse a great many engagements in analyses and other scientific matters for the manufacturers who come to me. . . . I gave up some pupils a short time ago to enable me to have more time for original investigation."

Dr. Joule, Dr. Siemens, Mr. De la Rue, and other scientific authorities testify to the same effect, and urge the adoption of some form of remuneration for valuable work done, as a measure not merely just to the individual, but serviceable to the State by the encouragement it would afford to those able men of small means, who abound in this country, to engage in original researches of great importance to the community.

(*To be continued.*)

THE IRISH FISHERIES

Report of the Inspectors of Irish Fisheries on the Sea and Inland Fisheries of Ireland for 1874. Presented to both Houses of Parliament. (Dublin : Alex. Thom, 1875.)

DURING the last few years increased attention has been paid to the vast stores of food, which this country possesses, in the fish frequenting its inland

waters and territorial seas. Legislation, attended on the whole with marked success, has led to the development of the salmon fisheries of the United Kingdom; a much less successful attempt has been made to increase the produce of our exhausted oyster fisheries; and a very able Commission, which enjoyed the advantage of Prof. Huxley's assistance, has investigated and authoritatively disproved the allegation that our sea-fish were decreasing. In England and Scotland, at any rate, satisfaction is usually expressed at this state of things. With the single exception of the oyster, the harvest of the sea proves annually as productive, or even more productive, than ever, while the increasing consumption of a growing population and the greater destructiveness of modern implements of fishing, are not apparently unduly diminishing the numbers of our sea-fish. Ireland, however, to judge from the language of her representatives in Parliament, is less satisfied with her position. The very fish, if we may credit some authorities, are deserting the coasts of this unhappy country; and Irish fishermen, with their old tackle worn out, and with no money to purchase new, are emigrating to other fishing grounds on the other side of the Atlantic. The picture annually presented to us of the miserable condition of Irish fishermen was so deplorable, that Parliament, last year, was induced to interfere. The Ministry was surprised by a hurried division, and unexpectedly defeated by a narrow majority. Its defeat compelled it to place a portion of the Irish Reproductive Fund at the disposal of the Irish Inspectors of Fisheries; and the Inspectors are now enabled to lend small sums of money to needy fishermen on their personal security. No such loan has yet been made. But, on the eve of adopting a new policy, it is occasionally desirable to review the circumstances which have led to it; and we turn, for this reason, to the recently published report of the Inspectors of Irish Fisheries.

The Report is divisible into two portions. The first and shorter portion refers to Sea Fisheries, Oyster Fisheries, and Harbours; the second and longer portion to the Inland or Salmon Fisheries. The salmon fisheries of Ireland are fairly prosperous. The amendments which are required in the law are not numerous or important; and we do not therefore propose to follow the Inspectors into their review of them. But the ten pages of the Report which are devoted to the sea fisheries and oyster fisheries of Ireland, deserve for every reason most attentive consideration. The oyster fisheries occupy a very short space in the Report, and may be dealt with in the first instance. The Inspectors have exercised almost absolute powers in dealing with this question. They are authorised to appropriate to any individual who applies to them, large portions of the fore shore of Ireland, and 130 licensed beds, occupying 18,825 acres of fore shore and sea-bottom, have thus been appropriated. The result of this wholesale appropriation of public dredging ground might well have justified Parliamentary interference. "The chief object," say the Inspectors, "in granting licenses (cultivation) has not been fulfilled. In the majority of cases we believe there has not been anything deserving to be called an attempt to cultivate the ground granted. The proprietors in numerous instances content themselves with getting as much as they can for their private use, and do nothing to replenish. We would be fully justified in cancelling the majority of the licenses." We quite agree with the Inspectors in this view; but we should like to know why some of the licenses have not already been cancelled. Two years ago the Inspectors assured us that they had "warned some licensees that their licenses will be withdrawn unless within twelve months they proceed to cultivate." The public have a right to inquire whether the warning has been attended to, and if not, why the threat of the Inspectors has not been carried out. The Inspectors, indeed, say that they have so "many pressing duties to perform," that they have been compelled to postpone attending to the oysters. But can any duty be more pressing than the restoration to the public of ground really taken from them under false pretences? The Inspectors have found time to grant five new licenses; they would have done much more to promote oyster culture if they had cancelled five old ones. "Overdredging and a succession of bad spatting years" are of course given as the cause of the growing scarcity. But it is worth while remarking that we had nothing of bad spatting years till overdredging had decreased the stock of oysters. If an oyster bed be scraped clean of all the adult oysters, no spatting season, however favourable, can be a good one.

But the most important portion of the present report is undoubtedly that which relates to the Irish Sea Fisheries. There can be no question about the decrease of Irish fishermen. In 1846, or before the famine, 113,073 men and boys were employed in 19,883 vessels and boats on this industry. In 1874 the number of vessels was reduced to 7,246! the number of hands to 26,924! The decline both in boats and men has been continuous throughout the period. But, with due deference to the Inspectors, it is easy to account for it. The "melancholy ocean" which surrounds Ireland is subject to very severe storms: and no fishing-boat can prosecute its industry consecutively throughout the year. Under such circumstances one of two things must happen—either the Irish Seas must be fished by men who, in strong weather, may resort to quieter fishing-grounds, or the Irish fisherman must combine other operations with his fishing. Before the famine the last of these things occurred. Every Irishman was a cottier. He tended his potatoes and his pig in bad weather: and he went a-fishing in calm weather. But, since the famine, the cottiers have gradually been worked out. Large farms have swallowed up small ones: and the occupiers of large farms, and their servants have no time to go out fishing. The class from which the mass of Irish fishermen were drawn had ceased, or is ceasing, to exist; and Irish fishermen are consequently decreasing in numbers. But, though Irish fishermen are decreasing, the Irish fisheries are not decaying. What do the Inspectors tell us? There were only 187 Irish boats engaged last year in the herring fishery off Howth. But there were 343 English, Scotch, and Manx boats. There were only 61 Irish boats in the mackerel fishery off Kinsale. But there were 226 English, Scotch, and Manx boats. The Englishmen, Scotchmen, and Manxmen, following the fish round the whole coasts of England, Scotland, and Ireland, beat the Irishmen, who never follow them at all. Every one has seen Cornish boats fishing for herrings in the North Sea; or Scotch boats beating the English in

their own waters. But no one ever saw an Irish fishing-boat in either a Scotch or English sea. The Englishmen and Scotchmen, with their capital continuously employed throughout the year, beat, of course, the Irishman who leaves it idle and unemployed for three-fourths of it.

The view which we have thus expressed is not, however, shared either by the friends of Ireland or the Irish Inspectors. In their eyes the decrease in the number of Irish fishermen is equivalent to the decay of the Irish fisheries; and both of these are due to the unsympathetic attitude of this country. Last year nothing would do any good but loans. Now that the Reproductive Loan Fund has been utilised for this purpose with effects which we shall immediately notice, nothing will do any good but a safe and commodious harbour at Arklow. Such a harbour "is most necessary for the successful prosecution of both herring and oyster fisheries," and "unless something be done, there is little hope of any substantial improvement." We have no desire to discourage the construction of safe and commodious harbours, but we should like to ask the Irish Inspectors whether they ever heard of a place in England called Yarmouth. It is as important a fishing station as Arklow, it is on as stormy a shore; but when a storm is raging, the Yarmouth fishermen have to stand out to sea to avoid being driven on to the coast. We never heard that the want of a harbour at Yarmouth had destroyed the Yarmouth fishery; and we think that Yarmouth has at least as good a claim as Arklow for the construction of such a harbour. The new system of loans to fishermen remains for consideration. There has, of course, been no want of applicants for the loans. 2,800 individuals have already applied for the money, and we have no doubt there are a good many more quite prepared to follow their example. 1,300 of the 2,800 applications emanate from County Galway, and 160 of these applicants live in one parish. No more than six of the 160 "fulfil the conditions which should entitle them to obtain a loan!" We presume that as the Inspectors pointedly refer to the 160 applicants, they may be regarded as fair examples of the 2,800 who have applied. In that case only 105 persons throughout Ireland will, in the lenient judgment of the promoters of the policy, be entitled to participate in the loan. Is it possible to conceive a more striking illustration of the consequences of the policy?

MAGNUS'S "ELEMENTARY MECHANICS"

Lessons in Elementary Mechanics introductory to the Study of Physical Science, with numerous Exercises. By Philip Magnus, B.Sc., B.A. (Longmans, 1875.)

IN order to assign any work to its proper place it is necessary that we should try to ascertain what is the author's aim in writing it, and also to see if that aim be to any fair extent attained; further, we should take into our account the consideration of the question whether if the author's end be attained it is one worth arriving at. If the verdict on all these issues be favourable, then we may say that the *raison d'être* of the work is justified. For the aim of the present volume the title will suggest at once that the author does not attempt to produce a treatise which shall enter into comparison with such works as those produced by Thomson and Tait. Let us hear his own statement: "The lessons are intended for the use of those who have had no previous acquaintance with the subject;" and so he has endeavoured to bring into prominence the leading principles of Mechanics, and to exemplify them by simple illustrations. Here we may observe that the term mechanics is used in the ordinary acceptation of that word now-a-days, *i.e.*, as the science of the motion and equilibrium of bodies, and not in the Newtonian sense to which Messrs. Thomson and Tait seek again to restrict it. Starting on the hypothesis that the idea of Motion is more elementary than that of Force, since it is only from a combination of forces that equilibrium can result, the author makes the subject of Statics depend upon the laws of Dynamics. Hence the proposition, which is generally cited as that of the Parallelogram of Forces, Mr. Magnus derives at once from Newton's second Law.

After a short preliminary introduction we have "Kinematics—Motion" treated under the heads of Measurement of Motion and Falling Bodies; then "Dynamics—Force," under which heading we have Measurement of Force, the Laws of Motion, Energy, Machines.

The second part of the book discusses "Statics—Rest," under the following heads: Theory of Equilibrium, Centre of Gravity.

The style is lucid, the solved exercises carefully chosen, the work compact. With the exception above mentioned, of Statics being made dependent on Dynamics, the arrangement and matter are much the same as we find in English treatises. An intelligent boy ought in a few months to be able to make himself master of the greater portion of this small book, which Mr. Magnus has aimed at making sufficiently elementary to be placed in the hands of a beginner. What we consider to be higher praise is that we believe it to contain nothing that the student will have to unlearn in a subsequent portion of his career. We can recommend it as a trustworthy introduction to more advanced text-books.

We have endeavoured to test its accuracy as regards the answers to the numerous questions scattered over its pages. Of these there are 279 in the Dynamical portion, 192 in the Statical portion, besides 79 questions in an appendix composed of papers from the Matriculation, South Kensington, College of Preceptors, Oxford Local, Cambridge Local, and other Examinations. These answers seem to us to be exceptionally correct, as, though we have tried them all, we differ from Mr. Magnus's results in only a dozen cases; some of these cases are apparently clerical errors. We make this statement, taking into account two or three slips of errata which have been subsequently distributed by the author.

In Ex. 23, p. 86, 1·368th should be 1-368th, *i.e.*, $\frac{1}{368}$; § 199, we think, would not be easy for the pupil unless he had some aid from a tutor. Some of the questions given to the Matriculation candidates of the University of London seem to us hardly suitable for them; we shall select one, because even so experienced a teacher as the writer of the work we have noticed at first fell into an error. The question is: "Suppose that at the equator a straight, hollow tube were thrust vertically down towards the centre of the earth, and that a heavy body were dropped through the centre of such a tube. It would soon strike one side; find which, giving a reason for your reply." The author gives an answer which we have heard

one or two "coaches" give also, but on a slip he has corrected his printed answer.

Again, in Ex. 27, p. 55: "A balloon has been ascending vertically at a uniform rate for 4·5 secs., and a stone let fall from it reaches the ground in 7 secs.; find the velocity of the balloon and the height from which the stone is let fall." Both Mr. Magnus and Dr. Wormell ("Natural Philosophy," p. 129, Ex. 45) work this question as if the balloon were at rest when the stone is let fall; we see no reason for their doing so in the wording of the question. They give the same height for the balloon, but differ in the velocity.

OUR BOOK SHELF

Game Preservers and Bird Preservers. By Capt. J. F. Morant. (Longmans, Green, and Co., 1875.)

To increase the annual rental of Scotch moorland, and to feel certain that at least thirty brace of grouse will fall to each gun after a whole day's sport, are the greatest delights of a certain few, according to whom every other consideration must be put in abeyance. Capt. Morant is one of these. "The red grouse is about the best game bird in the whole world, and deserves all the care we can bestow upon him." This care involves the annihilation of every creature that shows the least disposition to destroy and feed upon the eggs, young, or adult of *Lagopus scoticus*; and the death-list is no small one, including eagles, buzzards, hen harriers, all other Raptores, ravens, crows, magpies, wild foxes, polecats, stoats, and weasels. The stomachs of hawks are often found to contain the remains of weasels and rats; why kill them if they destroy those vermin? "If an alderman were shipwrecked on an uninhabited island, he would probably live upon the contents of a cask of biscuits which might be washed ashore. But the scientific gentleman among a party of savages who might examine him after his friends who happened to land on that island had killed him for their supper, would, we know, arrive at an erroneous conclusion if he entered it in his note-book as a fact that the animal *alderman* lived entirely on dry biscuit." This running analogy is the argument employed throughout the book, and it is this which makes it a particularly amusing one to glance through; whether it carries conviction with it is a different thing. The grouse disease is explained as depending on the fact that these birds, unlike others, eat only one food, heather, and when this is injured by cold or otherwise, they have no other to fall back on. That many shot-damaged birds survive and afterwards produce unhealthy offspring is considered unlikely. "Can we fancy a grouse telling his mate on a spring morning, My dear, I feel very poorly to-day; that No. 5 in my spine is troubling me dreadfully?" The author's raid against all the Raptores is very severe; he in this, as in other points, being much opposed to the general tenour of the report of the evidence given before the Parliamentary Select Committee appointed in 1873. His considerable experience adds great weight to the aspect of the question which he espouses.

The Handy-Book of Bees, being a Practical Treatise on their Profitable Management. By A. Pettigrew. Second Edition, revised and improved. (Edinburgh and London: Blackwood and Sons, 1875.)

A Manual of Bee-keeping. By John Hunter, Honorary Secretary of the British Bee-keepers' Association. (London: Hardwicke, 1875.)

THESE two volumes have different objects and will serve different purposes. The first edition of Mr. Pettigrew's book was favourably noticed in our columns five years ago (NATURE, vol. ii. p. 82), and we are glad to see that a second edition has been called for. Still more pleased are we to find that the author is open to conviction, and that he has acknowledged and corrected a few theoretical errors in the first edition. For the economical management of bees with a view to profit, there is no better guide than Mr. Pettigrew.

Mr. Hunter's volume, on the other hand, is essentially a book for the amateur, to whom profit is of less importance than the amusement and interest of bee-keeping. He gives an account of all the appliances of the modern apiarian, and of the most recent improvements in the treatment and study of bees. The various kinds of honey-extractors, feeders, guide-combs, and queen-cages; the methods of artificial swarming, queen-breeding, and ligurianising; the diseases and enemies of bees; and the various methods of preparing and preserving the honey and wax, are all briefly discussed. Some of the most recent observations on the habits and instincts of bees are given, including Sir John Lubbock's interesting proof that they distinguish colours. The book is illustrated with a number of useful woodcuts, chiefly of hives and apparatus; and it will be indispensable to amateurs who wish to acquaint themselves with the most recent improvements in the art of bee-keeping, and the latest discoveries as to the habits, instincts, and general natural history of the honey-bee. A. R. W.

LETTERS TO THE EDITOR

Personal Equation in the Tabulation of Thermograms, &c.

IN a late number of NATURE (vol. xii. p. 101) you have commented upon the work performed by the Meteorological Office. Although in no way interested in the defence of that department, I think objection may fairly be taken to the style of criticism adopted. Not only would it, in most cases, be necessary to refer to the original thermograms satisfactorily to detect the many small errors pointed out, but it is well known to practical men that owing to certain idiosyncrasies of individuals some of the numbers 1, 2, 3 . . . 8, 9, 0 do occur in estimations more often than others, and of course more often than they should do theoretically. In no case are such personal peculiarities likely to show themselves more than in the determination of the position of a hazy photographic trace of sensible breadth, as between two sharply defined lines. As an example of my meaning, I may refer to somewhat similar estimations of tenths of seconds, as tabulated by the highly-trained and experienced observers of Greenwich, only premising for the information of the uninitiated, that the tenth part of a second is far too large a measure of time to be trifled with by astronomers, and that practically the estimation is simply that of the position of one sharply marked puncture or dot as referred to two others equally well defined on either side of it, indicating the beginning and end of the second, and separated by about one-third of an inch. Referring to the Greenwich Observations of 1864 (the only volume I have at hand), and taking three days' observations at random for the experiment, I have determined the percentage of times that each of the numbers 1, 2, 3...8, 9, 0 occur as the tenth at which transits of stars took place. As there is no theoretical reason why one number should predominate over another, we may expect that the percentage for each figure will be accurately 10, or each a tenth of the entire number.

The following are the percentages founded upon 511 estimations on April 21, upon 379 on April 19, and upon 393 on Nov. 5, 1864, respectively:—

	1.	2.	3.	4.	5.	6.	7.	8.	9.	0.
Percentages	5·7	6·5	9·0	21·1	11·7	11·0	6·3	8·4	5·9	14·3
	6·9	9·2	10·0	13·7	10·8	12·4	7·4	8·7	5·3	15·6
	8·4	8·1	7·6	13·7	10·9	9·4	8·1	9·7	8·9	15·0
Mean of 3 days	7·0	7·9	8·9	16·2	11·1	10·9	7·3	8·9	6·7	15.0

Although no one acquainted with the care bestowed upon this description of work at Greenwich would for one moment think of impugning the accuracy of these estimations, they show precisely the excess of whole seconds that is taken in the before-mentioned article as indisputably proving the carelessness of the tabulations at the Kew Observatory.

As regards these averages, it is to be remarked that with one slight exception all the numbers that are above or below the theoretical average in one example are above or below in all, and that there is only one case in which the range of difference exceeds 3 per cent. The partiality shown for the figures 0 and 4 is also most marked, and of itself would be enough to show that the same person had made all the estimations.

There is another light in which we may regard these results, which still more plainly indicates my meaning. The decimals ·1, ·2, &c., ought to include all possible positions of the puncture between ·05 and ·15, between ·15 and ·25, and so on; but according to the reader of the chronographic sheets, ·1 includes only those positions of the puncture between ·081 and ·151; ·2 includes those between ·151 and ·230; ·3 those between ·230 and ·319; ·4 those between ·319 and ·481, and so on. Thus the error of any single determination is very small indeed, a remark that will apply equally to the tabulations Meteorological Office.

To show that different observers have very different idiosyncrasies, I may append the following averages similarly determined, this time from the purely astronomical estimations of the time of transit of stars across the well-defined spider lines of the telescope by the method known as eye and ear observation, these estimations being made on a precisely similar principle. From the Greenwich observations of 1864 I find 206 such estimations by Mr. Dunkin, the standard observer at that time; 259 by Mr. Ellis; and lastly, 500 by myself in the present year, made at this observatory, yield the following:—

	1.	2.	3.	4.	5.	6.	7.	8.	9.	0.
D., 1864 ...	7·8	16·5	11·7	12·1	13·6	7·8	9·2	13·6	6·8	1·0
E., 1864 ...	5·4	8·5	7·7	9·7	8·5	11·2	12·4	13·5	12·4	10·8
P., 1875 ...	13·4	13·0	10·6	10·8	7·8	8·6	8·8	13·6	4·8	8·4

Although founded on rather too few estimations, there is little doubt that the salient features would be preserved in a more extended discussion. Thus D's avoidance of whole seconds and the adjacent numbers 1 and 9, E's avoidance of the former of these, and my own of the latter, may be expected confidently, however large a number of estimations are taken into account. The universal fondness for 8 is also noteworthy.

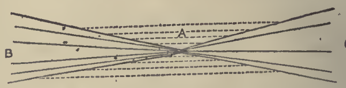
Orwell Park Observatory, near Ipswich — JOHN J. PLUMMER

Source of Volcanic Energy

IN your report of the meeting of the Geological Society in NATURE, vol. xii. p. 79, I find notes of a communication submitted by the Rev. O. Fisher, F.G.S., on Mr. Mallet's theory of volcanic energy, and as I consider Mr. Mallet's paper to be one of surpassing value, I wish to make a few remarks on the criticism of it by Mr. Fisher. Mr. Fisher objects to the possibility of assuming high *local* temperatures to be produced by the transformation of tangential forces into heat, within the earth's crust.

If the strata of which the earth's crust is composed could be represented in a diagram by so many concentric circles of perfect regularity, the crushing force resulting from tangential pressures caused by the regular contraction of the mass would of course be equal all through the mass; but, as a matter of fact, such a diagram would not be a faithful representation of the lie of strata in the earth's crust. These strata occur at all sorts of angles, and are broken in upon by faults of great extent; so the pressures produced upon various parts of the earth's crust are far from equal. These inequalities are also increased by the differences in density of strata as also by the thinning out of strata of the same density.

For instance, a strain may occur somewhat in the manner of the annexed diagram. A set of strata may bear upon a point A, considering the forces to act in the direction BA, CA, and so cause the pressure upon a square foot at A to be a hundredfold greater than on a square foot at B. The work done, therefore, may not be equally distributed over certain areas; but forces may *converge* upon various points, and if the work is thus intensified in certain points, the heat developed in such points must be greater than where the forces are not so concentrated. It seems to me, then, that the rocks at A may be crushed to *fusing-point* by converging forces, while at the same time the rocks of the same set of strata at B may be at a much lower temperature.



If what I have attempted to point out contains no "untenable assumption," the possibility of the developed heat being localised remains intact; and this is certainly the main feature of Mr. Mallet's theory.

Mr. Fisher's objection to the primeval formation of our present existing ocean beds and continents seems a fair one, notwithstanding the fact of the remarkable steepness of the western coasts of all continents remarked upon by Mr. Mallet, but this remarkable similarity of formation may be no more remarkable than the fact of all the great promontories of the world pointing to the south and none to the north. Still, however, Mr. Mallet's paper may help us, for if the tangential pressures produced in the earth's crust be sufficient in some cases to produce long lines of volcanic activity, may they not in other cases be resolved into motions acting in various directions and causing the upheaval of continents and depression of ocean beds?

In conclusion I may remark that if *mere* cooling is not considered sufficient to account for the development of such forces, may not forces produced by gravitation acting in the very same direction be well acknowledged? Not mere gravitation of the surface upon a retreating nucleus, which of course is part of Mr. Mallet's theory, but gravitation of the *whole* mass to itself, which enormous source of energy must also express itself in tangential pressures in the more resisting crust of the earth?

Kenmare — W. S. GREEN

Sanitary State of Bristol and Portsmouth

IN reference to the peculiar low mortality of some large towns in Great Britain, stated in the abstract of a communication to the Scottish Meteorological Society in NATURE, vol. xii. p. 281, as Portsmouth and Bristol, in contradistinction to others apparently in similar circumstances, having a high death-rate, I beg leave to point out that each of these towns is differentiated from the others mentioned in the paper in a *social* point of view more than in physical conditions. There is a large district in each of them, inhabited chiefly by visitors, tourists, retired professionals, and mercantile people, who take up their quarters in Southsea and Clifton, for the period of the regular seasons in each, or for limited tenure of occupation, either with reference to health, pleasure, or education of their families.

These divisions or quarters of Portsmouth and Bristol are under different physical conditions from the parent cities they are attached to, in that they are of separate growth, of later date of construction, better built, and inhabited by a wealthier class of people.

They might be compared to the apple-grafting on a crab-tree, on the old stem of which they flourish, but bear more showy flowers and more luxuriant fruit, and they thus tend to ameliorate the inherent deficiencies of the original tree by adding a higher and more cultivated life.

Topographically speaking, again, these two districts are entirely different from each other, though equally healthy, as above stated, Southsea being built upon a plain near the sea, and Clifton being built upon a hill above a river: the one lies on gravel and the other on limestone, so that these and other material circumstances, oddly enough, can scarcely be thought likely to produce a common result on their sanitary state.

The original towns of Portsmouth and Bristol, however, are nearly alike in some points, but not in others. Both are shipping ports, both are on tidal harbours, both are built along the banks on each side, and are therefore low in altitude above the sea; but the former lies on gravel, while the latter is built on alluvium and red sandstone. Most other large towns are of a homogeneous constitution, as Manchester in manufactures, Liverpool in shipping, Scarborough as a seaside resort, and Cheltenham as an inland watering-place; but Portsmouth and Bristol are peculiar in having this double social composition of a shipping

port and a health-resort in one borough, and which, therefore, might be taken into account in any deductions from statistics of health or mortality of their united populations.

A Lunar Rainbow?

THERE can be little doubt that your Australian correspondent, Mr. Lefroy (vol. xii. p. 329), has seen one of the phases of an Aurora Australis. Similar appearances have been observed by me in Scotland, passing south of the zenith (and nearly through the anti-dip, as at Fremantle). Their sudden occurrence and temporary persistence are perplexing to those who have not seen this particular display before. The first seen by myself (in 1844, I think) was a single beam which remained in the same position during some hours; it was described by me next day in a local paper, while a well-known observer in a communication to an Edinburgh journal had taken it for a comet.

It is pleasant to see accounts of such phenomena sent to NATURE from all parts of the world, even when the true cause has not always been apparent. It is not improbable that the magnets at Melbourne will have shown some slight disturbance about 8h. 30m. P.M. of May 16.

JOHN ALLEN BROUN

I DO not see any reason to doubt that the phenomenon seen by "J. W. N. L." in Australia, and described by him in vol. xii. p. 329, was an aurora. I never saw one with so many arches as he mentions (eighteen or twenty), but there can be no reason for supposing so large a number to be impossible. In almost every other respect his description agrees exactly with auroras such as may occasionally be seen. T. W. BACKHOUSE

West Hendon House, Sunderland, Sept. 4

The House-Fly

I WAS somewhat interested in Mr. Cole's remarks on the house-fly in NATURE (vol. xii. p. 187), and recently had an example of another of its enemies. On touching a rather small decrepit house-fly which was making its way across a sheet of paper, three minute, active animals, apparently beetles, tumbled out of it; they were light brown in colour, and very much the shape of *aphides*, and about the size of the hole a medium sized pin would make when pushed through paper. F. P.

OUR ASTRONOMICAL COLUMN

M. LEVERRIER'S THEORY OF SATURN.—Early in the year 1874, M. Leverrier presented to the Paris Academy of Sciences the conclusions he had drawn from the comparison of his analytical theory of the planet Jupiter with the meridian observations made at Greenwich and Paris during the long period of 120 years, which he found to be represented thereby with all desirable precision; thus proving that the motion of Jupiter is not subject to any sensible action beyond the effects of the known planets.

The comparison of the theory of Saturn with a similar extended course of normal positions, each one based upon a great number of observations, has not run quite so smoothly, but, on the contrary, has presented some slight difficulties, upon which M. Leverrier makes known his opinion, in a communication to the Paris Academy on the 23rd of last month. During the thirty-two years of modern observations, 1837-69, the differences between theory and calculation, except in two instances, remain below 0·2s. in the times of passage observed on the meridian; for the older observations of Maskelyne and Bradley, somewhat larger discordances are shown. The residuals are, however, upon the whole, very small, and a question arises, whether such quantities can be legitimately neglected, or, if not, whether their cause is to be sought in incompleteness of the analysis or in errors of the observations themselves. M. Leverrier has not been content to rest upon the first supposition, but states that he has used every effort to elucidate the source of the remaining differences. To satisfy himself and astronomers generally that there is no defect or inaccuracy of theory, M. Leverrier has taken extraordinary pains to guard against error or omission. When he found in his earlier researches a discordance between theory and observation in the case of Mercury, he was able to explain the whole by admitting an increase in the motion of the perihelion, which might be attributed to the existence of cosmical matter or the action of small bodies nearer to the sun than the planet; and again, when the comparison of theory with the observations of Mars showed differences, they were explainable by a similar assumption of increased motion of the perihelion, necessitating an increase in the mass of the earth, and consequently of the solar parallax. In the case of Saturn, the smallness of the residuals has rendered it a much more difficult matter to pronounce with confidence upon their cause. Having reviewed the whole of his analytical theory, M. Leverrier, with the view to further verify it, considering this theory as a first, though exact approximation, proceeded by methods of interpolation to reconstruct it, taking account at once of the terms of all orders. Every possible verification having been thus accumulated, he concluded that no error was to be apprehended in this direction. The comparison with the normal positions having been certified with equal care, he ascertained the effect of small changes in the masses of Jupiter and Uranus, the errors being exhibited in functions of the corrections to these masses, and the results prove that no alteration in the adopted value of either mass will destroy the residuals as a whole; if they are somewhat diminished thereby in one part of the series, it is only at the expense of increasing them in other parts. Indeed, M. Leverrier establishes one point, and a very remarkable one it will no doubt be considered, viz., that the 120 years of meridian observations of Saturn are insufficient to afford a reliable value of the mass of Jupiter; or, in other words, that the mass of Jupiter which has so great an importance in the elements of the solar system, is not yet determinable from the comparison of the theory of Saturn with observations. This was not the case as regards the mass of Saturn, which M. Leverrier found from his researches upon the motion of Jupiter to be $\frac{1}{3529{\cdot}56}$ a somewhat smaller value than that resulting from Bessel's measures of the Huygenian satellite.

Under the above circumstances, the probability that errors of observation are the cause of the remaining differences from theory is much increased, and M. Leverrier appears inclined to attribute these errors to the interference of the rings under their various phases, an explanation which practical men will assuredly regard with favour. Considering that at certain times the rings disappear entirely, when the planet's centre may be well observed, while at others intervening in an elliptical form, projecting shadows and occasionally rendering impossible the observation of one of the limbs, there is nothing unlikely, as M. Leverrier remarks, in an uncertainty of some tenths of a second in R.A., which would sufficiently explain all. At any rate, whatever influence the interference of the rings may have upon the observations, it is doubtless of a variable character, as well on account of the physical fact itself, as from the effect it may exercise on personal equations.

MR. DE LA RUE'S TABLES FOR REDUCTION OF SOLAR OBSERVATIONS.—"Auxiliary Tables for determining the angles of position of the Sun's Axis and the Latitude and Longitude of the Earth referred to the Sun's equator," which have been employed in the reduction of the ten-year series of solar photograms taken at the Kew Observatory, have just been printed by Mr. De la Rue, professedly for private circulation, though, as they have been imposed in the size and type of the "Philosophical Trans-

actions," it may possibly be the author's intention to append them to a future communication to the Royal Society, in continuation of other important papers already published in the "Transactions,"—a place which the Tables will advantageously occupy. They give with sun's longitude as argument, the inclination of the solar axis to the circle of declination, reckoned positive when the axis is west of the north point of the sun's disc, and assuming the inclination of his equator to the ecliptic to be $7° 15'{\cdot}0$, and the longitude of its ascending node $74° - \nu$; and with argument, sun's longitude $+ \nu$, the "Heliographical latitude of the earth" and "Reduction of longitude." The obliquity of the ecliptic is taken, $23° 27'{\cdot}5$, but to correct the angle between the circle of declination and the sun's axis, for difference of true and assumed obliquity, a supplementary table is provided.

The Tables have been calculated by Mr. Marth, and it will be obvious to anyone initiated in such work, that considerable trouble has been taken to ensure their accurate production.

MIRA CETI.—A *minimum* of this variable star is set down in Schönfeld's ephemeris for September 30. The minima have not been properly observed nearly so often as the maxima, though equally important in the investigation of the laws which regulate the fluctuations of light, and which, according to Argelander's researches, involve a more complicated formula than has yet been deduced for any other variable. The circumstances of the approaching minimum are very favourable for observation.

SCIENCE IN GERMANY

(*From a German Correspondent.*)

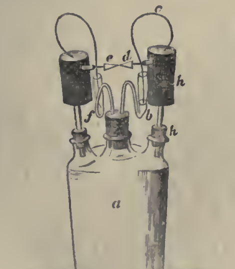
ONLY for a small number of elements and their compounds is the relatively low temperature of the non-luminous gas flame sufficient to produce spectra which can be of use in analytical researches; by far the larger number turn into vapour at such degrees of temperature as we can obtain solely by the electric spark. We are therefore confined to spark spectra for such bodies which do not give spectra in the flame, and these spark spectra can all the less be dispensed with in those cases where *new* elements are sought for, or where it is a question of proving beyond all doubt the presence of certain bodies, which in their chemical properties are so much alike that ordinary reagents do not suffice for their discovery or separation.

But there are difficulties in the way of practically using spark spectra, which have been the reason why these important means of reaction have not yet found their entry into all chemical laboratories. First of all, a simple method has been wanting by which spark spectra can be obtained at any time. Whoever has been obliged to use currents of great intensity with temporary interruptions of days, weeks, or months, knows how much unpleasantness is caused by fitting, taking to pieces, and cleaning the ordinary constant batteries used hitherto. Another difficulty lies in the fact that spectrum tables are still wanting which would be of sufficient service for all practical purposes. It is true that a large quantity of measurements have been published, and doubtless some of them are extremely accurate, but with the greatest part of them the purity of the substances experimented with is not in the least guaranteed, and very often it can be proved not to have been attended to at all. If it is attempted to reduce to a universal scale all the spectrum drawings at hand which have been obtained by different observers, with different refractive media, with different widths of the slit, some at a higher, and some at a lower temperature, tables are obtained which are completely and utterly useless in the laboratory.

Lately Prof. Bunsen, of Heidelberg, has tried to remove all these difficulties. In a very important treatise, the first part of which has just been published, he first describes a new battery and a new spark apparatus, by means of which spark spectra can at any time be obtained with the same ease and facility as ordinary flame spectra. The battery is the charcoal-zinc battery without clay cells. The exciting liquid is a mixture of bichromate of potash and sulphuric acid. In order to prepare 10 litres of this liquid, Prof. Bunsen gives the following instructions:—0·765 kilogrammes of commercial powdered bichromate of potash, which as a rule contains about 3 per cent. of impurities, are mixed with 0·832 litres of sulphuric acid in a stone jar while the mass is being constantly stirred; when the salt is changed to sulphate of potash and chromic acid, 9·2 litres of water are added, the stirring being kept up and the water allowed to flow from a spout about $\frac{1}{2}$ inch wide; the crystal meal, which already is very warm, thus gets warmer and warmer and eventually dissolves completely. The exciters for this liquid are: a rod of the *densest* gas coal, 4 cm. broad, 1·3 cm. thick, and immersed 12 cm. deep into the liquid, and a rolled plate of zinc 4 cm. broad, 0·5 cm. thick, and immersed to the same depth as the coal; the zinc plate is entirely coated with a layer of wax (which is put on whilst hot), except that plane which is turned towards the coal and which is amalgamated. The distance between coal and zinc is entirely optional; in the spectral and analytical researches of Prof. Bunsen it varied according to circumstances between 3 and 10 millimetres. The results with this battery are, however, not very satisfactory with regard to duration and constancy of current, if the cell containing the exciting liquid is made of the same size and shape as those in the ordinary Grove or Bunsen battery. The reason of this lies in the circumstance that in the nitric acid of those batteries there is far more oxygen contained, which is employed for depolarisation, than in an equal weight of the chromate liquid, and that therefore a comparatively much larger quantity of the latter is used up to obtain the same effect. The chromic acid battery therefore, compared to Grove's battery, requires cells of at least three to four times more capacity. The best shape for these cells is that of narrow, high cylinders. The column of liquid, of about 1·6 litres, has a diameter of about 0·088 metres, and stands 0·28 metres high in the cylinder, which bears a mark at that height. The zinc-coal pair is only immersed up to half its height into the liquid column, and has an active zinc surface of about forty-eight square cm.

With regard to the constants of this chromic acid battery *without* clay cells, it considerably surpasses in electromotive force all other apparatus *with* clay cells hitherto used. It possesses an electromotive force which is about 13 per cent. larger than the ordinary charcoal-zinc or Grove battery. Its essential conduction resistance is about 12 per cent. smaller than that of Grove's battery with clay cells. In order to be able to judge the economical effect of the chromic acid battery, we will consider a little more in detail the chemical processes taking place in this battery. In unconnected freshly filled Grove batteries the consumption of zinc is very small, only when after prolonged use an electrolytic and endosmotic exchange has taken place between the two exciting liquids, a consumption of zinc, independent of the generation of the current, becomes apparent. In the unconnected chromic acid battery, however, the consumption of zinc at the very beginning is entirely the same as that which is observed in connected batteries during the generation of the current. This circumstance makes it indispensable to arrange the chromic acid battery in such a manner as to make it easy, at every interruption of the current, to bring the exciting plates out of contact with the liquid. This is attained by a simple hand lever arrangement by which the plates can be dipped into or raised out of the liquid. It is of particular interest, not

only for practical purposes, but also from a theoretic point of view, to compare the consumption of zinc during the generation of the current with that in the unconnected battery, as theory alone gives no basis on which to decide the question whether the zinc disssolved in the unconnected battery is entirely, partly, or not at all used in the connected battery for the generation of the current. Investigation showed that the quantity of zinc dissolved in the disconnected battery is a little under half of the consumption of zinc necessary according to theory to generate the current in the connected battery, and that only a part of the metal dissolved in the disconnected battery without current-generation is used up in the connected one for the generation of the current. This fact entirely corresponds with the view that the dissolution of the zinc must not be looked upon as the cause of the current, but as a necessary condition of the same. Investigation further showed that while in the chromic acid battery above described, on the average only 22 per cent. of zinc was lost, the loss in the nitric acid battery experimented with was 48 per cent. on the average. The chromic acid battery without clay cells is the least constant one amongst the ordinary constant batteries. But if used in a proper manner it may serve for a very long time. Prof. Bunsen possesses a battery of this kind, of forty pairs, with an active zinc surface on each plate of only forty square cm. For the last eight lecture-terms it has served for all experiments without its having been necessary during this long time to renew the zinc plates, or their coatings of wax, or the original exciting liquid, nor to clean the conducting connection parts; it has been merely necessary to renew now and then the amalgamation of the zinc plates (an operation which only takes a few minutes of time) and to replace that part of the liquid which was lost by evaporation in the air, by simply filling the cylinders with water up to the marks on their sides. The apparatus to this day still gives an electric arc between carbon points which amply suffices for the photo-chemical lecture experiments. The currents obtained by this battery, which has now been in use for already more than four years, are still powerful enough for demonstrations in electrolysis, spark spectra, decomposition of gases by induction sparks, &c., and will doubtless continue to suffice for all these purposes for some time to come. But we must again repeat that effects of such magnitude can only be expected if the precaution is used (and it is very easy to do so) not to leave the pairs in contact with the liquid for one moment longer than the duration of the current necessary for the experiments requires it.



The battery used for the production of spark spectra consists of four of the pairs above described. The pole wires conduct the primary current, of which a branch puts the current interruptor into action, to a Ruhmkorff apparatus, the induction coil of which has a diameter of nearly 0·2 metres and a length of 0·5 metres. The current induced in the same is conducted to the spark apparatus, standing in front of the slit of the spectroscope: *a*, a bottle with three necks, serves as a stand for the spark apparatus. The induced current goes from the mercury cup *b*, through the fine wire *c* to the carbon point *d*, which is fastened on a pointed platinum wire; thence it passes as a spark to the other carbon point *e*, and from this it reaches the second mercury cup *f*, which is connected with the other end of the induction coil. The platinum wires, which are surrounded by glass tubes sealed firmly upon them, can be moved upwards or downwards by the corks *h*, and this allows of a quick and exact fixing of the carbon points before the slit of the spectroscope.

The carbon points destined to receive the little quantities of liquids under examination are best prepared from the ordinary and not too light drawing charcoal, which is easily procurable. In order first to impart conducting power to the charcoal, a great number of the sticks are exposed to the most intense white heat for some time in a covered porcelain crucible, which stands in a larger clay crucible, and is on all sides surrounded by charcoal powder. Then the sticks are cut to points at one end, and the little charcoal cone thus obtained is cut off with a fine watchmaker's saw. In order to remove the silica, magnesia, manganese, iron, potash, soda, and lithia which the charcoal contains, about a thous and of the points are boiled in a platinum dish, first with hydrofluoric acid, then with concentrated sulphuric acid, then with concentrated nitric acid, and finally with hydrochloric acid, repeating each process several times, while between each manipulation each of the acids is removed by washing and boiling with water. After this treatment the carbon points are ready for use. A carbon cone of this description weighs about 0·015 grammes, and can absorb more than its own weight of liquid. The spark spectra obtained by aid of them are of very long duration.

We will report on the second part of Prof. Bunsen's treatise as soon as it has been published. W.

*HISTORICAL NOTE ON THE OBSERVATION OF THE CORONA AND RED PROMINENCES OF THE SUN**

So much interest attaches to the phenomena of the corona and red prominences, as observed during total solar eclipses, and correct views of their nature and of the proper means of observing them are so recent, that I feel it proper to give here a brief account of what I believe to be the first attempt to see these, under ordinary conditions, with an uneclipsed sun.† This account is contained in the private diary of the late G. P. Bond, formerly director of the Observatory of Harvard College, which has become known to me through the kindness of his daughters.

Bond observed the total solar eclipse of July 28, 1851, at Lilla Edet in Sweden, and his report is published in the Memoirs of the Royal Astronomical Society, vol. xxi., p. 97.

From Sweden, Bond went to Geneva, where he arrived in September 1851, and from this point I may transcribe from his diary, making no changes except the occasional insertion or omission of unimportant words.

"*Geneva, Sunday, Sept.* 14, 1851.—I think I must go to Chamounix to try whether it may be possible to discern the red flames on the sun's disc by occulting all but the very edge, upon one of the lofty peaks. It seems to me not altogether impossible. Certainly an experiment worth trying and a new application of the '*Aiguilles.*' . . .

"*Geneva, Sept.* 15, 1851.— . . . The weather looks dark and lowering, with an uncomfortable north-east

* By Edward S. Holden. Reprinted from the August number of the *American Journal of Science.*

† Airy, Nasmyth, Baden-Powell, Piazzi-Smyth, and others experimented in this direction, about this time, with various results. See Edinburgh Ast. Obs., vol. xi. p. 279; Mem. R. A. S., vol. xvi. p. 301, &c.

wind, but M. Plantamour thinks it is likely to be fine weather, and on this recommendation I took a place in the diligence for Chamounix. . . .

"*Chamounix*, *Sept.* 18, 1851.—Last evening the stars were shining through the opening clouds, giving promise of improving weather, but a glance out of the window this morning dispels all such anticipations. . . .

"*Chamounix*, *Sept.* 19, 1851.—I woke this morning at five, and my first impulse was to go to the window to see the signs of the weather. Last night I had hopes of an improvement. But I was surprised to find a clear sky; some clouds were resting round the *aiguille*, but the summit of Mont Blanc was clear. Started for Montanvert at 7.15 with a guide. . . .

"*Mer de Glace.*— . . . Attempted two or three times to hide the sun's disc by projecting rocks to try to see the red prominences, but could not get a station far enough off. . . .

"*Chamounix*, *Sept.* 20, 1851.—Snowing fast in morning. Weather desperately bad. But before going to bed it was quite clear. . . .

"*Chamounix*, *Sept.* 21, 1851.— . . . The fine prospects of last night were effectually put aside by another snowstorm. . . .

Chamounix, *Sept.* 22, 1851.—The morning bad as usual. . . .

Chamounix, *Sept.* 23, 1851.—This morning still cloudy, yet the prospect for an improvement was encouraging. Soon after breakfast the sun appeared struggling in the clouds, and I hurried off with a spy-glass not to lose the slightest chance of seeing the phenomena I wished to. . . . I spent two or three hours in the wet fields to no purpose. In the afternoon there was an effort at clearing again.

"*Chamounix to Martigny*, *Sept.* 24, 1851.—The clouds this morning still hung on the mountains, but overhead there seemed some signs of clear sky. To make sure of losing no chance I took an early breakfast and left for the fields with the ordinary spy-glass belonging to the hotel under my arm. Sometimes it would be almost clear, and then again it began to rain, and I was undecided whether to give up and start for Martigny or to stay another day. At last I saw the sun's disc and took up my station on the edge of the shadow of the *Aiguille de Blettière*. It was still cloudy, but I was satisfied from the nature of the experiment—

"1st. That a very clear air is necessary.

"2nd. Plenty of time to choose projections, affording views of as large a portion of the circumference of the disc as possible while the rest is hidden.

"And lastly, a good achromatic telescope easily moved.

"I did not expect to find it so easy an experiment, nor to find a mass so well fitted for the purpose as the *Aiguille de Blettière*, which has a smooth edge, inclined, so as to allow the sun to disappear slowly behind it,

"The naked eye easily bears a small portion of the sunlight. From 7 to 9½ I followed the shadow over the valley. It was nearly clear for a few moments before it reached the woods on the side of the mountain, but there were still some light clouds over the sun, and nothing could be seen certainly of the corona; the clouds and mist would account for what I did see, and on the other hand the colour of the telescope supplied too much red just at the edge for one to be able to see any of the red flames, if they existed there.

"On the whole, I am more than ever sure that the experiment can be made, and I think will be by some one more fortunate than I."

SOLAR OBSERVATION IN INDIA

NOW that the subject of solar observation in India is likely to occupy the attention of the scientific public, he following details of the Solar Observatory now in progress of construction at Calcutta may be of interest to readers of NATURE.

The suggestion emanated in the first place from the well-known Italian astronomer and spectroscopist, Prof. Tacchini, who was sent to India by the Italian Government as director of the Transit of Venus Expedition. The idea thus put forth was at once taken up by Père Lafont, the principal of St. Xavier's College. A subscription was opened to enable the work to be carried on, and in a short time the collections had amounted to 10,000 rupees, to which the Indian Government added 5,000 rupees. So warmly does the idea seem to have been taken up, that a theatrical benefit was given, at the suggestion of Col. Wyndham, in aid of the Observatory fund.

The observations proposed to be carried out are to supplement those made in Italy, where from November to March (inclusive) the sky is often unfavourable for observation. A complete annual record of changes in the sun's chromosphere, &c., will thus be kept up. With regard to instruments, an equatorial of 7-inch aperture is now being constructed by Merz, but more funds are needed to complete the instrumental "plant" of the Observatory. In course of time it is to be hoped that a transit instrument and a complete set of meteorological apparatus will be added.

The Italian Transit of Venus Expedition has thus been the means of sowing seeds which, finding themselves in a soil most favourable for development, are calculated at no very distant period to bear fruit of the greatest value to science. When in Calcutta with the Royal Society's Eclipse Expedition, last April, I visited the Observatory in company with Prof. Tacchini, and the work of construction was then in a very advanced state. Prof. Tacchini has recently written to say that the building is now almost completed.

The energy which has been displayed in connection with the Calcutta Observatory * redounds greatly to the credit of our Indian colleagues. It is only by systematic observations of this kind, carried on by public enterprise, that we can ever hope to detect cyclical changes in the sun's composition and constitution—changes which, taking enormous periods for their completion, may demand continuous records to be carried on even through many generations.

R. MELDOLA

THE LAWS OF STORMS †

M. FAYE, in the article referred to below, and of which we propose to give an abstract at considerable length, begins by referring to the stupendous force of tropical tempests as contrasted with those of Europe, and to the practical importance of knowing the laws which regulate them. Many persons, he believes, on reading the title of his paper, will be surprised to learn that hurricanes have laws, or will ask what an author means by proposing to expound and vindicate the Law of Storms.

Laws of Storms.—Not only are storms subject to laws of great interest to science, but from these laws practical rules may be deduced which will enable us to avoid these dangers, or escape from them, should we happen to be caught in a storm. These rules are taught in all naval schools, and are the foundation of the sailor's safety. The validity of the laws on which they are based has, however, been disputed by some writers on Meteorology, and therefore the Bureau des Longitudes has authorised the publication of M. Faye's paper, in which he attempts clearly to expound and to defend the disputed laws.

Referring to the valuable labours of Piddington in India and Redfield in the United States, and of Reid, M. Faye says that the only premises they had to start

* The Observatory is situated in St. Xavier's College, Park Street, Calcutta.

† Abstract of a paper, "Défense de la Loi des Tempêtes, par M. Faye, Membre de l'Institut," in the *Annuaire* of the Bureau des Longitudes for 1875.

from were the idea that there ought to be something regular in the progress of hurricanes, and the observed fact that in every disastrous storm the wind appeared to move in a circle. They said to themselves: "We do not seek to know how storms are formed, but how they progress." Instead of speculating, as did former meteorologists, on storms of aspiration, on the rôle of electricity, on the conflict of opposing currents, &c., they collected for each tempest extracts from the log-books of all the ships which had been involved in it. After having abstracted and arranged this immense quantity of material, they marked upon a chart, at certain dates, the positions of these ships and the direction of the winds observed. Then, by placing on this chart, after several trials, a series of tissue-papers on which had been drawn concentric circles, they made sure that the wind-arrows at the same instant closely coincided with these circles, so that at that very instant, over all the region subjected to the storm, the mass of air resting on the ground or on the sea must have been acted on by a vast gyrating movement around a centre. Some idea of the nature of these researches will be obtained from Fig. 1, which shows a very small part of the chart of the hurricane which ravaged the island of Cuba in 1844. Redfield collected sufficient information to determine the figure of the hurricane at twenty-five different times, between Oct. 4 and 7; the figure shows two of these. The same phenomenon was reproduced at all the other times; everywhere the hurricane assumed this strikingly circular form.

All tornadoes, typhoons, hurricanes, present the same character wherever they occur, and they preserve it throughout the entire duration, and over all their area, which often extends to more than 600 leagues. The conclusion is evident; there is evidence here of a vast rotatory movement, definitively confined to one portion of our atmosphere, which is at the same time subjected to a movement of translation.

It is remarkable that when all the separate results obtained over the whole of the northern hemisphere are compared, it is seen that the gyration takes place always and everywhere from right to left, in a direction opposite to that of the hands of a watch (see Fig. 1). Still more remarkable is it that over all the southern hemisphere the same law, the same gyration is found, but in a direction opposite to that of the preceding, from left to right, *i.e.*, the same direction as that of the hands of a watch. There is here evidently one law, and that a law without exception; these terrible gyratory movements turn constantly

FIG. 1.—Hurricane at Cuba from Oct. 5 to 7, 1844.

to the left in the northern hemisphere, to the right in the southern hemisphere.

Finally, the trajectories present some very striking common characteristics in each hemisphere, and in both hemispheres a remarkable symmetry. The lines tracked by the centres of these cyclones do not descend directly from the equator to either pole; on the contrary, they incline first to the west, then, after having passed the limit of the trade-winds, they bend towards the east, in a final direction roughly perpendicular to the former. Fig. 2 will enable the reader to follow in the two hemispheres the development of cyclones. Originating not far from the zone of calms or of variable winds, on both sides of the equatorial zone, they measure scarcely more than two or three degrees at the outset, but as they proceed towards higher latitudes their area gradually enlarges. In the two temperate zones they attain a diameter of more than ten degrees, and frequently occupy upon the terrestrial globe a space considerably larger than that of France.

Thus all is symmetrical on each side of the equator, or rather of the zone of calms, which oscillates a little each year with the course of the sun. There is symmetry in the direction of rotation, symmetry in the direction of progressive motion, general symmetry in the figure of all these trajectories; and this holds good all over the globe.

Such are the storm laws, the discovery of which is mainly due to England and the United States, "the two greatest maritime powers of the world." The product purely of observation, of empiricism, to use that word in its highest sense, they have not yet reached the stage of theory. On the contrary, in order to discover these laws, it has been necessary to cast aside contemporary prejudices and doctrines, the deadening influence of which we have hourly opportunities of witnessing.

Practical Rules.—But the practical object of these investigations is to save human life. Do we know of no premonitory signs? After the cyclone has commenced, have we any means of discovering the direction of the centre where the rotation is accelerated, where all the sources of danger are accumulated? How can we find out the direction of its march? How learn whether a ship is caught in the dangerous region, where the rate of the wind is the sum of the rates of rotation and of progress; or in the moderate region, where the rate of the wind is only the difference? Finally, what manœuvres are necessary in order to avoid the tornado or to escape from it if by mischance we should be caught in it?

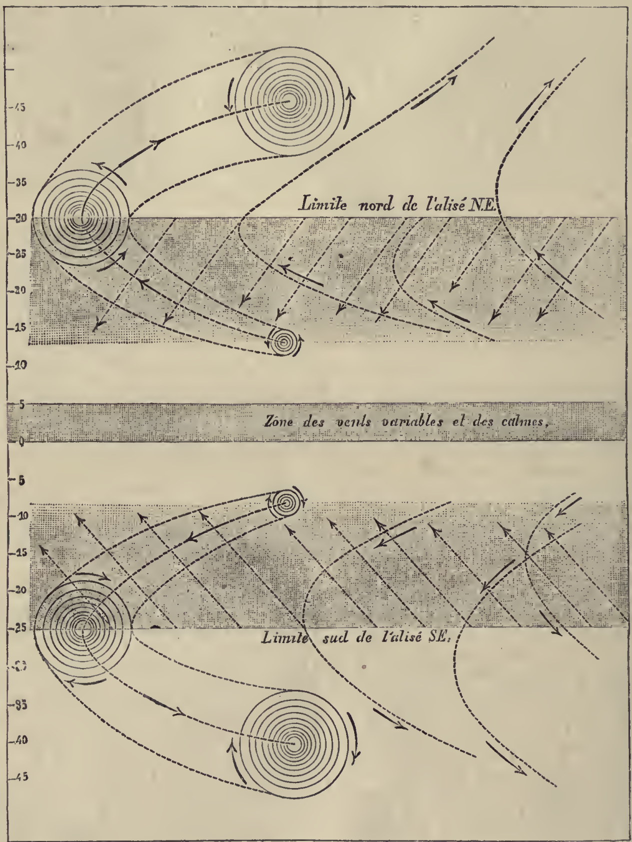
To all these questions there are answers, some exact, imperative as are the exigencies of the danger; others more elastic, leaving room for tact and ability on the par of a commander.

By a fall continuous and prolonged, the barometer, which is never at fault in the tropics, announces that a cyclone is at a distance. As soon as the wind blows with

a certain force, it is easy to determine the direction in which the centre of the cyclone will be found. The following is Piddington's rule:—Turn the face to the wind and stretch out the right arm; the centre is in this direction. The left arm must be used when a ship is in the southern seas. Soon the wind increases, and the fall of the barometer becomes more rapid; the centre is getting nearer, for the cyclone has an onward motion. If the wind continues to increase without changing direction, you are in the very path of the centre, and soon you will be in the very heart of the tempest. Then suddenly a calm ensues; at the centre of the cyclone exists a circular space where a relative calm prevails. There the sky reassuming its serenity, the sailor might be led to believe himself safe; but this space is soon passed, and immediately the tempest recommences. Only the wind has suddenly jumped round 180 degrees; it blows now in the direction opposite to the previous one, at right angles to the trajectory of the centre of the cyclone.

The situation which we have just supposed is a peculiar case; in general the vessel will be found to the right or the left of this trajectory, whose direction, moreover, an

FIG. 2.—Hurricanes of the northern hemisphere (July to October).



Hurricanes of the southern hemisphere (January to April).

attempt must be made to determine.* The alternative is far from being a matter of indifference; it is a question of life or death, for the one corresponds to the favourable semicircle, the other to the dangerous. The following is Reid's rule, which eliminates all uncertainty:—In whatever hemisphere, if the wind changes direction successively by turning in the same direction as the cyclone itself, the favourable semicircle is indicated; if the wind changes by turning in the direction opposite to that of the proper rotation of the cyclone, the dangerous semicircle is indicated.

This may be accounted for by examining Fig. 3. The observer, supposed to be immovable, has his face turned towards the series of winds which will strike him successively as the cyclone passes over him.

In the favourable semicircle (southern hemisphere), if the ship behaves well in a rough sea, it is possible to avoid the centre and the cyclone itself by the shortest way, perpendicularly to its trajectory. The storm is

* We do not dwell on this last point, which can only be solved by skilfully comparing the indications of the barometer with those of the direction and force of the winds.

always formidable, but it is manageable. If, however, the violence of the wind, the state of the sea, and the weakness of the ship should make flight impossible, there should be no hesitation in putting about ship and bringing to on the starboard tack (the wind on the right side). The vessel appears then to make for the centre of the

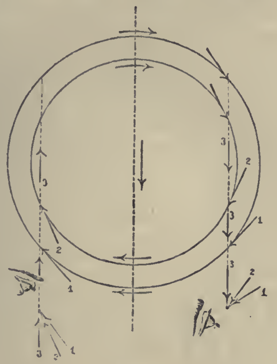


FIG. 3.

hurricane, but it makes no headway; it thus escapes being covered by the wind, and there is no risk of being struck by seas behind, inevitable consequences of a port tack. Soon the hurricane disappears by its motion of translation, good weather reappears, and at last sail may be made.

(*To be continued.*)

THE BRITISH ASSOCIATION

THE second *soirée* was very interesting, although not remarkable for novelties. The Post Office Telegraphic staff appeared in force, showing all varieties of method and apparatus. A splendid series of Geissler vacuum tubes was exhibited by Mr. F. J. Fry. Sir W. Thomson's tide-gauge and tide-calculator, the apparatus for deep-sea sounding, models of railway signals, means of communication between passengers and guard, and Dr. Leitner's collections from Dardistan were among the most attractive objects.

The concluding general meeting presented no remarkable feature, and called forth no very notable speeches. Among the papers to be printed in full in the Report is that of Prof. Cayley, on the application of mathematical trees to chemical theory. The local committee and officials were thanked most heartily and deservedly. They have had the best intentions, adequate means, and good plans, and have employed the energy needed for the fruition of their ideas. The actual number of members, associates, and ladies present during the meeting was 2,249, the number having been somewhat swelled by late arrivals.

The vote of thanks to the President, moved by Sir W. Thomson and seconded by Dr. Carpenter, was not merely formal. Sir W. Thomson eulogised Sir John Hawkshaw as a man who believed that good practice proceeded from good theory. Certainly the President's tone of mind seems to have influenced the work and proceedings of the meeting, for it has been on the whole quiet and genial, yet busy and important in useful results obtained by the scientific employment of common sense, if not of imagination. Thus ended the formal proceedings of a meeting in which three Sections had to sit up to the latest moment in order to get through their work.

The following is the list of grants of money appropriated to scientific purposes. The names of the members who would be entitled to call on the general treasurer for the respective grants are prefixed :—

* Re-appointed.

I was fortunate enough to get a ticket for the Salisbury and Stonehenge excursion, for which the applications were very numerous. Mr. Blackmore's magnificent museum illustrating the Stone Age was a delight to all scientific minds; and the presence of the founder, his brother, and his brother-in-law, Mr. E. T. Stevens, enhanced the pleasure of the visit. The Cathedral and Stonehenge, in addition, made up a very full day's round. The Mayor of Bristol took a party to Bowood and Avebury. How the Rev. Bryan King obtained his data for estimating that Avebury was about seven centuries older than Stonehenge I cannot conceive. The Silbury tumulus afforded a splendid view to the visitors, if very little science could be got out of it. A third party, that drove through the Cheddar valley, saw at Stanton Drew yet a third of the famous stone erections so conveniently placed around Bristol. The Tortworth excursion was a really hard day's work among many varieties of rock, especially palæozoic, but it was as profitable as it was hard, for the geologist. The Bristol waterworks were of high interest for engineers; and the attractions of Bath, Wells, and Tintern were displayed to every advantage by reason of beautiful weather and hearty welcomes.

REPORTS.

Report of the Committee on Mathematical Tables.—The portion of the report that had been prepared by Prof. Cayley during the year contained a *résumé* of works and memoirs on the theory of numbers. The publication of the elliptic function tables had, under the direction of Mr. J. W. L. Glaisher, proceeded during the year, and the first sixty-four pages of the table, printed from the stereotype plates, were exhibited to the Section. It was expected that the whole table would be printed by the next meeting. Mr. Glaisher stated that considerable additions had been received from mathematicians relating to the report on general tables, and that it was probable a supplementary report on this subject might be presented at the next meeting of the Association.

Hyperelliptic Functions.—Mr. W. H. L. Russell stated the contents of the portion of his report that he had written in the year, and which related chiefly to memoirs of Weierstrass. His report would be completed in two more parts.

Report of the Committee on Mathematical Printing, by Mr. W. Spottiswoode.—At the Belfast meeting the committee, consisting of Mr. Spottiswoode, Professors Stokes, Cayley, Clifford, and Mr. J. W. L. Glaisher, was appointed to report on mathematical notation and printing, with the view of leading mathematicians to prefer in optional cases such forms as are more easily put into type, and of promoting uniformity of notation. The report related wholly to printing, and contained a list of forms having the same signification, the one requiring "justification," and the other not (such as *ex. gr.* $\sqrt{a+x}$, and $\sqrt{(a+x)}$.) There were also attached diagrams showing the mechanical operation of setting up mathematical expressions in type, so that when there were two forms equally satisfactory from the mathematical point of view, writers might choose the one that would give the printer less trouble; as everything that tended to cheapen mathematical printing tended to the spread of the science. With regard to notation, the committee had thought it better not to report, feeling that in presence of the differences of opinion that must exist, it would be desirable that the matter should be discussed by a larger committee. The committee was reappointed to report on mathematical notation, with the addition of Sir Wm. Thomson, Professors H. J. S. Smith and Henrici, and Lord Rayleigh.

Report of the Committee on Tides, by Sir William Thomson.—He remarked that tides rise and fall in a series of harmonic vibrations, like the various tones in music, some tidal waves being due to the moon, others to the sun, others to meteorological causes. Even the overtones in music—so thoroughly studied by Helmholtz—were represented in the tidal waves. The committee had been engaged upon tides for a long time, and had shown the Government, harbour authorities, and others interested, the way to continue the work, but it could do so itself no longer, for he believed that day to be the last of the existence of the committee. The calculations connected with tidal observations were of a laborious nature. Col. Walker, of the Trigonometrical Survey of India, had helped the committee very much by printing the forms required for the calculations. Col. Walker had also had a series of tidal observations made in the Indian seas, and might possibly send the results home to have the calculations made from them. The Indian Government would probably have further observations made, especially in an important new harbour they were constructing at Madras. A great mass of other observations was accumulating. Mr. H. C. Russell, the Government astronomer at Sydney, had made several years' tidal observations, but had been obliged to stop them on account of the cessation of the grant for the work, but he hoped that the duty would be undertaken once more; as yet, the committee had no reductions whatever of tidal observations in the southern hemisphere, and knew nothing about the tides there. He had been promised a long series of observations, extending over eighteen years, from Brest, and he had applied for a series of eighteen years' observations from Toulon; so that he expected to obtain some information about tides on the French coast. The Tidal Committee had had some assistance from the Royal Society, which had given it a grant of 100*l*. to carry on tidal calculations. It had thus ascertained that the tides in Erebus Bay were connected with the Atlantic and not with the Pacific. Sir William Thomson then exhibited to the meeting and described his tide-gauge and tide-calculating machine, the latter being an improvement on that first described at Brighton and shown at Bradford two years ago. Although the old committee on tides ceased to exist at this meeting, a new one was appointed, consisting of Sir W. Thomson, Prof. J. C. Adams, Rear-Admiral Richards, General Strachey, Mr. W. Parkes, Col. Walker, Prof. Guthrie, Mr. J. W. L. Glaisher, Mr. John Exley, Mr. J. N. Shoolbred, and Mr. J. R. Napier, and the sum of 200*l*. was granted to them for completing and setting up in London, where it may be available for use, Sir William Thomson's tide-calculating machine. It was suggested that perhaps the machine might be placed at South Kensington.

Report of the Committee on Wave Numbers.—Portions of a letter were read from Mr. G. Johnstone Stoney relating to the work done in the year. At the Belfast meeting it was arranged that Mr. Stoney should interpolate Kirchhoff's lines into the table of wave numbers of the solar spectrum which Mr. Burton had prepared for the committee. When this was attempted, however, it was found that there were points requiring personal explanations from Mr. Burton, who was absent at Rodriguez on the Transit of Venus expedition, and the delay so occasioned had prevented any portion of the table being as yet printed. About thirty-four folios in manuscript, forming about two-thirds of the whole, were complete and were exhibited to the section.

An *interim Report of the Committee for testing experimentally Ohm's Law*, by Prof. Clerk-Maxwell, was read. It stated that he had had two compound resistance coils constructed by Warden and Co., one containing five equal, or nearly equal, coils of thirty ohms each, and the other two similar coils of thirty ohms, and by means of these he had devised a satisfactory test of Ohm's Law which could be worked to about $\frac{1}{10000}$. Nothing had, however, been done as yet. It was mentioned that Mr. Chrystal had compared the resistances of the standard coils belonging to the Association, and now in the Cavendish Laboratory at Cambridge.

Prof. Thorpe presented a preliminary *Report of the Committee appointed for the purpose of determining the specific volumes of liquids*. It gave a *résumé* of experiments upon certain liquids and gases, experiments made with a view of following up the work of Hermann Kopp, to whom almost all our knowledge of the subject is due, and further to arrive at definite conclusions with reference to the laws laid down by Kopp.

Prof. Corfield, on reading the *Report of the Sewage Committee*, observed that want of funds during the past year had prevented them from employing a sufficient amount of labour to obtain many useful results, but he was happy to state that the prospect for the ensuing year was brighter, as they had had a very liberal offer of pecuniary assistance. The observations which have been made on the Sewage Farm (situated near Romford) go to show that the weight of the crops removed from the land has increased each year. The great thing required is to make a comparison between the nitrogen taken up by the crops and the effluent nitrogen, and in order to accomplish this with accuracy it was necessary that the experiments should be constantly repeated, and should extend over a considerable number of years.

Report of Committee for considering the desirability of establishing a close time for the Protection of Indigenous Animals.—This report expressed regret that it had been found impossible to introduce the desired measure into Parliament this year in time to allow of its being carried; but Mr. Henry Chaplin, M.P. for that part of the Atlantic Doldrums which lies in the track of Mid-Lincolnshire, holds out the hope that he will bring forward such a measure early next session. The committee continue to receive assurances of the efficient working of the Sea Birds' Perservation Act of 1869.

The report (unfortunately the last) of the Sub-Wealden Exploration states that the new bore-hole has failed to penetrate to the Palæozoic rocks. The small diameter prevents tubing, and the sides now appear to be too friable to preserve verticality. Cessation of the work is hourly expected. The most noteworthy result of this heroic but unsuccessful investigation is the great thickness of the Kimmeridge clay, which, as was predicted by Mr. Searles Wood, considerably exceeds the estimate of the Sub-Wealden Boring Committee.

SECTIONAL PROCEEDINGS

SECTION A—MATHEMATICS AND PHYSICS

Dr. J. Janssen made four communications to the Section, the first of which related to the eclipse of April 1875, as observed at Bangchallô (Siam). He used a special telescope for the study of the corona. The results were—1. The establishing that the line 1474 is infinitely more pronounced in the corona than in the protuberances. This line seems even to stop abruptly at the edge of the protuberances without penetrating them. The light, then, which gives the line 1474 belongs entirely to the corona. This observation is one of the strongest proofs which can be

adduced to prove that the corona is a real object, a matter radiating by itself. The existence of a solar atmosphere situated beyond the chromosphere—an atmosphere which M. Janssen had recognised in 1871, and proposed to call the coronal atmosphere—thus receives confirmation. 2. *Height of the coronal atmosphere.* In 1871 Dr. Janssen announced that the coronal atmosphere extended from half the sun's radius to a whole radius at certain points. This assertion has been confirmed not only by the direct views of the phenomenon, but also by photography. At Dr. Janssen's request Dr. Schuster took photographs of the corona with exposures of one, two, four, and eight seconds. In this series of photographs the height of the corona increases with the time of exposure. The height of the corona in the eight-seconds' photograph exceeds at some points a solar radius. (It is true that we ought to take account of the influence of the terrestrial atmosphere.) 3. As the sky was not of perfect clearness at Bangchallô, Dr. Janssen observed phenomena that explain previous observations of eclipses which seemed to invalidate the existence of the corona as a gaseous incandescent medium. On the whole, the observations of the 5th of April, 1875, have advanced us a fresh step in the knowledge of the corona by bringing forward new proofs of the existence of an atmosphere round the sun, principally gaseous, incandescent, and very extended.

In his second paper Dr. Janssen stated the results obtained by the expedition to Japan to observe the Transit of Venus. The expedition, which was under Dr. Janssen's direction, divided into two parts, the one taking up its station at Nagasaki and the other at Kobí. At Nagasaki Dr. Janssen observed the transit with an equatoreal of 8 inches aperture. (1) He obtained the two interior contacts. (2) He saw none of the phenomena of the drop or of the ligament; all the appearances were geometrical. (3) He observed facts which establish the existence of an atmosphere to Venus. (4) He saw the planet Venus before her entry on the sun, with suitable coloured glasses. This important observation proves the existence of the coronal atmosphere. (5) There was taken at Nagasaki a plate of the revolver for the first interior contact. (6) M. Tisserand observed the two interior contacts with a 6-inch equatorial; the contacts were sensibly geometrical. (7) Sixty photographs of the transit on silvered plates were obtained; and (8) also some other photographs (wet collodion and albumenised glass). At Kobí (weather magnificent) fifteen good photographs of the transit (wet collodion and albumenised glass) were obtained of about 4 inches in size; they will admit of being combined with the English photographs at the southern stations. The astronomical observation of the transit was successfully made by M. De la Croix, who was provided with a 6-inch telescope. His observations attest the existence of an atmosphere round Venus.

Dr. Janssen's third communication related to his magnetic observations in the Gulf of Siam and the Gulf of Bengal. He made observations at Bangkok, Bangchallô, Ligor, Singora, and Singapore, and concluded that the magnetic equator passes actually between Ligor and Singora, about 7° 43′ N. latitude. The *line without declination* passes very near to Singapore. In the Gulf of Bengal the equator passes through the north of Ceylon (the precise position will be given). The position of Ligor has been rectified. It is erroneously placed on the maps lat. 8° 24′ 30″.

Dr. Janssen had also made some observations which relate to mirage at sea. He had paid great attention to the phenomena in all his journeys since 1868, and had observed some very curious facts relating to mirage chiefly at sunrise and sunset. He found that (1) the mirage was almost constant at the surface of the sea; (2) that the appearances were explained by admitting the existence of a plane of total reflection at a certain height above the sea; (3) that the phenomena are due to a thermic and hygrometric action of the sea on the neighbouring atmospheric strata; (4) that there exist at sea direct, inverse, lateral, and other mirages; (5) that the phenomena have a very general influence on the apparent height of the sea horizon, which is sometimes diminished, sometimes increased. This variation of the apparent horizon it is very important to take into account, if we remember the use made of the horizon in nautical astronomy.

Prof. Hennessy, of Dublin, read two papers, one *On the influence of the physical properties of water on climate*, and the other *On the possible influence on climate of the substitution of water for land in Central and Northern Africa.* In the former the author referred to his earlier writings, in which he had taken an opposite view to Sir John Herschel, who stated that the effect of land under sunshine was to throw heat into the general atmosphere, and to distribute it by the carrying power of the air over the whole earth, and that water was much less effective in this respect, the heat penetrating its depths and being there absorbed, so that the surface never acquires a very elevated temperature even under the equator. Prof. Hennessy had arrived at the conclusion that of all substances largely existing in nature, water was that which was the most favourable to the absorption and distribution of solar heat throughout the external coating of the earth.

In his second paper, the author referred to the fact that more than six years since he had put forward proofs of the connection between some of the hot winds that blow from the south-west in Central and Southern Europe with the currents of the Atlantic, and not with the Desert of Sahara, as has been usually supposed. Similar views had been enunciated by Prof. Wild, director of the Physical Observatory of Russia, and others. The attention excited by the great midday heat of Central Africa caused many to overlook the remarkably low nocturnal temperature, and thus to ascribe to the desert a thermal influence that it does not possess. The author's views with regard to the physical properties of water in connection with climate, indicate that the substitution of an area of water over the Sahara for the existing dry land would be followed by the storing up of the heat received so largely in that region from the sun's rays which is now partly dissipated by nocturnal radiation. A great mediterranean sea in Africa would become a source of positive thermal influence on distant places. In the Red Sea the temperature is high by night as well as by day, and this would also occur in the hypothetical mediterranean of the Sahara. The climatal effect of this sea would upon the whole result in a higher mean temperature for these parts of the globe, and it would undoubtedly not operate in producing a lower temperature in Europe so as to cause a descent of the snow line. Its operation would probably be the reverse.

Prof. Osborne Reynolds read a paper *On the Force caused by the communication of Heat between a Surface and a Gas.*—This paper dealt chiefly with the remarkable discovery recently made by Mr. Crookes, that, under certain conditions, discs of pith suspended in a very perfect vacuum, and at the end of arms free to rotate, are made to spin round when light or radiant heat falls upon them. Prof. Reynolds said that he believed that Mr. Crookes asserted that radiant heat was attended by a force which produced this effect, but no such assumption would, he thought, explain the results. When a candle was presented the disc would tend to run away, and when a piece of ice was presented it would tend to follow; this showed that the force was not a radiative one, and he thought that, except as regarded the raising of the temperature of the body, radiant heat had nothing to do with the motions. The suspended body might give up its heat to the ether or to the surrounding gas, and thus propel itself, for the communication of this heat to the surrounding medium must be accompanied by a reaction. It had been said that Mr. Crookes used a perfect vacuum, so that there could be no gaseous reaction; but it remained to be proved that he used a vacuum so absolutely perfect. The greater the perfection of the vacuum the less was the resistance, and that was why the body appeared under such circumstances to be driven by a greater force. He had not witnessed the experiments with light, made by Mr. Crookes, but he thought that the results were probably due to the conversion of light into heat.—The discussion on this paper was adjourned, as it was hoped that Mr. Crookes would be able to be present; unfortunately, however, he was not able to arrive in time, and Prof. Balfour Stewart, the president, remarked that, as had been said by Prof. Stokes, it was doubtful whether Prof. Reynolds's explanation covered the whole ground. There was something else besides residual gas in the bulbs, viz., ether, and the particles of the radiometer might communicate more force to the ether when moving in one direction than when falling back again; consequently, motion might be given to the whole body to restore the balance. At all events Mr. Crookes's experiments were among the most interesting in the range of physical science.

Capt. H. Toynbee read a paper *On the physical geography of that part of the Atlantic Doldrums which lies in the track of ships crossing the Equator.* The paper was accompanied by diagrams, which showed the isobaric lines of mean pressure for each ·05 of an inch, together with arrows showing the prevailing winds and their force, also the isothermal lines for every second degree of air temperature, and further the isothermal lines for every second degree of sea temperature, together with arrows showing the prevailing currents and their speed in twenty-four

hours. The paper called attention to important facts relating to atmospheric pressure, temperature, wind, currents, weather, sea-charts, natural history, earthquakes, &c. The diagrams gave monthly pictures of the Doldrums, showing how in some months they are wedge-shaped, as the late Commodore Maury remarked. The whole paper was a *résumé* of a work about to be published by the Meteorological Office.

Sir W. Thomson gave an account of the graphical process employed by him and Mr. J. Perry (now professor in Japan) for determining the form of a hanging drop, and other cases of the capillary surface of revolution.

On account of the interest attaching to the address of the President of the Mechanical Section *On Stream Lines*, and to the fact that as it was being delivered simultaneously with Prof. Balfour Stewart's address only a few members of this Section were able to hear it, Mr. Froude repeated it and the experiments with which it was accompanied again in Section A on the Tuesday morning. One experiment in particular was very interesting. A wooden wheel was fixed at a height of about 14 feet, and an endless chain hanging loosely over the wheel in a loop drooped to within 4 feet of the ground. When the wheel with its suspended chain was made to rotate rapidly by means of multiplying gear, the links of the chain symbolised the particles of a running stream of water. When the chain was struck, while it was rotating, with a wooden mallet, the curved forms into which it was thus beaten were to some extent persistent, as if it were a stiff, fixed wire rope, instead of being a loose chain in motion. Mr. Froude said that this experiment illustrated how water in flowing through pipes did not tend to push them straight, but rather adapted its motions to their curvatures.

In a letter from Mr. Meldrum, of Mauritius Observatory, written to accompany forty-nine tables (which, however, had not arrived), he expressed an opinion that the evidence adduced in favour of a rainfall periodicity was so strong that he believed we should by and by be able to predict the general character of the seasons.

Communications were made to the Section by Mr. H. A. Rowland, of John Hopkins University, Baltimore, *On the Magnetising Function of Iron, Nickel, and Cobalt*, and *On Magnetic Distribution*; and Mr. A. Malloch explained a method he had found accurate and convenient for producing a sharp meridian shadow.

On the whole, the physical papers read before the Section were not equal to the average of recent years, either in number or importance; but, as a compensation, the number of mathematical papers was unprecedented, and the Bristol meeting will be remembered both on this account and for the numerous attendance of mathematicians. On the Saturday, which has by custom long been set apart for mathematics, no less than twenty-four papers (including the three reports noticed in another column) on pure mathematics were read. Prof. Cayley explained the theory of the analytical functions which he had termed factions. Sir W. Thomson had three papers all relating to the mathematical treatment of the differential equations that occur in Laplace's theory of the tides. Prof. H. J. S. Smith explained the effect of the quadric transformation on the singular points of a curve, showing how singularities lying upon one side of the triangle of reference became transformed into singularities of a higher order at the opposite angle; and in another paper of great interest he pointed out the connection between continued fractions and points in a line (for example, between $\frac{24}{7}$ expressed as a continued fraction, and the order in which the points of section occur if a given line be divided into twenty-four and also into seven parts). Prof. Smith also spoke on the subject of singular solutions. Prof. Clifford's communications related to the theory of linear transformations, and one contained a graphical representation of invariants. Mr. J. W. L. Glaisher gave some theorems on the nth roots of unity, and explained a formula of verification in partitions, which was founded on and is complementary to one communicated by Sylvester to the Edinburgh meeting in 1871, viz., that

$$\Sigma(1 - x + xy - xyz + \ldots) = 0,$$

while the theorem in the paper was that

$$\Sigma(1 + x + xy + xyz + \ldots) = \Sigma 2^r,$$

r being the number of different elements employed in any partition. Mr. H. M. Jeffery's papers related to cubic spherical curves with triple cyclic arcs and triple foci, and to the shadows of plane curves on spheres. Mr. H. M. Taylor's paper contained a contribution to the mathematics of the chess-board, and his process enabled him to determine by a mathematical procedure the relative values of the pieces at chess probably as accurately as they admit of being found. Prof. R. S. Ball's communication related to a screw-complex of the second order, and Prof. Everett spoke on motors. Prof. Paul Mansion, of Ghent, had sent two papers, one containing an elementary solution of Huyghens's problem on the impact of elastic balls, and the other relating to singular solutions. Mr. W. Hayden contributed some geometrical theorems.

SECTION C—Geology

After the President's address, a lengthy and elaborate paper on the Northern End of the Bristol Coalfield was read by Messrs. Handel Cossham, E. Wethered, and Walter Saise. The paper was illustrated by many maps and sections. This was followed by a paper by Mr. J. M'Murtrie on mountain limestone lying in isolated patches at Luckington and Vobster. The singularity of this case will be realised when it is mentioned that the mountain limestone lies above the coal-measures, which, when originally deposited, overlaid the limestone. The Geological Survey examined the ground many years ago, and came, not unnaturally, to the conclusion that the limestone areas were bounded on all sides by faults. Mr. M'Murtrie has been able to show that the coal-measures are continued without disturbance beneath the limestone. The whole thing is inverted, and much interesting talk arose as to the possible movements which could have produced so great a displacement. Mr. Moore, of Bath, followed with an account of the deposits of Durdham Down yielding *Thecodontosaurus*. The age of the deposit in which this most remarkable Dinosaurian occurs was discussed at some length, but no definite result was arrived at, and the discussion was deferred till Monday.

Mr. Stoddart described an auriferous limestone found at Walton. The metal was distributed through the mass in extremely minute quantity, and the difficulty of obtaining recognisable samples was very great.

Prof. Hughes's paper, *On the Classification of the Sedimentary Rocks*, began by pointing out that the great divisions are not now drawn where the greatest breaks, all evidence considered, occur in nature. The sequence may be shortly given in these terms. Laurentian—Gap—Labrador Series—Gap [? Huronian—Gap] — Cambrian (from red conglomerates of St. David's up to base of May Hill Sandstone)—Gap—Silurian (from May Hill Sandstone = Upper and Lower Llandovery, to top of Red Marls of Sawdde and Horeb Chapel)—Gap—Carboniferous (from bottom of Devonian and Upper Old Red to top of Upper Coal Measures)—Gap—Jurassic (from bottom of breccia and conglomerates of so-called Permian and New Red to top of fluviatile and estuarine deposits of Weald.) The author deferred the full consideration of the rocks above this horizon to a future time, merely commenting on some of the points which seemed to him more especially to call for change.

In supporting this classification he criticised the division of the May Hill Sandstone into Upper and Lower Llandovery, and commented severely upon the re-naming of these beds, which had been previously correctly described by Prof. Sedgwick under the title May Hill Sandstone. He went into the Cambrian and Silurian controversy at some length, and pointed out that not only was Sedgwick's classification found to be the best in the present state of our knowledge, but that Murchison's had not correctly placed any one of the beds about which he came in collision with Sedgwick. What Murchison then called Caradoc overlapping Llandeilo at Llandeilo, has turned out to be May Hill Sandstone; what Murchison then called Cambrian underlying Llandeilo Flags, has turned out to be Caradoc resting on them, and part of the Llandeilo has had to be turned the other way up. The Survey corrected this, and it has appeared corrected in Murchison's later works, but he has never allowed that Sedgwick was right and he was wrong in 1839. Prof. Hughes thought it was too bad that some should still claim for Murchison the credit of having correctly placed the Ludlow and Wenlock, Caradoc and Llandeilo, but say nothing of the names having at that time been applied to totally different rocks.

He considered the Devonian and Upper Old Red to have been deposited over a continental area which sunk first on the south: hence the earlier character of the Devonian fauna in the

south, and the greater denudation of the pre-Devonian land of the north. The Permian he wished to abolish as a separate formation, as it was a group made up of some stained carboniferous rocks and some of Sedgwick's previously described Magnesian Limestone and New Red. He thought that the continental area on whose submerged surface the New Red was deposited sunk unequally, and that conglomerates, where there was material to furnish them, were formed along the receding shore line, but at different dates as different parts of the land got down below the waves. He challenged anyone to show a section in which a greater break could be seen between the Trias and so-called Permian than several which occur amongst various members of the Upper New Red itself—and commented upon the unsatisfactory character of the palæontological evidence and of the stratigraphical evidence derived from tracing lines through a district where the rock was seldom seen.

Prof. Hull commented upon the difficulty of introducing any material changes in a nomenclature now so widely accepted. Prof. Harkness stated that he was in favour of adopting the classification of Silurian rocks given in Lyell's "Student's Manual." In reply, Prof. Hughes maintained his original claims with much humour and energy.

Prof. Hébert's very interesting communication on Undulations in the chalk of the North of France had special reference to the strata likely to be encountered in the drift-way of the Channel Tunnel. The Professor considered that observations of dips established the existence of two series of folds, one transverse to the other, which by their intersection produce bosses, or geological hills. The lower rocks, and notably the Greensand, may thus come to the surface in the Channel, and admit the sea-water through their porous substance. Sir John Hawkshaw was present, and combated the geological difficulties with great success. A course of no fewer than five hundred borings, made by a plunger from the side of a vessel, had satisfied him of the substantial accuracy of the geological map of the Straits constructed from shore observations, and the information yielded by these borings was in his opinion adequate to prove that the tunnel will run through Lower Chalk in its whole extent. A small irregularity, bringing in some less compact rock, may be successfully and easily encountered by the engineer. In answer to a suggestion that the shallow holes made by the plunger might be deceptive, owing to a superficial detritus along the floor of the Straits, Sir John Hawkshaw explained that the strong wash of the Channel produced a perfectly clean floor. All along the Straits the instrument had brought up chalk where chalk was expected, and gault where gault was expected, and these formations had a perfectly definite boundary upon the floor of the sea.

A paper by Mr. Sanders described some large bones from the Rhætic beds of Aust Cliff. The dimensions of these fragments are so great as to suggest a large Dinosaurian, but the absence of any medullary cavity seems to imply that the body was habitually submerged. The articular ends, which might be expected to yield useful characters, are not preserved. A communication from Mr. Brodie opened the question of the extent and classification of the Rhætic beds. The interesting discovery of these deposits at Leicester formed the chief and most novel feature of the discussion. Confident statement was on the whole more conspicuous than matured reasoning in this part of the proceedings of the Section, and much evidently remains to be done to elucidate the palæontological and physical relations of the deposits in question. For the moment the preponderance, at least of authority, rests with those who affirm the universal spread of a Rhætic age, and look in every quarter of the globe for a bone-bed with Ceratodus and an *Avicula-contorta* zone.

A large audience assembled to hear Dr. Carpenter's paper on the red clay found by the *Challenger*. The substance of his remarks has already appeared in the Proceedings of the Royal Society.

The greater part of Tuesday's sitting was occupied by papers and discussion upon the Glacial Period. By this time the easily observable glacial phenomena have been co-ordinated, and there is not quite so much room as formerly for supposition and unconnected facts. The discussion elicited a few curious points, and was interesting, if not particularly instructive. Most readers of such modern summaries as are given in Lyell's "Principles" or Geikie's "Ice Age" would demur to the too sweeping language in which the Chairman summed up the argument. Dr. Wright's opinion that no man living knows anything of the Glacial Period may possibly be just, but it is not sufficiently incontestable to be enunciated *ex cathedrâ*. The most novel points of Dr. Carpenter's communication upon the "Sea Bottom of the North Pacific" were the low temperature of the water at great depths, and the supposed existence of coral reefs, drowned by too rapid submergence, upon all the submarine summits. The species are believed to be recent, and the submergence comparatively modern. Some notice was taken of the results obtained by the *Valorous*, and of Mr. Gwyn Jeffreys' view that the Arctic shells of the Sicilian Tertiaries were derived from polar areas by migration through a marine gap not far distant from the present canal of Languedoc. Mr. Thomson's views as to some new genera of fossil corals, which met heavy criticism at the Geological Society, were brought up once more here, but gained no support of consequence. The method of investigation is curious, but it has hitherto proved somewhat barren of results.

Among other good papers may be cited Prof. A. H. Green's account of the Millstone Grit of North Derbyshire and South Yorkshire. This was a highly-condensed statement of the stratigraphical relations of an extensive group of very interesting rocks. The variations in thickness of the different grits were referred to inequalities of the old sea-floor upon which they were accumulated, hollows permitting a greater thickness to form. Had discussion been allowed, it would have been interesting to notice the remarks thrown out by those classifiers of strata who regard the formation of every rock as a definite and almost universal event in the earth's history. Rarely has a better example been given than this of the local conditions, often quite trivial in themselves, which regulate the extent, divisions, and thickness, as well as the mineral and fossil characters of a large formation.

SECTION D.

Biology.

Opening Address by Dr. P. L. Sclater, M.A., F.R.S., F.L.S., President.*

V.—NEOTROPICAL REGION.

The Neotropical Region is, I suppose, on the whole the richest in animal life of any of the principal divisions of the earth's surface. Much work has been done in it as regards every branch of zoology of late years, and I must confine myself to noticing the most recent and most important of the contributions to this branch of knowledge.

I believe the following † to be altogether the most natural sub-divisions of the Neotropical Region, which are nearly as they are set forth in Hr. v. Pelzeln's "Ornithology of Brazil."

1. *Central American Sub-region*, from Southern Mexico to Panama.

2. *Andean* or *Columbian Sub-region*, from Trinidad and Venezuela, along the chain of the Andes, through Columbia, Equador, and Peru, down to Bolivia.

3. *Amazonian Sub-region*, embracing the whole watershed of the Orinoco and Amazons up to the hills, and including also the highlands of Guiana.

4. *The South Brazilian Sub-region*, containing the wood-region of S.E. Brazil and Paraguay and adjoining districts.

5. *The Patagonian Sub-region*, containing Chili, La Plata, Patagonia, and the Falklands.

Besides these we have :—

6. *The Galapagos*, which, whether or not they can be assigned to any other sub-region, must be spoken of separately.

I. The Central American Sub-region

was, up to twenty years ago, very little known, but has recently been explored in nearly every part, and is perhaps now more *nearly* worked out than any other of the above-mentioned sub-regions. There is as yet no complete work on the zoology of any portion of it, and the discoveries of Sallé, Boucard, de Saussure, and Sumichrast in Mexico, of Salvin in Guatemala, of v. Frantzius and Hoffman in Costa Rica, of Bridges and Arcé and Veragua, and of McLeannan in Panama, together with those of numerous other collectors, are spread abroad among the scientific periodicals of Europe and America. Even of Mexican zoology, long as it has been worked, we have no general account. To mention all these memoirs in detail would be impossible within the limits of this address; but I will say a few words about the more important of them that have lately appeared.

* Continued from p. 382.

† A general sketch of the Mammal-life of this region is given in my article on the Mammals of South America in the Quar. Journ. of Science for 1865, and a Summary of the Birds in Sclater and Salvin's "Nomenclator Avium Neotropicalium."

The French are now publishing a work on the results of their scientific expedition to Mexico during the short-lived Empire. Three parts on the Reptiles by Duméril and Bocourt were issued in 1870, and a part on the Fishes, by L. Vaillant, has recently appeared.

A paper on the Mammals of Costa Rica has lately been published by v. Frantzius in Wiegmann's Archiv. Unfortunately, it seems to have been drawn up mainly from notes without reference to the specimens in the Berlin Museum, but nevertheless contains much that is useful and of interest.

Dr. Günther's admirable memoir of the fishes of Central America, published in the Zoological Society's "Transactions" in 1869, is based upon the collections made by Capt. Dow in various parts of the coast, and by Messrs. Salvin and Godman in the freshwater lakes of the highlands of Guatemala and in other localities.

Its value in relation to our general knowledge of the fishes of this portion of America, heretofore so imperfectly known, can hardly be over-estimated. As regards the birds of Central America, it is much to be regretted that we have at present no one authority to refer to. The collection of Messrs. Salvin and Godman embraces very large series from different parts of this region, and together with those of my own collection, wherein are the types of the species described in my own papers, would afford abundant materials for such a task. Mr. Salvin and I have often formed plans for a joint work on this subject, and I trust we may before long see our way to its accomplishment. A similar memoir on the Mammals of Central America is likewise of pressing necessity for the better understanding of the Neotropical Mammal Fauna. There are considerable materials available for this purpose in the collections of Salvin and Arcé in the British Museum, and I trust that some naturalist may shortly be induced to take up this subject.

2. The Andean or Columbian Sub-region.

Of this extensive sub-region, which traverses six or seven different States, there is likewise no one zoological account; but I may mention some of the principal works lately issued that bear upon the subject. Léotaud's "Birds of Trinidad" gives us an account of the ornithology of that island, which forms a kind of appendage to this sub-region, and Dr. Finsch has more recently published a supplementary notice of them. Of Venezuela, Columbia, and Ecuador there are only scattered memoirs in various periodicals on the numerous collections that have of late years been made in those countries to be referred to. Several excellent collectors are now, or lately have been, resident in these republics, Herr Georing and Mr. Spence in Venezuela, Mr. Salmon in Antioquia, Professor Jameson and Mr. Fraser in Ecuador, whose labours have vastly added to our knowledge of the zoology of these districts. When we come to Peru, we have Tschudi's "Fauna Péruana" to refer to, which, though unsatisfactory in execution, contains much of value. How far from being exhausted is the rich fauna of the Peruvian Andes, is sufficiently manifest from the wonderful discoveries lately made by Jelski in the district east of Lima, which was in fact that principally investigated by Tschudi. Of these, M. Taczanowski has lately given an account as regards the birds in the Zoological Society's "Proceedings"; and Dr. Peters has published several notices of the more remarkable Mammals and Reptiles.

Further south, in Bolivia, our leading authority is still the zoological portion of D'Orbigny's "Voyage dans l'Amérique Méridionale." This rich and most interesting district has, it is true, been visited by several collectors since D'Orbigny's time; but the results of their journeys have never been published in a connected form, though many of their novelties have been described. Bolivia, I do not doubt, still contains many new and extraordinary creatures hid in the recesses of its mountain valleys; and there is no part of South America which I should sooner suggest as a promising locality for the zoological collector.

3. The Amazonian Sub-region.

On Guiana, where the Amazonian fauna seems to have had its origin, we have a standard work in Schomburgk's "Reise," the third volume of which, containing the Fauna, was drawn up by the Naturalist of the Berlin Museum. For the valley of the Amazons itself, the volumes of Spix and Martius, though not very accurate, and rather out of date, must still be referred to, as likewise the zoology of Castelnau's "Expédition dans l'Amérique du Sud," for the natural history of the Peruvian confluents. As regards the birds, however, we have several more recent authorities. In 1873 Mr. Salvin and I published in the Zoological Society's "Proceedings" a *résumé* of the papers treating of Mr. E. Bartlett's and Mr. John Hauxwell's rich ornithological collections on the Huallaga, Ucayali, and other localities in Eastern Peru. Subsequently we communicated to the same Society an account of Mr. E. L. Layard's collection of birds made near Para, and took occasion to deduce therefrom some general ideas as to the relations of the Avifauna of the Lower Amazons.

As regards the two lower great confluents of the Amazons, Rio Madeira on the right bank, and the Rio Negro on the left bank of the mighty river, our knowledge of their avifaunas is mainly due to the researches of Johann Natterer—one of the most successful and energetic zoological collectors that ever lived—of whose discoveries in ornithology a complete account has lately been first published by Mr. A. v. Pelzeln, of Vienna. It is much to be wished that a similar *résumé* of Natterer's discoveries and collections of Mammals, in which order his investigations were of hardly less importance, should be given to the world; and I trust Herr v. Pelzeln will forgive me if I press this subject on his attention.

The fishes of the Amazons and its confluents are many and various, and fully deserve a special monograph. The late Professor Agassiz made his well-known expedition up the Amazons in 1865 with the particular view of studying its fishes, and amassed enormous collections of specimens for the purpose.* Whether (as other naturalists have hinted) Professor Agassiz's estimate of the number of new and undescribed species contained in their collection was exaggerated or not is at present uncertain, as the specimens unfortunately lie unstudied in the Museum of Comparative Zoology at Cambridge, Mass. It is a thousand pities this state of things should continue; and I venture to suggest to the great Professor's numerous friends and admirers in the U. S. that no more appropriate tribute to his memory could be raised than the publication of a monograph of Amazonian fishes based on their collections.

4. The South-Brazilian Sub-region.

This sub-region, which embraces the wood region of S.E. Brazil and adjoining districts, and contains in nearly every branch of zoology a set of species and genera allied to but separable from those of the Amazonian Sub-region, has been much frequented by European naturalists. Its productions are consequently tolerably well known, though there is even here still very much to be done. Burmeister's "Systematische Ubersicht" and "Erläuterungen" may be referred to for information on its Mammals and Birds; likewise Prince Max. of New Wied, "Beiträge," which, although of old standing in point of date, is still of great value. The late Dr. Otto Wucherer, a German physician resident at Bahia, paid much attention to the Reptiles of that district, and has written an account of its Ophidians which will be found in the Zoological Society's "Proceedings."

Hr. Hensel has also recently published in Wiegman's "Archiv" a valuable memoir on Mammals collected in South Brazil, which should be referred to. Prof. Reinhardt has recently completed an excellent account of the avifauna of the Campos of Brazil, based on his own collections and those of Dr. D. W. Lund; and Hr. v. Berlepsch has treated of the birds of Santa Catharina. These are all three most useful contributions to our knowledge of this sub-region. But it is melancholy to think that although a (*soi-disant*) highly civilised European race has resided in the Brazilian Empire so long, and has introduced railways, steamboats, and many other of the appliances of modern Europe, there has never, so far as I know, been produced by them any one single memoir worthy of mention on the teeming variety of zoological life that everywhere surrounds them.

For information on the animals of Paraguay we must still refer to the writings of Don Felix d'Azara, and to Dr. Hartlaub's reduction of his Spanish terms to scientific nomenclature. But modern information about this part of the South-Brazilian Sub-region would be very desirable.

5. The Patagonian Sub-region.

For the zoology of the Argentine Republic, which forms the northern portion of this sub-region, the best work of reference is the second volume of Dr. Burmeister's "La-Plata Reise," which contains a synopsis of the Vertebrates of the Republic. Dr. Burmeister, who is now resident at Buenos Ayres as director

* See "Travels in Brazil," by Prof. and Mrs. Louis Agassiz, Boston, 868.

of the public museum of that city, has lately devoted himself to the study of the extinct Mammal-fauna, and specially to that of the Glyptodont Armadillos, of which he has lately completed a splendidly illustrated monograph. He has likewise been the chief adviser of the Government in their plans for recognising the University of Cordova, which will ultimately no doubt do much for the cause of natural science in the Argentine Republic. Mr. W. H. Hudson, of Buenos Ayres, has long studied the birds and other animals of that country, and deserves honourable mention in a country where so few of the native-born citizens pursue science. His bird-collections have been worked out by Mr. Salvin and myself, and Mr. Hudson has likewise published a series of interesting notices on the habits of the species.

The "Zoology of the Voyage of the *Beagle*" contains much information concerning the animals of La Plata, Patagonia, and Chili. The "Mammals" by Waterhouse, the "Birds" by Gould and G. R. Gray, the "Fishes" by Jenyns, and the "Reptiles" by Bell, illustrated with notes and observations of Mr. Darwin, will ever remain among the leading authorities on the animals of this part of America. On the Rio Negro of Patagonia, where Mr. Darwin made considerable collections, we have a more recent authority in Mr. W. H. Hudson, whose series of birds from this district was examined by myself in 1872.

Dr. R. O. Cunningham has recently followed on the footsteps of Mr. Darwin in Patagonia, and besides his journal of travels has published notes on the animals met with, in the Linnean Society's Transactions. Mr. Salvin and I have given an account of his ornithological collections in several papers in the "Ibis."

As regards the Falkland Islands, two excellent collectors and observers have of late years been stationed there, and have provided the means of our becoming well acquainted with the native birds. Capt. Packe's collections have been examined by Mr. Gould and myself, and Capt. Abbott's by myself in a paper to which he has added many valuable notes.

Lastly, as regards Chili, we have Gay's somewhat pretentious "Fauna Chileña," forming the zoological portion of his "Historia Fisica y Politica de Chile." The volume on the Mammals and Birds was compiled at Paris by Desmurs, and that on the Reptiles and Fishes by Guichenot, but they are not very reliable. The naturalists of the National Museum of Santiago, Philippi and Landbeck, have of late years published in Wiegman's "Archiv" many memoirs on the zoology of the Chilian Republic, of which I have given a list in a paper on the Birds of Chili in the Zoological Society's "Proceedings" for 1867. More recently Messrs. Philippi and Landbeck have published a catalogue of Chilian birds in the "Anales de la Universidad de Chile." But Mr. E. C. Reed, F.Z.S., who is likewise attached to the museum of Santiago, writes me word that he is now engaged in preparing for publication a complete revision of the Vertebrates of the Republic, which will no doubt give us still better information on this subject.

6. Galapagos.

Until recently our knowledge of the very singular fauna of the Galapagos was mainy based upon Mr. Darwin's researches, as published in the "Zoology of the *Beagle*," above referred to. Recently, however, Mr. Salvin and I have described some new species of birds from these islands from Dr. Habel's collection, and Prof. Sundevall has published an account of the birds collected there during the voyage of the Swedish frigate *Eugénie* in 1852. Mr. Salvin has likewise prepared and read before the Zoological Society a complete memoir on the Ornithology of the Galapagoan Archipelago, which will shortly be printed in the Society's "Transactions." Much interest has likewise been recently manifested concerning the gigantic Tortoises of the Galapagos, which, Dr. Günther has reason to believe, belong to several species each restricted to a separate island.* Indeed, I am much pleased to hear that the Lords of the Admiralty, incited by Dr. Günther's requests, have despatched H.M.S. *Tenedos* for the Pacific squadron at Panama to the Galapagos, for the express purpose of capturing and bringing to England specimens of the tortoises of each of the islands. We may, therefore, hope to be shortly more accurately informed upon this most interesting subject.

Va. The Antillean Sub-region.

The study of the fauna of the West India Islands presents problems to us of the greatest interest: first, on account of the relics of an ancient and primitive fauna which are found there, as indicated by the presence of such types as *Solenodon*, *Dulus*, and *Starnœnas*; and, secondly, from the many instances of representative species replacing each other in the different islands. Much, it is true, has been done towards the working out of Antillean Faunas of late years, but much more remains to be done; and it is indeed scandalous that there should be many islands under the British rule, of the zoology of which we are altogether unacquainted. The greater activity of our botanical fellow-labourers has supplied us with a handy volume of the Botany of these islands;* and it is by no means creditable to the zoologists to remain so far behind in this as in other cases already alluded to. Within the compass of the present address it would not be possible for me to enumerate all our authorities upon Antillean zoology, but I will mention some of the principal works of reference under the following heads:—

1. *The Bahamas.*
2. *Cuba.*
3. *Jamaica.*
4. *Haiti.*
5. *Porto Rico.*
6. *The Lesser Antilles.*

1. *The Bahamas.*

The late Dr. Bryant has published in the *Boston Journal of Natural History* several articles upon the birds of the Bahamas, where he passed more than one winter. These islands, however, merit much more minute investigation than has as yet been bestowed upon them.

2. *Cuba.*

Ramon de la Sagra's "Historia Fisica y Politica de Cuba" and Lenbeye's "Aves de la Isla de Cuba," were up to a recent period our chief authorities upon Cuban zoology. But Cuba has long had the advantage of the residence within it of an excellent naturalist—Don Juan Gundlach—who has laboured hard towards the more complete investigation of its remarkable zoology. We are indebted to him for collecting the specimens upon which Dr. Cabanis based his revision of Cuban ornithology, published in Wiegmann's "Archiv," as also for a tabular list of Cuban birds, published in the same journal for 1861, and for several supplements thereto, for the more recent reviews of the mammals and birds of the island, published in the first volume of Poey's "Repertorio," and for many other contributions to the natural history of Cuba. This last-named work, as also the previous "Memorias sobre la historia natural de la Isla de Cuba" of the same author, contains a number of valuable contributions to our knowledge of the rich fauna of this island, and should be carefully studied by those who are anxious to become acquainted with the peculiarities of the Cuban fauna.

3. *Jamaica.*

Mr. Gosse's meritorious work on the Birds of Jamaica, and his "Naturalists' Rambles," are still the main source of our information on the fine island of Jamaica, and very little has been done since his time. A young English naturalist, Mr. W. Osburn, made some good collections in Jamaica in 1860, of which the Mammals were worked out by Mr. Tomes and the Birds by myself. Mr. W. T. March has also more recently sent good series of the birds of the island to America, and Prof. Baird has edited his excellent notes on them. I must not lose the opportunity of calling special attention to the Seals of the Antilles (*Monachus tropicalis* and *Cystophora antillarum* of Gray), of which, so far as I know, the only specimens existing are the imperfect remains in the British Museum brought home by Mr. Gosse. More knowledge about these animals (if there be really two of them) would be very desirable.

4. *Haiti.*

Of this large island very little more is known as regards its zoology than was the case in the days of Buffon and Vieillot. Of its birds alone we have a recent account in a paper which I wrote upon M. Sallé's collection, and in a more recent memoir drawn up by the late Dr. Bryant, and published in the "Proceedings" of the Boston Society of Natural History for 1863.

5. *Porto Rico.*

Nearly the same story holds good of this Spanish island, of which our only recent news relates to the birds, and consists of two papers—one by Mr. E. C. Taylor in the "Ibis," and the other by the late Dr. Bryant, in the journal above mentioned.

6. *The Lesser Antilles.*

As I remarked above, every one of the numerous islands, from Porto Rico down to Trinidad, requires thorough examination.

* See Nature, vol. xii. p 238 (1875).

* Griesbach's "Flora of the West Indies."

It is remarkable that no one has yet been found to attack this interesting subject, which might easily be performed by excursions during the winter months of a few succeeding years.

As regards the ornithology of these islands, the subjoined summary of what we really know and do not know is mainly taken from a paper on the Birds of St. Lucia, which I read before the Zoological Society of London in 1871.

1. *The Virgin Islands.*—Of these islands we may, I think, assume that we have a fair acquaintance with the birds of St. Thomas, the most frequently visited of the group, and the halting place of the West Indian mail steamers. Mr. Riise, who was long resident here, collected and forwarded to Europe many specimens, some of which were described by myself,* and others are spoken of by Prof. Newton in a letter published in the "Ibis" for 1860, p. 307. Mr. Riise's series of skins is now, I believe, at Copenhagen. Frequent allusions to the birds of St. Thomas are also made by Messrs. Newton in their memoir of the birds of St. Croix, mentioned below. In the "Proceedings" of the Academy of Natural Sciences of Philadelphia for 1860, Mr. Cassin has given an account of a collection of birds made in St. Thomas by Mr. Robert Swift, and presented to the Academy; twenty-seven species are enumerated.

Quite at the extreme east of the Virgin Islands, and lying between them and the St. Bartholomew group, is the little islet of Sombrero, "a naked rock about seven-eighths of a mile long, twenty to forty feet above the level of the sea, and from a few rods to about one-third of a mile in width." Although "there is no vegetation whatever in the island over two feet high," and it would seem a most unlikely place for birds, Mr. A. A. Julien, a correspondent of Mr. Lawrence of New York, succeeded in collecting on it specimens of no less than thirty-five species, the names of which, together with Mr. Julien's notes thereupon, are recorded by Mr. Lawrence in the eighth volume of the "Annals of the Lyceum of Natural History of New York."

The remaining islands of the Virgin group are, I believe, most strictly entitled to their name so far as ornithology is concerned, for no collector on record has ever polluted their virgin soil. Prof. Newton ("Ibis," 1860, p. 307) just alludes to some birds from St. John in the possession of Mr. Riise.

2. *St. Croix.*—On the birds of this island we have an excellent article by Messrs. A. and E. Newton, published in the first volume of the "Ibis."† This memoir, being founded on the collections and personal observations of the distinguished authors themselves, and having been worked up after a careful examination of their specimens in England, and with minute attention to preceding authorities, forms by far the most complete account we possess of the ornithology of any one of the Lesser Antilles. It, however, of course requires to be supplemented by additional observations, many points having been necessarily left undetermined; and it is much to be regretted that no one seems to have since paid the slightest attention to the subject.

3. *Anguilla, St. Martin, and St. Bartholomew.*—Of this group of islands St. Bartholomew alone has, as far as I know, been explored ornithologically, and that within a very recent period. In the Royal Swedish Academy's "Proceedings" for 1869 will be found an excellent article by the veteran ornithologist Prof. Sundevall, on the birds of this island, founded on a collection made by Dr. A. Von Göes. The species enumerated are forty-seven in number.

4. *Barbuda.*—Of this British island I believe I am correct in saying that nothing whatever is known of its ornithology, or of any other branch of its natural history.

5. *St. Christopher and Nevis*, to which may be added the adjacent smaller islands *St. Eustathius and Saba.*—Of these islands also our ornithological knowledge is of the most fragmentary description. Mr. T. J. Cottle was, I believe, formerly resident in Nevis, and sent a few birds thence to the British Museum in 1839. Amongst these were the specimens of the Humming-birds of that island, which are mentioned by Mr. Gould in his well-known work. Of the remainder of this group of islands we know absolutely nothing.

6. *Antigua.*—Of this fine British island, I regret to say, nothing whatever is known as regards its ornithology. Amongst the many thousands of American birds that have come under my notice during the past twenty years, I have never seen a single skin from Antigua.

* Ann. N.H. ser. 3, vol. iv. p. 225; and P.Z.S. 1860, p. 314.
† "Ibis," 1859, pp. 59, 138, 252, and 365.

7. *Montserrat.*—Exactly the same as the foregoing is the case with the British island of Montserrat.

8. *Guadeloupe, Deseadea, and Marie-galante.*—An excellent French naturalist, Dr. l'Herminier, was for many years resident as physician in the island of Guadeloupe. Unfortunately, Dr. l'Herminier never carried into execution the plan which I believe he contemplated, of publishing an account of the birds of that island. He sent, however, a certain number of specimens to Paris and to the late Baron de la Fresnave, to whom we are indebted for the only article ever published on the birds of Guadeloupe or of the adjacent islands.

9. *Dominica.*—Dominica is one of the few of the Caribbean islands that has had the advantage of a visit from an active English ornithologist. Although Mr. C. E. Taylor only passed a fortnight in this island in 1863, and had many other matters to attend to, he nevertheless contrived to preserve specimens of many birds of very great interest, of which he has given us an account in one of his articles on the birds of the West Indies, published in the "Ibis" for 1864. It cannot be supposed, however, that the birds of this wild and beautiful island can have been exhausted in so short a space of time, even by the energetic efforts of our well-known fellow-labourer.

10. *Martinique.*—This island is one of the few belonging to the Lesser Antilles in which birdskins are occasionally collected by the residents, and find their way into the hands of the Parisian dealers. There are also a certain number of specimens from Martinique in the Musée d'Histoire Naturelle in the Jardin des Plantes, which I have had an opportunity of examining; but, beyond the vague notices given by Vieillot in his "Oiseaux de l'Amérique du Nord," I am not aware of any publications relating specially to the ornithology of this island. Mr. E. C. Taylor passed a fortnight in Martinique in 1863, and has recorded his notes upon the species of birds which he met with in the excellent article which I have mentioned above; but these were only few in number. The International Exhibition in 1862 contained, in the department devoted to the products of the French colonies, a small series of the birds of Martinique, exhibited by M. Bélanger, director of the Botanical Garden of St. Pierre in that island.* This is all the published information I have been able to find concerning the birds of Martinique.†

11. *St. Lucia.*—Of this island I gave an account of what is known of the birds in a paper published in the Zoological Society's "Proceedings" for 1871, based upon a collection kindly forwarded to me by the Rev. J. E. Semper. Mr. Semper subsequently communicated some interesting notes on the habits of the species.

12. *St. Vincent.*—St. Vincent was formerly the residence of an energetic and most observant naturalist, the Rev. Lansdowne Guilding, F.L.S., well known to the first founders of the Zoological Society of London, who, however, unfortunately died at an early age in this island without having carried out his plans for a fauna of the West Indies.

Mr. Guilding paid most attention to the invertebrate animals; but his collections contained a certain number of birds, amongst which was a new Parrot, described after his decease by Mr. Vigors as *Psittacus Guildingii*, and probably a native of St. Vincent.

13. *Grenada and the Grenadines.*—Of the special ornithology of this group nothing is known.

14. *Barbados.*—The sole authority upon the birds of Barbados is Sir R. Schomburgk's well-known work on that island. This contains (p. 681) a list of the birds met with, accompanied by some few remarks. It does not, however, appear that birds attracted much of the author's attention; and more copious notes would be highly desirable.

15. *Tobago*, I believe, belongs zoologically to Trinidad. Sir W. Jardine has given us an account of its ornithology from Mr. Kirk's collections.

VI.—THE AUSTRALIAN REGION.

Of the Australian Region I will speak in the following subdivisions:—

1. *Australia and Tasmania.*
2. *Papua and the Papuan Islands.*
3. *The Solomon Islands.*

* See an article on Ornithology in the International Exhibition, "Ibis," 1862, p. 288.
† On animals formerly living in Martinique but now extinct, see Guyon, "Comp. Rend." lxiii. p. 589 (1866).

That we know more of the fauna of Australia than of other English colonies in different parts of the world is certain, but no thanks are due from us for this knowledge either to the Imperial or to any of the Colonial Governments. The unassisted enterprise of a private individual has produced the two splendid works upon the Mammals and Birds of Australia, which we all turn to with pleasure whenever reference is required to a member of these two classes of Australian animals. Mr. Gould's "Mammals of Australia" was completed in 1863. Since that period the little additional information received respecting the terrestrial Mammals of Australia has been chiefly furnished by Mr. Krefft, of the Australian Museum, Sydney, in various papers and memoirs. Mr. Krefft has also written the letterpress to some large illustrations of the "Mammals of Australia," by Miss H. Scott and Mrs. H. Forde, in which a short account of all the described species is given. On the Marine Mammals, however, which were scarcely touched upon by Mr. Gould, we have a treatise by Mr. A. W. Scott published at Sydney in 1873, which contains a good deal of useful information concerning the seals and whales of the Southern Hemisphere.

The magnificent series of seven volumes of Mr. Gould's "Birds of Australia" was finished in 1848. In 1869 a supplementary volume was issued, containing similar full-sized illustrations of about 80 species. In 1863 Mr. Gould reprinted in a quarto form, with additions and corrections, the letterpress of his great work, and published it under the title of a "Handbook to the Birds of Australia." This makes a convenient work for general reference. Of two colonial attempts to rival Mr. Gould's series I cannot speak with much praise. Neither Mr. Diggle's "Ornithology of Australia" nor Mr. Halley's proposed "Monograph of the Australian Parrots" are far advanced towards conclusion—indeed, of the last-mentioned work I have seen but one number.

Several large collections of birds have been made in the peninsula of Cape York and adjoining districts of Northern Queensland of late years, and it is a misfortune for science that we have had no complete account of them. One of the largest of these, however, made by Mr. J. T. Cockerell, has luckily fallen into the hands of Messrs. Salvin and Godman, and will, I trust, be turned to better uses than the filling of glass cases and the ornamentation of ladies' hats.

It seems to me that there is still much to be done even in birds in Northern Australia, and I cannot help thinking that Port Darwin, the northern extremity of the trans-continental telegraph, would be an excellent station for a collecting naturalist, and one where many novelties, both zoological and botanical, would certainly be met with.

On the Snakes of Australia we have an excellent work published in 1869 by Mr. Gerard Krefft—one of the few really working Australian naturalists, who, it appears, is not appreciated in Sydney as he fully deserves to be. Mr. Krefft, during his long residence in Sydney, has become well acquainted with the Ophidians of the colony and has devoted special attention to them, so that he has the advantage of practical as well as scientific acquaintance with his subject. The late Dr. Gray has written many papers on the Tortoises and Lizards of Australia. Of the latter we have to thank Dr. Günther for a complete monographic list just published in one of the newly issued numbers of the "Voyage of the *Erebus* and *Terror*." Most of the plates of this work were also issued in 1867 by Dr. Gray in his "Fasciculus of the Lizards of Australia and New Zealand."

For information on the fishes of Australia reference must be made to the ichthyological portion of the "Zoology of the *Erebus* and *Terror*," by Sir John Richardson, and to the same author's numerous papers on Australian fishes in the "Annals of Nat. Hist." and "Transanctions" and "Proceedings" of the Zoological Society of London. The Count F. de Castelnau, who seems to be almost the only working ichthyologist in Australia, has recently published in the "Proceedings of the Zoological and Acclimatisation Society of Victoria," several papers on the fishes of the Melbourne fish-market and of other parts of Australia, which include a complete synopsis of the known Australian species.

2. Papua and its Islands.

I believe that my paper upon the Mammals and Birds of New Guinea, published by the Linnean Society in 1858, was the first attempt to put together the scattered fragments of our knowledge of this subject. In 1859 a British Museum Catalogue by Dr. J. E. and Mr. G. R. Gray, gave a *résumé* of the then known members of the same two classes belonging to New Guinea and the Aru Islands, and included notices of all Mr. Wallace's discoveries. In 1862 Mr. Wallace gave descriptions of the new species discovered subsequently to his return by his assistant, Mr. Allen. In 1863 Dr. Finsch published at Bremen an excellent little essay called "Neu-Guinea und seine Bewohner," in which is given a complete account of our then state of knowledge of the subject. But within these last ten years still more serious efforts have been made by naturalists of several nations to penetrate this *terra incognita*. Two emissaries of the Leyden Museum—Bernstein and V. Rosenberg—have sent home full series of zoological spoils to that establishment, and have discovered a host of novelties. Of these the birds have been described by Prof. Schlegel in his "Observations Zoologiques." An intrepid Italian traveller, Signor L. M. d'Albertis, made a still further advance, when in September 1872 he accomplished the first ascent of the Arfak Mountains,* and discovered the splendid Bird of Paradise and other new species which I described in 1873. Quickly following on his footsteps, Dr. A. B. Meyer penetrated still further into the unknown interior, and reaped the abundant harvest of which he has given us an account in six papers lately published at Vienna. Dr. Meyer has now become director of the Museum of Dresden, and is no doubt occupied in the further elaboration of his rich materials. In the meanwhile some accomplished Italian naturalists are engaged on the collections of D'Albertis and his quondam companion Beccari. Count Salvadori, who is at work on the birds, will take the opportunity of preparing a complete account of the ornithology of Papua and its islands, similar to that in Borneo, of which I have already spoken. The Marquis Giacomo Doria has already published one excellent paper on "The Reptiles of Amboina and the Ké Islands," collected by his compatriot Beccari, and is preparing other memoirs on the Mammals and Reptiles of New Guinea and the Aru Islands obtained by D'Albertis.

Dr. Meyer has lately given an account of his herpetological discoveries in New Guinea, which comprehend several new and most interesting forms, in a memoir read before the Academy of Berlin; and Dr. Bleeker some years ago gave a list of the reptiles obtained by V. Rosenberg in that island, and enumerated the Papuan reptiles then known to him.

All these expeditions, however, have been directed towards the western peninsula of New Guinea, which alone is yet in any way explored by naturalists. Of the greater south-eastern portion of the island (unless we are inclined to give credit to Capt. Lawson's wonderful exploits) we have as yet very little information. A cassowary † and a kangaroo, ‡ brought away by the *Basilisk* from the southern coast, both proved to be new to science, as did likewise a Paradise Bird obtained in the same district by Mr. D'Albertis. § This is sufficient to give us an idea of what we may expect to find when the interior of this part of New Guinea is explored. And I may take this opportunity of mentioning that a most active and energetic traveller is perhaps at this very moment at work there. M. L. M. d'Albertis, of whose previous labours I have just spoken, returned to the East last autumn. Letters received from him by his Italian friends in June last state that he had at the time of writing already succeeded in reaching Yule Island near Mously Bay, on the south-east coast of New Guinea, and proposes to establish his head-quarters there for expeditions into the interior.

3. New Ireland, New Britain, and the Solomon Islands.

I devote a few words specially to these islands because they are easy of access from Sydney, and because their productions are of particular interest, belonging, as they do, to the Papuan and not to the Polynesian fauna. I have put together what is known of the birds of the Solomon's group in a paper read before the Zoological Society in 1869. Seeing the interesting results obtained from the examination of one small jar of birds collected by an unscientific person, there can be little doubt of the value of what would be discovered on the more complete investigation of the group. As regards New Ireland and New Britain, we have but scattered notices to refer to. The last-named island is, we know, the home of a peculiar cassowary (*Casuarius bennetti*).

* See Nature, vol. viii. p. 501 (29).
† *Casuarius picticollis*, Scl., P.Z.S. 1875, p. 85.
‡ *Dorcopsis luctuosa* (D'Albertis), *v.* Garrod, P.Z.S. 1875, p. 48.
§ *Paradisea raggiana*, Sclater, P.Z.S. 1873, p. 559.

A list of the fishes of the Solomon Islands is given by Dr. Günther in Mr. Brenchley's "Cruise of the *Curaçoa*," which I shall allude to presently.

VII.—PACIFIC REGION.

Of this region, where Mammals (except a few bats) are altogether absent, and birds are the predominant form of vertebrate life, I will say a few final words under three heads:—
1. *New Zealand.* 2. *Polynesia.* 3. *The Sandwich Islands.*

1. *New Zealand.*

In New Zealand, of all our Colonies, most attention has lately been devoted to natural history, and several excellent naturalists are labouring hard and well—I need only mention the names of Dr. Hector, Dr. Haast, Capt. F. W. Hutton, and Dr. Buller. The commendable plan of affiliating the various local societies together to one institute has resulted in the production of an excellent scientific journal, already in its sixth volume, which contains a mass of most interesting papers on the fauna and flora of the colony. To refer to these memoirs in detail is quite unnecessary; but it is obvious, on turning over the pages of the volumes of the Transactions of the New Zealand Institute, how great are the exertions now being made to perfect our knowledge of the natural products, both recent and extinct, of our antipodean colony.

Dr. W. L. Buller's beautiful volume on the ornithology of New Zealand, finished in 1873, is likewise a most creditable production both to the author and to those who have supported and promoted his undertaking. Few, indeed, are the colonies that can boast of a similar piece of work!

In 1843 the late Sir John Richardson presented to this association a special report on the Ichthyology of New Zealand; but much advance has, of course, been made since that period.

The lizards of New Zealand have been recently enumerated along with those of Australia in Dr. Günther's memoir above referred to.

2. POLYNESIA.

Great additions have recently been made to our knowledge of the natural productions of the Polynesian Islands by the travellers and naturalists employed by the brothers Godeffroy of Hamburgh. These gentlemen not only have extensive collections *made*, but also trouble themselves to get them properly *worked out*. The excellent volume on the ornithology of the Fiji, Samoa, and Tonga Islands, published in 1867 by Drs. Finsch and Hartlaub, is based entirely upon materials thus obtained, as are likewise the many capital memoirs which fill the parts of the illustrated quarto *Journal der Museum Godeffroy*—a journal replete with information upon the geography, ethnography, and natural history of Polynesia. Amongst these memoirs I must call special attention to Dr. Günther's "Fische der Sudsee," founded upon Mr. Andrew Garrett's splendid collection of fishes and of drawings of them, coloured from life, of which three parts are already issued. We have now almost for the first time the after opportunity of becoming acquainted with the exceeding beauty of the tropical fishes in life.

The late Mr. Julius Brenchley's account of his cruise in H.M.S. *Curaçoa* among the South Sea Islands, and published in 1873, contains an appendix of "Natural History Notices," illustrated by figures of remarkable specimens obtained on the occasion. Of these the part relating to the birds is by the late Mr. G. R. Gray, and those concerning the reptiles and fishes by Dr. Günther.

3. THE SANDWICH ISLANDS.

The Sandwich Islands stand apart zoologically as geographically from the rest of Polynesia, and merit more special attention than has yet been bestowed upon them. Of their birds, which form the most prominent part of their vertebrate fauna, Mr. Dole has given a synopsis in the "Proceedings of the Boston Society of Natural History." In noticing this paper in the "Ibis" for 1871, I have introduced some supplementary remarks upon the general facies of the Avifauna.

CONCLUSION.

In concluding this address, which has extended, I regret to say, to a much greater length than I anticipated when I selected the subject of it, I wish to endeavour to impress upon naturalists the paramount importance of locality.

In the study of distribution more probably than in any other direction, if perhaps we except embryology, will be ultimately found the key to the now much vexed question of the origin of species. The past generation of naturalists could not understand the value of locality. A museum was regarded as a collection of curiosities, and so long as the objects were there it little mattered in their eyes whence they came. The consequence is that all our older collections, and even, I regret to say, our national collection itself, are filled with specimens utterly without a history attached to them, unless it be that they were purchased of a certain dealer in a certain year. Even in the present generation it is only the more advanced and enlightened thinkers that really understand the importance of locality. It is with the hope of impressing the value of locality and distribution more firmly upon you that I have devoted my address not to the general progress of biology, but to the present state of, and recent additions made to, our knowledge of the geographical distribution of the Vertebrata.

Dr. Carpenter, in moving a vote of thanks to the President for his address, said its value would only be fully appreciated by the working naturalist studying and consulting it in the prosecution of his researches. Such a stock-taking was of the highest value in guiding to the right study of what was known, and in laying bare deficiencies. Within a few years the subject of geographical distribution had arisen to great dimensions, both in relation to the origin of species and to the changes in the earth's surface since the present distribution of life had been approximately attained. Any single fact with regard to distribution had its value, but accuracy was vital; as he proceeded to show. The different species of fresh-water fish in Swiss lakes were now regarded as modifications due to differences of food, temperature, bottom, &c., having their slow effect in developing races since the time when the various waters were in communication, and if changes were admitted to such an extent in our existing fauna as the result of plain causes, it was legitimate to argue that much greater changes might have taken place in the ages of geological time.—Professor Allman spoke of the increased importance of all the results of exploration since the promulgation of the doctrine of descent, which was now almost universally accepted in one form or another.—Professor Rolleston said that Dr. Sclater's paper on Geographical Distribution had come out in 1858, before Messrs. Darwin's and Wallace's papers had been published; and yet what he had laid down in 1858, he had in no important points had to modify. He did not know of any biological doctrines that had undergone so little change since that period.—Dr. Sclater announced that he proposed to add an appendix to his address, containing the full titles of all the works he had referred to.

Department of Zoology and Botany.

Professor Newton read a paper "On certain neglected subjects of ornithological investigation." He said that it seemed to him that ornithologists had been getting into certain well-worn ruts, to the abandonment of other tracks which were well worth travelling upon. He had recently had occasion to take stock of our present ornithological knowledge, and on the whole the result was gratifying. Some departments had received an enormous impetus from the doctrines of evolution, and that impetus would continue and would probably be increased. Some years ago there was a very general disposition to cry down species-mongers, as they were called in opprobrium; but it was a very short-sighted view; and in his opinion they were having their revenge, for their work had now a value far above that which it had in the Pre-Darwinian days. The result of labours on geographical distribution was good, and was gradually helping to build the edifice of evolution; not that the edifice was erected yet; its walls were still far from complete. Yet he thought its completion was about as sure as anything well could be. The subject of what he might call developmental osteology, in which the illustrious name of Parker stood practically alone, was one in which it might truly be said that the harvest was plenteous and the reapers few. There was room for a score of Parkers; yet it was no more likely that they would get them than that they would get a score of Shakespeares. Fossil ornithology had not as yet produced very great results, but descriptive anatomy was in a fairly good condition, although he was afraid that a great many skilled observers of the outsides of birds knew very little about it. As to pterylography, he feared it was not very much thought of, and that a vast majority of ornithologists did not know the meaning of the word. He recommended all to read the translation of Nitzsch's great work on the subject in the Ray Society's publications. He noticed the greatest falling-off in observational ornithology. They had outdoor ornithologists by

dozens, all going on in exactly the same way as their predecessors, each trying to find out the same facts for himself; so that they were almost at a standstill, especially on the subject of the migration of birds. Observers were content not to do anything more than had been done by Gilbert White, forgetting that he had had to prove or disprove the fact of migration, about which there was no question now. We wanted to know something of the causes of migration and of the faculties by which it was performed. Hundreds of records of dates of arrival of birds would bring us no nearer to these discoveries. He thought a digestion and collation of the immense mass of facts on these subjects already existing in Great Britain was wanted, such as had already been prepared for Germany; but one thing that would *not* come of it, he was persuaded, was an answer to the questions he had indicated. There was great want of information as to the routes taken in migration, and also as to the facts of partial migration. He thought they must look in this direction for the solution of the larger question. It would be very enlightening if they could know something of the reasons which induced the migration of the majority of individuals of a species, leaving some behind. It had been suggested by Dr. von Mittendorff that probably birds in their migrations were guided by a knowledge of the situation of the magnetic pole; and however much they might disbelieve that, they had really no facts which could controvert that or any other wild theory on the subject. As to birds learning the way by experience, and by the teaching of those who had traversed the route before, that would not explain migrations which took place by night, or over a thousand miles of sea. The laws of plumage and of moulting were little known, and might with advantage be studied by those who had constant access to zoological gardens, such as those at Clifton. The duration of the periods of incubation of birds was almost unknown, as well as the reasons for the variations. Nothing was known for certain as to the effect of variations of atmospheric temperature or other conditions in shortening or lengthening the period. Out of more than 200 species of British birds, the duration of incubation was known in only about twenty; and of foreign birds even less was known. He could mention other branches in which knowledge was deficient, but perhaps what he had said would be sufficient to induce some of those who had not adopted any special branch of study to prosecute some of the inquiries he had recommended. The good workers at present labouring were fully occupied with important subjects. He could not expect that they would be able to divert their attention from their chosen departments.—In the discussion which followed, Canon Tristram remarked on the ease with which many who go abroad for the winter or summer might make valuable records of the time of arrival or the latest time of seeing migratory birds. Mr. Elwes urged on country clergymen the valuable service they might easily render by taking ornithology as a recreation; much was lacking in regard to osteology and nidification; skins were too much attended to. Mr. Bettany urged the study of Mr. Parker's papers on all ornithologists who could make themselves capable of comprehending them, in order to prepare the way for a better understanding of the genetic affinities of birds in the future; and also mentioned the service that might be done to such men as Mr. Parker by any naturalist who would collect a series of specimens from the earliest to the adult stage of any single species, and preserve them for study by such an authority.

On the reading of the report on the Zoological Station at Naples, which we have abstracted elsewhere, Mr. Spence Bate said it was greatly to be desired that such schools of study should be established in Great Britain. He did not think they should have to go to Naples for one. They should be attached to the various aquariums now being established.

Dr. C. T. Hudson read an able paper, the result of many years' study, on the classification and affinities of the Rotifera. It was illustrated by a large number of beautiful magnified drawings of their anatomy, bearing testimony to the industry and ability of the author. He commenced by discussing Ehrenberg's classification, and showed that its fundamental principles were erroneous, for it was based on a supposed structure of the trochal disc which did not really exist, on a forced interpretation of the term lorica, and on the presence, absence, and number of certain red spots, which Ehrenberg took for granted as eyes, but which were not always so. Moreover, those that really were eyes were often present in the young animal, but invisible in the adult. Ehrenberg's symmetrical system brought together widely dissimilar forms, and separated those that were intimately connected. Not a single Rotifer, as far as the author could find, properly came under Ehrenberg's Monotrocha. A new Melicerta had been found, that did not make a tube; and his Sorotrocha included every form of head. There was no such thing really as a Holotrochous form. The systems of Leydig and Dujardin were then examined and shown to be inferior to Ehrenberg's, though it was pointed out that each naturalist had contributed a happy idea, the former having brought into prominence the great value of the foot as a characteristic for classification, the latter having the thought of classifying the Rotifers by their mode of locomotion. Dr. Hudson then proceeded to offer a natural classification, using the best results of preceding observers, based on the habits, teeth, water, vascular and nervous systems. There were four great groups, subdivided into families. (1) *Rhizota*, the permanently attached forms, all having teeth of the same pattern, including the Floscularina and Melicertidæ; (2) *Bdelloida*, those that swim and creep like a leech, including the Philodinidæ, the lowest and most worm-like forms; (3) *Ploïma*, or free-swimmers, including Brachionidæ, Pterodinidæ (a new genus and species of his own), Euchlanidæ, and Notommatina; (4) *Scirtopoda*, or jumpers, including Pedalionidæ, and Synchætidæ. As to the affinities of the Rotifers, while giving up Philodinidæ to the Vermes, he advanced numerous reasons for believing that the other Rotifers were allied to Entomostracans, and ought to be classed with them. He claimed to have destroyed some of the arguments of Professor Huxley on this point, by finding male forms which had been previously unknown, and among them the male of *Lacinularia socialis*, the very species taken as the text of Professor Huxley's remarks on the whole class. The resemblance of Pedalion to some Entomostracous larvæ was insisted on, as also its connection by other aberrant rotifers with those of typical form.—Mr. Spence Bate spoke highly of the labour and skill which Dr. Hudson had spent upon this class, but he must say that in regard to the affinities of Rotifera the evidence brought forward had been such as to convince him most conclusively that they were *not* related to the Crustacea.

On the Primary Divisions of the Chitonidæ, by P. P. Carpenter, B.A., Ph.D., Montreal.—He divided them into articulated or perfect, and non-articulated or imperfect; each of these were naturally divided into regular and irregular. The Palæozoic Chitons were all imperfect, and culminated in the Carboniferous period; very few are now living. The Neozoic epochs gradually developed perfect Chitons which culminate at the present time. The writer sought information as to unusual forms, recent or fossil, to be posted to 508, Guy Street, Montreal.

Department of Anatomy and Physiology.

ADDRESS BY PROFESSOR CLELAND, M.D., F.R.S., VICE-PRESIDENT.

I shall not venture to occupy the time of the Section with any *résumé* of the work done in anatomy and physiology during the past year, as such information is readily accessible in the pages of journals and year-books. I shall content myself with making some comments on the condition of anatomy at the present time in a few important particulars.

I had intended to speak also of some subjects connected with physiology; but I find that I cannot do so without lengthening my remarks to a greater extent than might be desirable. I shall be content, therefore, so far as that science is concerned, to mention that, although experimental physiology is probably less cultivated in this country than in any other in which biology is studied, it has been practically decided by Parliament that it is quite time to put some check on investigation in that direction; for, as everyone knows, a Royal Commission has been appointed to inquire into vivisection. In the scientific world all are agreed, whatever opinions may prevail in other sections of the community, that the man who would wantonly inflict pain on a brute beast is himself a brute, and deserving to be roughly handled; and because there is no difference of opinion on that subject, and because no experimental science can well prosper if one man is to judge for another what experiments are justifiable to institute or to repeat, or are likely to give important results, I do deplore the clamour which well-meaning persons have raised, and regret that it has been so far yielded to.

In anatomy the most important progress in recent years has been made in those departments which abut most closely on physiology, namely, the microscopy of the tissues and development. The whole conception of the nutrition of the body has become altered in comparatively recent years by the additions to our knowledge of the nucleated corpuscles, which are the living

elements of which it is composed; and principally by the recognition of the secondary nature of cell-walls, the close connection or even continuity of the nerves with other textures, and the identity of the white corpuscles of the blood with amœboid or undifferentiated corpuscles outside the vessels. The origin of every living corpuscle from corpuscles pre-existing is no longer difficult to imagine, but may, I incline to think, be almost looked on as proved. The history of each may be traced back through conjugated germs to the corpuscles of preceding generations in uninterrupted succession, and the pedigree of the structural elements is seen to differ in no way from that of individual plants or animals. It is true, indeed, that no absolute proof exists that new living corpuscles originating by mere deposit are not added to the others; but the evidence against such a thing taking place is exactly of the same description as that which exists against spontaneous generation of independent organisms, namely, that things previously unexplained by the theory of parentage are explained now, while, on the other hand, there is no sufficient evidence of the origin of life by any other mode.

Leaving histology (he said), I shall devote the rest of my remarks to the morphology of the *Vertebrata*. Here I am less disposed to indulge a gratulatory vein. No doubt within the last dozen years we have had work to be grateful for. Worthy of a prominent place in this, as in other departments of anatomy, is the encyclopædic work, the "Leçons," of Milne-Edwards, invaluable as a treasury of reference to all future observers; while the memoirs of Gegenbaur on the carpus, on the shoulder-girdle, and on the skulls of Selachian fishes, and Kitchen Parker's memoirs devoted to mature forms, may be taken as examples that morphological problems suggested by adult comparative anatomy have not lost their attraction to men capable of elaborate original research. And I the more willingly select the names of these two writers, because on one subject on which they have written, the shoulder-girdle, I am compelled to differ from their conclusions and to adhere rather to those of Owen, so far as the determination of the different elements in fishes is concerned; and by stating this (although the subject cannot be now discussed) I am enabled to illustrate that the appreciation of the value of elaborate and painstaking work is a matter totally distinct from agreement with the conclusions which may be arrived at in the investigation of complicated problems, although wisdom and penetration as to these must ever command admiration.

But when one looks back on the times of Meckel and Cuvier, and on the activity inspired by the speculations of the much-abused Oken, the writings of Geoffroy St.-Hilaire, the less abstrusely speculative part of the works of G. C. Carus, and the careful monographs of many minor writers; when one reflects on the splendid grasp of Johannes Müller, and thinks of the healthy enthusiasm created in this country for a number of years by Owen's "Archetype and Homologies of the Vertebrate Skeleton," and then contemplates the state of vertebrate morphology at the present moment, it seems to me that its homological problems and questions of theoretical interest do not attract so much attention as they did, or as they deserve.

The Origin of Species by Natural Selection.

There can be no doubt that a great and curious influence has been exercised on morphology by the rise of the doctrine of the origin of species by natural selection. Attention has been thereby directed strongly for a number of years to varieties, and probably it is to this doctrine that we owe the larger number of observations made on variations of muscles, nerves, and other structures. Particularly elaborate have been the records of muscular variations, very praiseworthy, interesting to the recorders, very dry to most other people, and hitherto, so far as I know, barren enough of any general conclusions. So much the more credit is due to those who have worked steadily in faith that beauty will emerge to gild these results some day.

But the doctrine of natural selection has had a further effect in anatomical study, aiding the reaction against the search for internal laws or plans regulating the evolution of structures, and directing attention to the modifying influences of external agencies. This effect has happened naturally enough, but it has been far from just; rather is it a pendulum-like swing to another extreme from what had previously been indulged in. The doctrine of natural selection starts with the recognition of an internal formative force which is hereditary; and in the development of the doctrine, the limits of hereditary resemblance have een greatly studied; and further, it will be observed that one of the fundamentals of the doctrine is, that the formative force alters its character gradually and permanently when traced from generation to generation in great tracts of time. Now I am not going to enter on a threadbare discussion of the origin of species in this company; suffice it to say that, while the existence and extensive operation of such a thing as natural selection seems to have been convincingly proved, it is a very different thing to allege that it has been the sole, or even the principal agent in producing the evolutions of living forms on the face of the earth. So far as anatomy is concerned, it is a secondary matter whether the link between the members of the evolving hosts of life have been genetic or not. But I wish to point out that, even pushing the Darwinian theory to the utmost possible extreme, the action of external agents infers the existence of something acted on; and the less directly they act, the more importance must be given to the hereditary or internal element. We are therefore presented with a formative force, which exhibited itself in very simple trains of phenomena in the first beginnings of life, and now is manifested in governing the complex growth of the highest forms. We are set face to face with that formative force, and are obliged to admit its inherent capability of changing its action; and that being the case, is it more of an assumption to declare that the changes are all accidental and made permanent by accident of external circumstances, or to consider that it has been the law proper to this force to have been adequate to raise forms, however liable to modification by external circumstances—to raise them, I say, from the simple to the complex, acting through generations on the face of the earth, precisely as it acts in the evolution of a single egg into an adult individual? This is that formative force which has been elaborately shown by Mr. Darwin, in launching his theory of "pangenesis," not only to be conveyed through whole organisms and their seed, but to pervade at all times the minutest particles of each; and I merely direct attention to the fact that its extension over the whole history of life on the globe must be granted, and ask if, in the range of forms which furnish at the present day an imperfect key to the ages which are past, there is not exhibited a development comparable, in its progression to definite goals, with what is shown in the life of a single plant or animal. For my own part, I am fully convinced of a unity of plan running through animal forms, and reaching, so far as the main line is concerned, its completion in the human body. I confess that I think that there is evidence that animal life has reached its pre-ordained climax in humanity; and I cannot think it likely that, as myriads of years roll on, descendants differing *in toto* from man will be developed. To argue the subject would be to enter on the largest subjects of morphological anatomy, and on speculations on which agreement could not be expected. Even, however, in the nature of the variations in the human race there seems to be some evidence that the progress of evolution is to be traced from man, not to other animal forms yet to appear, but, through his physical nature, into the land of the unseen. Those variations, keeping out of view differences of bulk and stature, which appear to have some relation to geographical position, are principally to be found in the head, the part of the body most closely connected with the development and expression of the mental character; and I may mention that when, some years ago, my attention was directed to the variations of the skull, the only part whose variations in different races I have had opportunity of studying with any degree of minuteness, I became satisfied that in uncivilised races there might be distinguished skulls which had undergone hereditary degeneration, others which had reached the most advanced development possible for them, and a third set, notably the Kaffirs, with large capabilities for improvement in the future. Indeed it is beyond doubt that there is a limit for each type of humanity beyond which it cannot pass in the improvement of the physical organisation necessary for mental action.

There are also some curious indications in human structure of the formative force nearing the end of its journey. In the details of the skeletons of other animals one sees the greatest precision of form; but there are various exceptions to this neatness of finish in the skeleton of man, and they are found in parts specially modified in connection with the peculiarities of his development, and not requiring exactness of shape for physiological purposes; while, on the other hand, physiognomical mould and nicety of various physiological adaptations are found in perfection. Look at the variations in the breast-bone, especially at its lower extremity, which is never shapely, as it is in the lower animals. Look at the coccygeal vertebræ; they

are the most irregular structures imaginable. Even in the sacrum and in the rest of the column the amount of variation finds no parallel in other animals. In the skull, except in some of the lowest forms of humanity, the *dorsum sellæ* is a ragged, warty, deformed, and irregular structure, and it never exhibits the elegance and finish seen in other animals. The curvature of the skull and shortening of its base, which have gradually increased in the ascending series of forms, have reached a degree which cannot be exceeded; and the nasal cavity is so elongated vertically, that in the higher races nature seems scarcely able to bridge the gap from the cribriform plate to the palate, and produces such a set of unsymmetrical and rugged performances as is quite peculiar to man; and to the human anatomist many other examples of similar phenomena will occur.

Questions of homology are matters which must be ever present in the study of structure, as distinct from function—both the correspondence of parts in one species to those in others, and the relations of one part to another in the same animal; and perhaps I shall best direct attention to the changes of opinion on morphological subjects in this country during the last twenty-five years by referring shortly to the homological writings of three eminent anatomists—Professors Owen, Goodsir, and Huxley.

Changes of Opinion on Morphological Subjects.

For the first time in English literature the great problems of this description were dealt with in Prof. Owen's work already referred to, published in 1848; and it is unnecessary to say that, notwithstanding the presence of unquestionable errors of theory, that work was a most valuable and important contribution to science. The faults in its general scope were justly and quietly corrected by Goodsir at the meeting of this Association in 1856 in three papers, one of them highly elaborate; and in these he showed that the morphology of vertebrate animals could not be correctly studied while reference was made exclusively to the skeleton. He showed the necessity of attending to all the evidence in trying to exhibit the underlying laws of structure, and especially of having constant regard to the teachings of embryology. Among the matters of detail which he set right it may be mentioned that he exposed the untenability of Prof. Owen's theory of the connection of the shoulder-girdle with the occipital bone, and pointed out that the limbs were not appendages of single segments corresponding with individual vertebræ. Referring to the development of the hand and foot, he showed the importance of observing the plane in which they first appear, and that the thumb and great toe are originally turned towards the head, the little finger and little toe toward the caudal end of the vertebral column. But he probably went too far in trying to make out an exact correspondence of individual digits with individual vertebral segments, failing to appreciate that the segmentation originally so distinct in the primordial vertebræ becomes altered as the surface of the body is approached—a truth illustrated in the vertebral columns of the plagiostomatous fishes, in the muscle-segments over the head in the pleuronectids, and in the interspinal bones bearing the dorsal and anal fin-rays of numbers of fishes, but, so far as I know, not hitherto sufficiently appreciated by any anatomist.

In 1858 Prof. Huxley delivered his Croonian Lecture on the vertebrate skull, and in 1863 his lectures at the Royal College of Surgeons on the same subject. He profited by the wisdom of Goodsir, and studied the works of Rathke, Reichert, and other embryologists. But, rightly or wrongly, he took a step further than Goodsir. He assumed from the first that the homologies of adult structures could be determined by development, and that by that study alone could they be finally demonstrated. As regards the skull, the constitution of which always remains the central study of the vertebrate skeleton, his writings marked the introduction of a period of revulsion against not only the systems of serial homologies previously suggested, but even against any attempt by the study of the varieties of adult forms to set them right. Mr. Huxley has added materially to the previously existing number of interpretations as to what elements correspond in different animals, and in doing so has found it necessary to make various additions to the already troubled nomenclature. Those who consider these changes correct will of course see in them a prospect of simplicity to future students; but to those who, like myself, have never been able to agree with them, they are naturally a source of sorrow. Among the changes referred to may be mentioned the theory of the "*periotic bones.*" That theory, I venture to think, a very unfortunate one, introducing a derangement of relations as widespread as did Goodsir's theory of the frontal bone. And do not think me presumptuous in saying so, seeing that this theory is in antagonism with the identifications of every anatomist preceding its distinguished originator, not excepting Cuvier and Owen; nor is it easy to discover what evidence it has to support it against the previously received decision of Cuvier as to the *external occipital* and *mastoid* of fishes. Without entering into the full evidence of the subject, it may be stated that, so far as this theory affects the *alisphenoid* in the skull of the fish, it must be given up, and the determination of Prof. Owen must be reverted to, when it is considered that in the carp the third and fourth nerve pierce what that anatomist terms the *orbitosphenoid*, the bone which is *alisphenoid* according to the theory which terms the *alisphenoid* of Owen the *prootic*. A proof still more striking is furnished by *Malapterurus* and other Silurids, in which the bone in question is pierced by the optic nerve. That being the case, the prootic theory will be seen to have arisen partly from giving too much importance to centres of ossification, and partly from considering the nerve-passage in front of the main bar of the *alisphenoid* of Owen as corresponding with the *foramen ovale* of man rather than with the *foramen rotundum* and sphenoidal fissure. A spiculum, however, separating the second from the third division of the fifth nerve, and having therefore the precise relations of the mammalian *alisphenoid*, does exist in the carp and other fishes. But in reptiles Prof. Huxley's determination of the *alisphenoid* is right, and Prof. Owen's clearly wrong; for in the crocodile the *alisphenoid* of Huxley and others is perforated by the sixth nerve, so that it cannot have any claim to be called *orbitosphenoid*. I must, however, maintain, against Prof. Huxley's view, Prof. Owen's determination of the *nasal* in fishes, notwithstanding that Prof. Owen has failed to appreciate the exact relation of that bone to the nasals of mammals, and has thereby laid his position open to attack. The arguments on that point Prof. Huxley was good enough to lay before the public fourteen years ago, by kindly reading for me before the Royal Society a paper which subsequently appeared in its "Transactions;" and I am not aware that anyone has since attempted to controvert them.

I shall not trouble you further with such matters of detail; but it will be clear from what has been said that the beginner in comparative anatomy must at the present day find himself at the outset, in the most important part of his osteological studies, faced with a diversity of opinion and confusion of nomenclature sufficient to produce much difficulty and to have a repelling effect on many minds. Such difficulties might well be encountered with enthusiasm where a belief existed that behind them lay a scheme of order and beauty; but not many will spend time in investigating such intricate details if they doubt the interest of the general conclusions likely to be reached by mastering them. On this account it is a great pity that the scepticism generated partly by the difficulties of the subject, and partly by reaction from the dogmatism of the admirers of Oken, does too frequently discourage the investigation of the serial homologies of the parts entering into the segments of the skull, and the determination of the nature and number of those segments. It is a pity that so much clamour has been made for a number of years against the expression "vertebral theory of the skull," because fighting against words is but stupid warfare at the best, and because all that was really meant, and could be justly stated, could have been brought into prominence without objecting to a time-honoured phrase. It is questionable if anyone who ever used the convenient term "vertebral theory" meant to indicate more than a certain community of plan on which were built the segments of the skull as well as those of the spinal column; that, in fact, the two constituted one complete chain, of which the first few segments were so different from the rest, that till Oken pointed the fact out, it was not recognised that they were segments lying in lineal continuity with the rest. But the matter has recently stood thus:—that to some minds, in the imperfect state of our knowledge, one thing seemed essential to a segment comparable to the rest, and to others something else seemed requisite; and the oddity of the position of affairs is this, that the objectors to the phrase "vertebral theory" have been as crotchety in setting up imaginary essentials to a segment as their neighbours. On the one side we were taught to expect certain definite osseous elements in each segment, to which definite names were given; while, on the other, in opposition schemes, centres of ossification have been built on as matters of primary consequence, although a glance at the modifications in the vertebral column proper might convince anyone that they are things of the very slightest importance morphologically. Also

those who have objected to speaking of cranial vertebræ have put great importance on the point at which the *chorda dorsalis* terminates, although it has been long known that in one animal the *chorda dorsalis* runs right on to the front, that in others it fails to enter the skull at all, while in the majority it passes for a certain distance into the base. Johannes Müller, on such grounds, concluded thirty years ago that the presence of *chorda dorsalis* was not necessary to constitute a cranial vertebra; and there seems no reason to doubt that he was right. Looking at the early embryo, the cerebro-spinal axis is seen to be one continuous structure; and the walls of the canal containing it are likewise manifestly continuous, not at first distinguishable into a spinal and a cranial portion. Looking at the adult condition, in the higher classes the vertebræ of the tail are seen dwindling into mere bodies developed round the *chorda*, and giving off rudimentary processes without separate centres of ossification, while towards the head the bodies diminish and the arches enlarge; and in the skull the *chorda*, round which the bodies in the rest of the column are developed, comes to an end, and the neural arches are enormously enlarged and have additional centres of ossification, precisely as in the mammalian thorax costal centres of ossification are found which do not exist in the costal elements of cervical vertebræ. It would therefore be quite as justifiable to object to the term vertebra as applied to a joint of the tail because it has no *laminæ*, or none with separate centres of ossification, as to object to its applicability to segments of the skull because the *chorda* is absent, or the osseous elements different in number from those found usually in the segments of the trunk.

However, it is gratifying to observe that among the most recent additions to morphological anatomy there is a highly suggestive paper by Prof. Huxley, appearing in the Royal Society's "Proceedings" for December last, and entitled "Preliminary Notes upon the Brain and Skull of *Amphioxus lanceolatus*," in which the learned Professor, who has for many years been the most determined opponent to the mention of cranial vertebræ, declares, so far as I can apprehend his meaning, that the region of the head represents no less than fourteen segments, all of which he terms *protovertebræ* in *Amphioxus*. This determination of correspondences is made the more remarkable by being followed up with a suggestion that the numerous protovertebræ lying in front of the fourteenth in *Amphioxus* are represented only by muscles and nerves in the higher vertebrates.

I hail this paper as being practically at last an ample acknowledgment that there is no escape from admitting the correspondence of the region of the head with the segments of the trunk: but the details of the new theory scarcely seem convincing; and I might have preferred to leave its discussion to others, were it not that the notions which it opens up are far too important to allow it to be passed over in any account of the present state of opinion on the subject of vertebrate morphology. The argument in this new theory runs thus: that the palate-curtain of *Amphioxus* is homologous with that of the lamprey, and that the palate-curtain of the lamprey is attached below the ear; that therefore all the seven segments seen in front of the palate-curtain of *Amphioxus* are represented by parts in front of the ear in the lamprey and the other Vertebrata. Again, the branchial arches of the higher Vertebrata are assumed to be of the nature of ribs, and in none of the Vertebrata next above *Amphioxus* "are there more than seven pairs of branchial arches, so that not more than eight myotomes (and consequently protovertebræ) of *Amphioxus*, in addition to those already mentioned, can be reckoned as the equivalents of the parachordal region of the skull in the higher vertebrates." Everything, observe, depends on the segment to which the palate-curtain of *Amphioxus* belongs. Now I have already pointed out to you that the segmentation of the vertebrate body is not perfect; and there is no method by which the alimentary canal, of which the mouth and palate are the first part, can be divided into segments corresponding with the cerebro-spinal nerves. Most certainly we cannot judge that a portion of a viscus belongs to a particular segment from its lying underneath some other structure in definite relation, like the ear, to the cerebro-spinal system; for then should we be obliged to grant that one-half or more of the heart belongs to segments in front of the ear, since it is undoubtedly so situated in a chick of the thirty-sixth hour. But the branchial arches are in front of the heart, and, according to the theory which we are considering, are behind the ear; thus the principle assumed in the starting-point of the theory is taken away.

Again, it is important to observe that the branchial skeletal arches cannot be ribs, for they lie internal to the primary circles of the vascular system formed by the branchial arteries and veins, while the ribs are superficial to both heart and aorta. If the ribs are represented at all in the branchial apparatus (and I doubt it very much), it is by the cartilages superficial to the gills in sharks, rays, and dog-fishes; and it would seem impossible for anyone who has dissected them to doubt that those cartilages are homologous with the branchial skeleton of the lamprey, which they somewhat resemble. In fact, if the external and internal branchial openings of the lamprey be enlarged, its gills are reduced to a form similar to those of the shark.

There is nothing in this, however, which interferes seriously with the proposed theory of the skull. It is merely a point in the argument which I have thought right to clear. More important it is to remark that, on the supposition that numerous protovertebræ are represented in the region of the head, there are most serious difficulties interfering with the idea that they are, as Prof. Huxley states, "represented only by muscles and nerves in the higher Vertebrata," and that there is any correspondence between "the oculo-motor, pathetic, trigeminal, and abducens nerves with the muscles of the eye and jaws" and the regular nerves and muscle-segments of the fore part of *Amphioxus*. Even in the lamprey the eye-balls are supplied with muscles similar to those to which, in other vertebrates, the oculo-motor, pathetic, and abducens are distributed; and I find in the large species that, notwithstanding this, the series of regular muscle-segments is continued over the head, not indeed in the same way as in *Mixine*, but in a highly instructive and curious manner. After further dwelling upon this point, Prof. Cleland said:—

It may be noticed as a wholesome symptom in anatomical speculation, that the new theory which has led to these remarks is founded on arguments drawn altogether from comparison of different species, and not from embryology, a very remarkable circumstance as coming from one who so lately as last autumn reiterated in this Section his slowness to believe in reasonings founded on adult forms, and even on "later development." The wisest know so little, that humanity must be content to gather information from every possible source, and leave no set of ascertained facts out of view in attempting to arrive at generalisations. If we had before us all the adult anatomy of every species that ever lived on the earth, we should only then have the record completed from which to frame a full system of morphology; and as matters stand we must translate embryological phenomena with the aid of the series of adult forms, as well as translate the teachings of the adult series with the aid of embryology.

Falling back on my proposition, that the segments of the vertebrate body are nowhere complete, and that segmentation at one depth may exist to a greater extent than at another, I may mention certain embryological phenomena in the brain, which have received too little attention, and which to some extent warrant belief in a larger number of segments in the head than is usually admitted; although I do not see that they are necessarily at variance with that theory of seven segments in every ossified skull which I indicated in 1862. In the chick, in the middle of the second day of hatching, already is the third cerebral vesicle divided into a series of five parts, separated by slight constrictions, the first part larger than those which succeed, and the last part narrowing to the spinal cord. The auditory vesicle lies opposite the constriction between the fourth and fifth parts. At the end of the second day and during the third, these divisions assume dimensions which give them a general appearance exceedingly similar in profile to the protovertebræ of the neck. In the following day they exhibit a more complex appearance, and after that the first compartment alone remains distinct as cerebellum, while the divisions between the others disappear in the thickening of the cerebral walls. In their first two stages, Mr. Huxley, whom I have already referred to so often, has figured these crenations, but he has not, so far as I know, described them.

I may also direct attention to another embryological point, to which I referred last year at Belfast as a probability. I speak now from observation. That which is termed the first cerebral vesicle in the early part of the second day of hatching of the chick, is an undifferentiated region of the brain from which a number of parts emerge successively from behind forwards. As early as the thirty-sixth hour the optic nerves can be traced, separated from the rest of the vesicle by distinct elevations of the floor of the brain, reaching inwards to the constriction between the first and second vesicles: and as early as this date the first trace of bifidity of the brain in front may be discerned—

that bifidity which, to my thinking, is only one of several instances of longitudinal fission in the fore part of the head, the trabeculæ presenting another instance of the same thing, and the cleft between the maxillary lobe and the part of the head above it a third; while in the muscular system such longitudinal cleavage or fission is common even in the trunk. In a chick of the third or fourth day, when rendered very transparent, the optic nerves can be seen extending from beneath the front of the

optic lobes; while in front of the optic lobes there are placed in series from behind forwards a posterior division of the first vesicle, an anterior division, the cerebral hemispheres, and the olfactory lobes. Thus there is a large supply of material presented in the brain for the study of segmentation; the difficulty to be overcome by future inquiry and careful collation of all available facts is to determine the value of the parts placed one in front of another.

Perhaps I have occupied time too long with matters involving a large amount of technical detail; but I trust that I may have, in some measure, illustrated that both in aim and in accomplished work anatomy is no mere collection of disconnected facts, no mere handmaid of the physician and surgeon, nor even of phy-

siology. I do not doubt that it is yet destined, as dealing with the most complex sequences of phenomena, to take the highest place among the sciences as a guide to philosophy. One cannot help noticing the increased importance now given to Natural History studies as a part of education; and it is worth while to note that it is most of all in anatomy and physiology that the close connections of matter with mind are brought under review,—physiology exhibiting the relations of our own mental being to our bodies, and anatomy revealing a body of organised nature, whose organisation points to a source of beauty and order beyond.

The people of Bristol do well to rally round their Medical School. They do well to furnish it with buildings suitable for the prosecution of all the Natural History studies which adhere to medical education; and they do well to join with that school a complete college of literature and science. Let us hope that they will make it worthy of so wealthy and historic a city. But if they will have their medical school the success which in so flourishing a locality public enthusiasm may well make it, and if they will have it aid as well as be aided by a school of general education, let them follow the system latterly adopted in Oxford and Cambridge, long carried out in the Universities of Scotland, and recognised, though not in all instances sufficiently provided for, in Ireland. Let anatomy, human and comparative, receive its place as an important and fundamental science. Let thorough and adequate provision be made for its being taught as a science; and see that it do not, as in too many medical schools which shall be nameless, degenerate to the etymological and original meaning of the word, a mere cutting up of carcases.

Mr. H. B. Brady exhibited a series of micro-photographs chiefly from physiological and pathological preparations, taken by a new and simple process, devised by Mr. Hugh Bowman, of Newcastle. The apparatus was also shown and described. It consisted of a simple mirror of speculum metal, placed at an angle of 45 degrees in front of the eye-piece of the microscope, and directed downwards. The image was received upon a collodion plate set in the frame of a common photographic camera, and the photograph taken in the usual way. About 11 seconds was stated to be a sufficient exposure for the purpose.

A paper was read by Dr. Martyn entitled *Some New Researches on the Anatomy of the Skin*. Dr. Martyn had discovered that the cells which appeared "spinous" or "echinate," when isolated from their connection, if they could be at any time seen in single layers, were simply united together by delicate bands. These are so constantly seen broken across that they assume the form of tubercles or "prickles." As repeated observations confirmed this, the name "conjoined epithelium" had been proposed for this form or stage in the cell life.

A paper *On the Physiological Action of the Chinoline and Pyridine Bases*, by Dr. J. G. M'Kendrick and Prof. Dewar, was read by the former gentleman. The following are the general conclusions arrived at:—1. There is a marked gradation in extent of physiological action of the members of the pyridine series of bases, but it remains of the same kind. The lethal dose becomes reduced as we rise from the lower to the higher. 2. The higher members of the pyridine series resemble in physiological action the lower members of the chinoline series, except (1) that the former are more liable to cause death by asphyxia, and (2) that the lethal dose of the pyridines is less than one half that of the chinolines. 3. In proceeding from the lower to the higher members of the chinoline series, the physiological action changes in character, inasmuch as the lower members appear to act chiefly on the sensory centres of the encephalon and the reflex centres of the cord, destroying the power of voluntary or reflex movement; while the higher act less on these centres, and chiefly on the motor centres, first, as irritants, causing violent convulsions, and at length producing complete paralysis. At the same time, while the reflex activity of the centres in the spinal cord appear to be inactive, they may be readily roused to action by strychnine. 4. On comparing the action of such compounds as C_9H_7N (chinoline) with $C_9H_{13}N$ (parvoline, &c.), or $C_8H_{11}N$ (collidine) with $C_8H_{15}N$ (conia, from hemlock), or $C_{10}H_{10}N_2$ (dipyridine) with $C_{10}H_{14}N_2$ (nicotine, from tobacco), it is to be observed that the physiological activity of the substance is, apart from chemical structure, greatest in those bases containing the larger amount of hydrogen. 5. Those artificial bases which approximate the percentage composition of natural bases are much weaker physiologically, so far as can be estimated by amount of dose, than the natural bases; but the kind of action is the same in both cases. 6. When the bases of the pyridine series are doubled by condensation, producing dipyridine, parapicoline, &c., they not only become more active physiologically, but the action differs in kind from that of the simple bases, and resembles the action of natural bases or alkaloids having a similar chemical constitution. 7. All the substances examined in this research are remarkable for not possessing any specific paralytic action on the heart likely to cause syncope; but they destroy life either by exhaustive con-

vulsions, or by gradual paralysis of the centres of respiration, thus causing asphyxia. 8. There is no appreciable immediate action on the sympathetic system of nerves. There is probably a secondary action, because after large doses the vasomotor centre, in common with other centres, becomes involved. 9. There is no difference, so far as could be discovered, between the physiological action of bases obtained from cinchonine and those derived from tar.

This paper, besides its purely scientific value, is of some interest to general readers on account of the fact discovered by Vohl and Eulenburg, that chinoline and pyridine are produced during the combustion of tobacco, and that the effects of tobacco smoking are to a great extent due to the action of these and similar bases.

Department of Anthropology.

Mr. John Evans, in moving a vote of thanks to Prof. Rolleston for his address, said it supplied the strongest evidence of the necessity for the application of the natural history method to anthropology; and the value of the study was shown by the way in which it had been brought to bear on questions of the present day.—Dr. Carpenter, in supporting the resolution, desired to refer to Dr. Prichard as a Bristol man, and because he had been mainly instrumental in directing his course at the outset of his public life; by his advice he had read his first paper before the British Association at its former visit to Bristol. His thoughts were those of a physiologist among physiologists, and a scholar among scholars, but he was resolved to keep the threads together if possible. He was perhaps the first to bring a large idea of species to bear upon the origin of man, and to trace out intermediate links and gradational characters, and to investigate the analogous features in the history of domesticated animals. With regard to the antiquity of man, he believed that Prichard was the first to propound the doctrine, now so generally accepted, of the much greater antiquity of man than could be supposed if the genealogies of Genesis were accurate. He made a careful and scientific investigation of those genealogies, and found it absolutely necessary to conclude that they could not be relied upon for chronological evidence; and when he further came to consider the amount of time necessary to produce such strongly marked races as the Jewish and the Egyptian, on the hypothesis of the unity of the race and the time which would be required to produce such divarications of language as existed in the early historical period, he was additionally supported in his view as to the antiquity of the human race.

Col. Lane Fox gave a most interesting account of recent excavations in Cissbury Camp, near Worthing, of which full details will be published at the earliest possible time. He said that the entrenchment was one of the largest in the south of England, and had all the peculiarities of a British earthwork. Camden spoke of this camp as the work of Cissa, the Saxon king of the district, from whom, in his opinion and in great probability, it derived its name of Cissbury. He believed the first notice of the place as a flint factory was by himself in 1868, when, finding a large quantity of flint flakes on the surface and a number of large pits which filled the interior of the camp on the west side, he dug into some of them to a depth of four or five feet, and found in them a still further number of flakes, together with finished and unfinished flint tools. It was evident that here was a flint factory, and that it was established because of the much greater ease of working the flints when first removed from the chalk. He had no idea then of the great extent of the mining operations of these chalk people, nor did he think it necessary to dig deeper, some of the pits as left open, and further opened by himself, being twenty feet deep. They appeared to be quite deep enough for a sufficient quantity of flints to be got. The true nature of these flint works was illuminated by accident, viz., by the cutting of a railway from Franières to Chimay, when fifty-five deep shafts of this kind were cut through, with galleries proceeding from them. In 1870 Canon Greenwell had excavated pits at Brandon, and found similar shafts and galleries. Since then Mr. Tindall, of Brighton, had opened one of the pits at Cissbury, and found a shaft thirty-five feet deep, with *Bos primigenius* and other remains of wild animals. Mr. E. Willett had excavated another twenty-five feet deep, and found galleries leading from them; and it was established that the flints did not exist so near the surface as he (Col. Lane Fox) had supposed. The question now became of great importance as to the relative age of the flint factory and the entrenchment in which it was situated. Since June last, and up to the week before the meeting of the Association, he had superintended work at these pits, aided by subscriptions from members of the Anthropological Institute. In April last he had opened a section in the ditch round the entrenchment in layers of eighteen inches to two feet, and found, in the upper layer, two oval flint implements, fragments of red earthenware, oyster shells, snail shells, bones of domestic animals, and fragments of Romano-British pottery. In the second layer there was ferruginous chalk rubble, with untouched nodules, and abundance of *Helix nemoralis.* In the third layer was found white chalk rubble, with bones of pig and ox, and oyster shells, and small fragments of British pottery. There was no indication of anything absolutely of the Roman period; any such indications were in the upper layer, and they were not conclusive. In the subsequent investigations he had been assisted by Professors Rolleston and Hughes, Mr. Harrison, and others. He saw that there were pits on the outside of the camp, that they were shallower, and that there were no flints about. He thought that if he dug out one or two nearest the entrenchment, he might see whether they were the mouths of old shafts. He found that they were so, and became satisfied that they were all shafts. Then he thought that the best means of ascertaining the relative ages of shafts and entrenchment was to dig in the ditch at the point where the line of shafts intersected the rampart. He first dug out the bottom of the ditch in layers as before, and in the second layer below the surface found fragments of Romano-British pottery, but none in the bottom layers. It was evident that this filling in of the ditch was due to the degradation of the central part of the entrenchment. It was also clear that pottery of the kind found was *not* used when the ditch was sunk. The side of the ditch sloped inwards to the west, but towards the east the inner side was perfectly upright, and the rubble near the upright part was quite white instead of yellow, showing that the excavators, when they came to the shafts, had cut through the rubble which had been used previously to fill up the shaft; the excavation was then continued into the shaft to 6 feet 6 inches below the old bottom of the ditch, and deer-horn tines and the scapula of an ox were found. In the bottom of the shaft galleries were found opening out of it; one ran north for twenty feet, and was two feet high. It rose at an angle of 5°, which was the angle of stratification of the chalk. In the sides of the galleries, at a height of a foot and a half, here and there, flints were found *in situ,* so that it was plain that the seam of flints had been followed. The flints were not reached till they got to seventeen feet below the original surface of the ground. Another gallery was found running south, and then a chamber was entered, which became high, and it was discovered that it communicated with a shaft in the counterscarp of the ditch. It was conclusively proved that the shaft had been filled in before the ditch was made, and that afterwards the rubble which filled in the inner shaft had been thrown up over the outer shaft forming the rampart. The shaft had been filled in up to the top, apparently by the people who had made it. In filling it they had partly used rubble and partly clay. It was found in layers sloping down, intersected with seams of clay; these seams were quite unconformable with the shaft or with the surrounding strata, but they were evidently derived from clay which was to be met with near the surface of the upper part of the entrenchment. They then followed out another shaft, and when nearly at the bottom he was astounded by a human jaw-bone falling down at his feet from the wall of the shaft; and looking up, he saw the skull resting with the base downwards between two of the blocks of chalk rubble. He procured at once other eyes to see it in its actual position, and then it was taken away, for it was in a very precarious situation. It and the accompanying human bones would be commented on by Prof. Rolleston. This and another shaft gave the same evidences, and had galleries running out of them, and it was clear that the outer rampart had been formed by the rubble thrown out from these filled-up shafts. A seam of flints was found in one of the galleries, and around and on the surfaces of some of them were found a number of marks which corresponded exactly with the deer-horn tines found, so that evidently the flints had been picked out by the aid of deer-horns. As to the implement found, in his opinion there were all transitions between Palæolithic and Neolithic implements. But the resemblance to palæolithic might be, he thought, more apparent than real, and partly might be due to their being unfinished. It was very difficult to command the breaking of flints, as he had found by actual experiment; and thus many unfinished implements were left in the pits. But there was one celt which was finished at the thin end, and was evidently of the Palæolithic type; and others were

plainly roughened at the broad end so as to be held in the hand. He thought at any rate that these flints were of a very early Neolithic period, and showed considerable traces of the Palæolithic, though there might yet remain a gap between the periods. The shafts had been kept open, and would still be open for another fortnight, when, by agreement with the owner, they were to be closed up. Many of the leading authorities in this department had visited the place, but subsequently the only actual plan of the workings would be the wooden model which he exhibited, showing all the strata, shafts, and galleries.

Prof. Rolleston then proceeded to speak of the animal remains. He said the snail and other shells found were of great use, and supplied a cogent argument, without ambiguity, as cogent as Euclid. Here was the sharp line of the shaft, and at a depth of fourteen feet from the original surface were found an immense number of *Cyclostoma elegans*, *Helix nemoralis*, and other hybernating snail shells. They were not brought down to be eaten by the excavators, as was supposed, but the opercula were still found exactly *in situ*, giving evidence that they had gone down for warmth and shelter while still alive. They had also found plenty of food in the moist conditions of the shaft. They had undoubtedly gone down the shaft at a time when it was still open; and further evidence was that no snail shells at all were to be found in the rubble which had gradually dribbled down. He thought that the abundance of the shells was to be explained by the fact that these prehistoric Britons, like our own countrymen of the present day, were a little negligent in putting an end to nuisances, whether they were open shafts or otherwise, and thus the shaft had been open a good while, and a large series of snails had lived here. And among other results of this negligence was, he believed, the fall of a young British lady into the shaft. At any rate her bones had been found in a position quite compatible with this idea. With the skeleton were found a large number of pig-bones; there were at least four individuals, one old and three younger. We have not the entire skeleton of any one of them, and it was quite compatible with the evidence that these bones might have been thrown in piecemeal. Other bones were found, all of domestic animals, especially a small animal which might be a sheep or a goat; the critical pieces of the skeleton were absent. As to the *Bos primigenius* there was not the smallest doubt, and it was found in a position which showed it to have occurred before the advent of the small domestic animals; and wild animals of the same kinds must have then been much larger, or they would speedily have been exterminated by the wolves. As to the female skeleton, nearly all the bones were preserved, scarcely three of the vertebræ being missing. She was evidently between eighteen and twenty-five years of age, by various indications of the bones. She had a large head, yet it was an early type of skull, older than that of the people who built the rampart. The lower jaw contained a large number of teeth. The wisdom teeth were just through, and were scarcely worn at all; yet the two molar teeth in front of them on each side, above and below, were ground down nearly to the stumps. From this he inferred that the food had been of such a character as to produce wearing of the teeth. The evidence of the bones was conclusive as to her youth. The only parallel he could find to this was in the Indians of Vancouver's Island, who fed on fish dried in the sand-blowing winds, and their teeth were thus worn down to the stumps. Similarly these people might have fed on food dried in the wind, in which a large amount of fine sand got embedded. The cubical capacity of the cranium was very large; as measured by rape-seed it was 105·75 cubic inches; and the largest cubical capacity he knew of was one of a great Roman officer out of their burial grounds, whose capacity was 108 cubic inches. The people who made the shafts were undoubtedly older than the Britons who made the great rampart, and *they* were still in a stone-using period.

Mr. John Evans, in the discussion which followed, said that the main difference between Palæolithic and Neolithic was not that in one the implements were merely chipped and in the other polished, but in the manner of occurrence in the strata and the animals associated with them. In the Neolithic he estimated that ninety-five per cent. of all that was found was unpolished—all the smaller tools, &c. He acknowledged that he was not justified in saying that the pointed end of some of the implements from Cissbury was not intended to be used; and there were some cases in which it was impossible to tell which end was to be used. Even granting this exceptional resemblance, there is a great Neolithic facies in the things found at Cissbury. Still, he was quite willing now to accept the particular implement found at Cissbury as a new type of implement to be held in the hand; it might have been used in digging up roots.

SECTION E

Geography.

Address by Lieut.-General R. Strachey, R.E., C.S.I., F.R.S., President.

In accordance with the practice followed for some years past by the Presidents of the Sections of the British Association, I propose, before proceeding with our ordinary business, to offer for your consideration some observations relative to the branch of knowledge with which this Section is more specially concerned.

My predecessors in this chair have, in their opening addresses, viewed geography in many various lights. Some have drawn attention to recent geographical discoveries of interest, or to the gradual progress of geographical knowledge over the earth generally, or in purticular regions. Others have spoken of the value of geographical knowledge in the ordinary affairs of men, or in some of the special branches of those affairs, and of the means of extending such knowledge. Other addresses again have dwelt on the practical influence produced by the geographical features and conditions of the various parts of the earth on the past history and present state of the several sections of the human race, the formation of kingdoms, the growth of industry and commerce, and the spread of civilisation.

The judicious character of that part of our organisation which leads to yearly changes among those who preside over our meetings, and does not attempt authoritatively to prescribe the direction of our discussions, will no doubt be generally recognised. It has the obvious advantage, amongst others, of ensuring that none of the multifarious claims to attention of the several branches of science shall be made unduly prominent, and of giving opportunity for viewing the subjects which from time to time come before the Association in fresh aspects by various minds.

Following, then, a somewhat different path from those who have gone before me in treating of Geography, I propose to speak of the physical causes which have impressed on our planet the present outlines and forms of its surface, have brought about its present conditions of climate, and have led to the development and distribution of the living beings found upon it.

In selecting this subject for my opening remarks, I have been not a little influenced by a consideration of the present state of geographical knowledge, and of the probable future of geographical investigation. It is plain that the field for mere topographical exploration is already greatly limited, and that it is continually becoming more restricted. Although no doubt much remains to be done in obtaining detailed maps of large tracts of the earth's surface, yet there is but comparatively a very small area with the essential features of which we are not now fairly well acquainted. Day by day our maps become more complete, and with our greatly improved means of communication the knowledge of distant countries is constantly enlarged and more widely diffused. Somewhat in the same proportion the demands for more exact information become more pressing. The necessary consequence is an increased tendency to give to geographical investigations a more strictly scientific direction. In proof of this I may instance the fact that the two British naval expeditions now being carried on, that of the *Challenger* and that of the Arctic seas, have been organised almost entirely for general scientific research, and comparatively little for topographical discovery. Narratives of travels, which not many years ago might have been accepted as valuable contributions to our then less perfect knowledge, would now perhaps be regarded as superficial and insufficient. In short, the standard of knowledge of travellers and writers on geography must be raised to meet the increased requirements of the time.

Other influences are at work tending to the same result. The great advance made in all branches of natural science limits more and more closely the facilities for original research, and draws the observer of nature into more and more special studies, while it renders the acquisition by any individual of the highest standard of knowledge in more than one or two special subjects comparatively difficult and rare. At the same time the mutual inter-dependence of all natural phenomena daily becomes more apparent; and it is of ever-increasing importance that there shall be some among the cultivators of natural knowledge who specially

direct their attention to the general relations existing among all the forces and phenomena of nature. In some important branches of such subjects, it is only through study of the local physical conditions of various parts of the earth's surface and the complicated phenomena to which they give rise, that sound conclusions can be established; and this study constitutes physical or scientific geography. It is very necessary to bear in mind that a large portion of the phenomena dealt with by the sciences of observation relates to the earth as a whole in contradistinction to the substances of which it is formed, and can only be correctly appreciated in connection with the terrestrial or geographical conditions of the place where they occur. On the one hand, therefore, while the proper prosecution of the study of physical geography requires a sound knowledge of the researches and conclusions of students in the special branches of science, on the other success is not attainable in the special branches without suitable apprehension of geographical facts. For these reasons it appears to me that the general progress of science will involve the study of geography in a more scientific spirit, and with a clearer conception of its true function, which is that of obtaining accurate notions of the manner in which the forces of nature have brought about the varied conditions characterising the surface of the planet which we inhabit.

In its broadest sense science is organised knowledge, and its methods consist of the observation and classification of the phenomena of which we become conscious through our senses, and the investigation of the causes of which these are the effects. The first step in geography, as in all other sciences, is the observation and description of the phenomena with which it is concerned; the next is to classify and compare this empirical collection of facts, and to investigate their antecedent causes. It is in the first branch of the study that most progress has been made, and to it indeed the notion of geography is still popularly limited. The other branch is commonly spoken of as physical geography, but it is more correctly the science of geography.

The progress of geography has thus advanced from first rough ideas of relative distance between neighbouring places, to correct views of the earth's form, precise determinations of position, and accurate delineations of the surface. The first impressions of the differences observed between distant countries were at length corrected by the perception of similarities no less real. The characteristics of the great regions of polar cold and equatorial heat, of the sea and land, of the mountains and plains, were appreciated; and the local variations of season and climate, of wind and rain, were more or less fully ascertained. Later, the distribution of plants and animals, their occurrence in groups of peculiar structure in various regions, and the circumstances under which such groups vary from place to place, gave rise to fresh conceptions. Along with these facts were observed the peculiarities of the races of men—their physical form, languages, customs, and history—exhibiting on the one hand striking differences in different countries, but on the other often connected by a strong stamp of similarity over large areas.

By the gradual accumulation and classification of such knowledge the scientific conception of geographical unity and continuity was at length formed, and the conclusion established that while each different part of the earth's surface has its special characteristics, all animate and inanimate nature constitutes one general system, and that the particular features of each region are due to the operation of universal laws acting under varying local conditions. It is upon such a conception that is now brought to bear the doctrine, very generally accepted by the naturalists of our own country, that each successive phase of the earth's history, for an indefinite period of time, has been derived from that which preceded it, under the operation of the forces of nature as we now find them; and that, so far as observation justifies the adoption of any conclusions on such subjects, no change has ever taken place in those forces, or in the properties of matter. This doctrine is commonly spoken of as the doctrine of evolution, and it is to its application to geography that I wish to direct your attention.

I desire here to remark that in what I am about to say, I altogether leave on one side all questions relating to the origin of matter, and of the so-called forces of nature which give rise to the properties of matter. In the present state of knowledge such subjects are, I conceive, beyond the legitimate field of physical science, which is limited to discussions directly arising on facts within the reach of observation, or on reasonings based on such facts. It is a necessary condition of the progress of knowledge that the line between what properly is or is not within the reach of human intelligence is ill defined, and that opinions will vary as to where it should be drawn; for it is the avowed and successful aim of science to keep this line constantly shifting by pushing it forward; many of the efforts made to do this are no doubt founded in error, but all are deserving of respect that are undertaken honestly.

The conception of evolution is essentially that of a passage to the state of things which observation shows us to exist now, from some preceding state of things. Applied to geography, that is to say to the present condition of the earth as a whole, it leads up to the conclusion that the existing outlines of sea and land have been caused by modifications of pre-existing oceans and continents, brought about by the operation of forces which are still in action, and which have acted from the most remote past of which we can conceive; that all the successive forms of the surface—the depressions occupied by the waters, and the elevations constituting mountain-chains—are due to these same forces; that these have been set up, first, by the secular loss of heat which accompanied the original cooling of the globe; and second, by the annual or daily gain and loss of heat received from the sun acting on the matter of which the earth and its atmosphere are composed; that all variations of climate are dependent on differences in the condition of the surface; that the distribution of life on the earth, and the vast varieties of its forms, are consequences of contemporaneous or antecedent changes of the forms of the surface and climate; and thus that our planet as we now find it is the result of modifications gradually brought about in its successive stages, by the necessary action of the matter out of which it has been formed, under the influence of the matter which is external to it.

I shall state briefly the grounds on which these conclusions are based.

So far as concerns the inorganic fabric of the earth, that view of its past history which is based on the principle of the persistence of all the forces of nature may be said to be now universally adopted. This teaches that the almost infinite variety of natural phenomena arises from new combinations of old forms of matter, under the action of new combinations of old forms of force. Its recognition has, however, been comparatively recent, and is in a great measure due to the teachings of that eminent geologist, the late Sir Charles Lyell, whom we have lost during the past year.

When we look back by the help of geological science to the more remote past, through the epochs immediately preceding our own, we find evidence of marine animals—which lived, were reproduced, and died,—possessed of organs proving that they were under the influence of the heat and light of the sun; of seas whose waves rose before the winds, breaking down cliffs, and forming beaches of boulders and pebbles; of tides and currents spreading out banks of sand and mud, on which are left the impress of the ripple of the water, of drops of rain, and of the track of animals; and all these appearances are precisely similar to those we observe at the present day as the result of forces which we see actually in operation. Every successive stage, as we recede in the past history of the earth, teaches the same lesson. The forces which are now at work, whether in degrading the surface by the action of seas, rivers, or frosts, and in transporting its fragments into the sea, or in reconstituting the land by raising beds laid out in the depth of the ocean, are traced by similar effects as having continued in action from the earliest times.

Thus pushing back our inquiries we at last reach the point where the apparent cessation of terrestrial conditions such as now exist requires us to consider the relation in which our planet stands to other bodies in celestial space; and vast though the gulf be that separates us from these, science has been able to bridge it. By means of spectroscopic analysis it has been established that the constituent elements of the sun and other heavenly bodies are substantially the same as those of the earth. The examination of the meteorites which have fallen on the earth from the interplanetary spaces, shows that they also contain nothing foreign to the constituents of the earth. The inference seems legitimate, corroborated as it is by the manifest physical connection between the sun and the planetary bodies circulating around it, that the whole solar system is formed of the same descriptions of matter, and subject to the same general physical laws. These conclusions further support the supposition that the earth and other planets have been formed by the aggregation of matter once diffused in space around the sun; that the first consequence of this aggregation was to develop intense heat in the consolidating masses; that the heat thus generated in the terrestrial sphere was subsequently lost by

radiation; and that the surface cooled and became a solid crust, leaving a central nucleus of much higher temperature within. The earth's surface appears now to have reached a temperature which is virtually fixed, and on which the gain of heat from the sun is, on the whole, just compensated by the loss by radiation into surrounding space.

Such a conception of the earliest stage of the earth's existence is commonly accepted, as in accordance with observed facts. It leads to the conclusion that the hollows on the surface of the globe occupied by the ocean, and the great areas of dry land, were original irregularities of form caused by unequal contraction; and that the mountains were corrugations, often accompanied by ruptures, caused by the strains developed in the external crust by the force of central attraction exerted during cooling, and were not due to forces directly acting upwards generated in the interior by gases or otherwise. It has recently been very ably argued by Mr. Mallet that the phenomena of volcanic heat are likewise consequences of extreme pressures in the external crust, set up in a similar manner, and are not derived from the central heated nucleus.

There may be some difficulty in conceiving how forces can have been thus developed sufficient to have produced the gigantic changes which have occurred in the distribution of land and water over immense areas, and in the elevation of the bottoms of former seas so that they now form the summits of the highest mountains, and to have effected such changes within the very latest geological epoch. These difficulties in great measure arise from not employing correct standards of space and time in relation to the phenomena. Vast though the greatest heights of our mountains and depths of our seas may be, and enormous though the masses which have been put into motion, when viewed according to a human standard, they are insignificant in relation to the globe as a whole. Such heights and depths (about six miles) on a sphere of ten feet in diameter would be represented on a true scale by elevations and depressions of less than the tenth part of an inch, and the average elevation of the whole of the dry land (about 1,000 feet) above the mean level of the surface would hardly amount to the thickness of an ordinary sheet of paper. The forces developed by the changes of the temperature of the earth as a whole must be proportionate to its dimensions; and the results of their action on the surface in causing elevations, contortions, or disruptions of the strata, cannot be commensurable with those produced by forces having the intensities, or by strains in bodies of the dimensions, with which our ordinary experience is conversant.

The difficulty in respect to the vast extent of past time is perhaps less great, the conception being one with which most persons are now more or less familiar. But I would remind you, that great though the changes in human affairs have been since the most remote epochs of which we have records in monuments or history, there is nothing to indicate that within this period has occurred any appreciable modification of the main outlines of land and sea, or of the condition of climate, or of the general characters of living creatures; and that the distance that separates us from those days is as nothing when compared with the remoteness of past geological ages. No useful approach has yet been made to a numerical estimate of the duration even of that portion of geological time which is nearest to us; and we can say little more than that the earth's past history extends over hundreds of thousands or millions of years.

The solid nucleus of the earth with its atmosphere, as we now find them, may thus be regarded as exhibiting the residual phenomena which have resulted on its attaining a condition of practical equilibrium, the more active process of aggregation having ceased, and the combination of its elements into the various solid, liquid, or gaseous matters found on or near the surface having been completed. During its passage to its present state many wonderful changes must have taken place, including the condensation of the ocean, which must have long continued in a state of ebullition, or bordering on it, surrounded by an atmosphere densely charged with watery vapour. Apart from the movements in its solid crust caused by the general cooling and contraction of the earth, the higher temperature due to its earlier condition hardly enters directly into any of the considerations that arise in connection with its present climate, or with the changes during past time which are of most interest to us; for the conditions of climate and temperature at present, as well as in the period during which the existence of life is indicated by the presence of fossil remains, and which have affected the production and distribution of organised beings, are dependent on other causes, to a consideration of which I now proceed.

The natural phenomena relating to the atmosphere are often extremely complicated and difficult of explanation; and meteorology is the least advanced of the branches of physical science. But sufficient is known to indicate, without possible doubt, that the primary causes of the great series of phenomena, included under the general term climate, are the action and reaction of the mechanical and chemical forces set in operation by the sun's heat, varied from time to time and from place to place, by the influence of the position of the earth in its orbit, of its revolution on its axis, of geographical position, elevation above the sea-level, and condition of the surface, and by the great mobility of the atmosphere and the ocean.

The intimate connection between climate and local geographical conditions is everywhere apparent; nothing is more striking than the great differences between neighbouring places where the effective local conditions are not alike, which often far surpass the contrasts attending the widest separation possible on the globe. Three or four miles of vertical height produce effects almost equal to those of transfer from the equator to the poles. The distribution of the great seas and continents give rise to periodical winds—the trades and monsoons—which maintain their general characteristics over wide areas, but present almost infinite local modifications, whether of season, direction, or force. The direction of the coasts and their greater or less continuity greatly influence the flow of the currents of the ocean; and these, with the periodical winds, tend on the one hand to equalise the temperature of the whole surface of the earth, and on the other to cause surprising variations within a limited area. Ranges of mountains, and their position in relation to the periodical or rain-bearing winds, are of primary importance in controlling the movements of the lower strata of the atmosphere, in which, owing to the laws of elastic gases, the great mass of the air and watery vapour are concentrated. By their presence they may either constitute a barrier across which no rain can pass, or determine the fall of torrents of rain around them. Their absence or their unfavourable position, by removing the causes of condensation, may lead to the neighbouring tracts becoming rainless deserts.

The difficulties that arise in accounting for the phenomena of climate on the earth as it now is, are naturally increased when the attempt is made to explain what is shown by geological evidence to have happened in past ages. The disposition has not been wanting to get over these last difficulties by invoking supposed changes in the sources of terrestrial heat, or in the conditions under which heat has been received by the earth, for which there is no justification in fact, in a manner similar to that in which violent departures from the observed course of nature have been assumed to account for some of the analogous mechanical difficulties.

Among the most perplexing of such climatal problems are those involved in the former extension of glacial action of various sorts over areas which could hardly have been subject to it under existing terrestrial and solar conditions; and in the discovery, conversely, of indications of far higher temperatures at certain places than seems compatible with their high latitudes; and in the alternations of such extreme conditions. The true solution of these questions has apparently been found in the recognition of the disturbing effects of the varying eccentricity of the earth's orbit, which, though inappreciable in the comparatively few years to which the affairs of men are limited, become of great importance in the vastly increased period brought into consideration when dealing with the history of the earth. The changes of eccentricity of the orbit are not of a nature to cause appreciable differences in the mean temperature either of the earth generally or of the two hemispheres; but they may, when combined with changes of the direction of the earth's axis caused by the precession of the equinoxes and nutation, lead to exaggeration of the extremes of heat and cold, or to their diminution; and this would appear to supply the means of explaining the observed facts, though doubtless the detailed application of the conception will long continue to give rise to discussions. Mr. Croll, in his book entitled "Climate and Time," has recently brought together with much research all that can now be said on this subject; and the general correctness of that part of his conclusions which refers to the periodical occurrence of epochs of greatly increased winter cold and summer heat in one hemisphere, combined with a more equable climate in the other, appears to me to be fully established.

These are the considerations which are held to prove that the inorganic structure of the globe through all its successive stages—the earth beneath our feet, with its varied surface of land and sea, mountain and plain, and with its atmosphere which distributes heat and moisture over that surface—has been evolved as the necessary result of the original aggregation of matter at some extremely remote period, and of the subsequent modification of that matter in condition and form under the exclusive operation of invariable physical forces.

From these investigations we carry on the inquiry to the living creatures found upon the earth; what are their relations one to another, and what to the inorganic world with which they are associated?

This inquiry first directed to the present time, and thence carried backwards as far as possible into the past, proves that there is one general system of life, vegetable and animal, which is coextensive with the earth as it now is, and as it has been in all the successive stages of which we obtain a knowledge by geological research. The phenomena of life, as thus ascertained, are included in the organisation of living creatures, and their distribution in time and place. The common bond that subsists between all vegetables and animals is testified by the identity of the ultimate elements of which they are composed. These elements are carbon, oxygen, hydrogen, and nitrogen, with a few others in comparatively small quantities; the whole of the materials of all living things being found among those that compose the inorganic portion of the earth.

The close relation existing between the least specialised animals and plants, and between these and organic matter not having life, and even with inorganic matter, is indicated by the difficulty that arises in determining the nature of the distinctions between them. Among the more highly developed members of the two great branches of living creatures, the well-known similarities of structure observed in the various groups indicate a connection between proximate forms which was long seen to be akin to that derived through descent from a common ancestor by ordinary generation.

The facts of distribution show that certain forms are associated in certain areas, and that as we pass from one such area to another the forms of life change also. The general assemblages of living creatures in neighbouring countries easily accessible to one another, and having similar climates, resemble one another; and much in the same way, as the distance between areas increases, or their mutual accessibility diminishes, or the conditions of climate differ, the likeness of the forms within them becomes continually less apparent. The plants and animals existing at any time in any locality tend constantly to diffuse themselves around that local centre, this tendency being controlled by the conditions of climate, &c., of the surrounding area, so that under certain unfavourable conditions diffusion ceases.

The possibilities of life are further seen to be everywhere directly influenced by all external conditions, such as those of climate, including temperature, humidity, and wind; of the length of the seasons and days and nights; of the character of the surface, whether it be land or water, and whether it be covered by vegetation or otherwise; of the nature of the soil; of the presence of other living creatures, and many more. The abundance of forms of life in different areas (as distinguished from number of individuals) is also found to vary greatly, and to be related to the accessibility of such areas to immigration from without; to the existence, within or near the areas, of localities offering considerable variations of the conditions that chiefly affect life; and to the local climate and conditions being compatible with such immigration.

For the explanation of these and other phenomena of organisation and distribution, the only direct evidence that observation can supply is that derived from the mode of propagation of creatures now living; and no other mode is known than that which takes place by ordinary generation, through descent from parent to offspring.

It was left for the genius of Darwin to point out how the course of nature, as it now acts in the reproduction of living creatures, is sufficient for the interpretation of what had previously been incomprehensible in these matters. He showed how propagation by descent operates subject to the occurrence of certain small variations in the offspring, and that the preservation of some of these varieties to the exclusion of others follows as a necessary consequence when the external conditions are more suitable to the preserved forms than to those lost. The operation of these causes he called Natural Selection. Prolonged over a great extent of time, it supplies the long-sought key to the complex system of forms either now living on the earth, or the remains of which are found in the fossil state, and explains the relations among them, and the manner in which their distribution has taken place in time and space.

Thus we are brought to the conclusion that the directing forces which have been efficient in developing the existing forms of life from those which went before them, are those same successive external conditions including both the forms of land and sea, and the character of the climate, which have already been shown to arise from the gradual modification of the material fabric of the globe as it slowly attained to its present state. In each succeeding epoch, and in each separate locality, the forms preserved and handed on to the future were determined by the general conditions of surface at the time and place; and the aggregate of successive sets of conditions over the whole earth's surface has determined the entire series of forms which have existed in the past, and have survived till now.

As we recede from the present into the past, it necessarily follows, as a consequence of the ultimate failure of all evidence as to the conditions of the past, that positive testimony of the conformity of the facts with the principle of evolution gradually diminishes, and at length ceases. In the same way positive evidence of the continuity of action of all the physical forces of nature eventually fails. But inasmuch as the evidence, so far as it can be procured, supports the belief in this continuity of action, and as we have no experience of the contrary being possible, the only justifiable conclusion is, that the production of life must have been going on as we now know it, without any intermission, from the time of its first appearance on the earth.

These considerations manifestly afford no sort of clue to the origin of life. They only serve to take us back to a very remote epoch, when the living creatures differed greatly in detail from those of the present time, but had such resemblances to them as to justify the conclusion that the essence of life then was the same as now; and through that epoch into an unknown anterior period, during which the possibility of life, as we understand it, began, and from which has emerged in a way that we cannot comprehend, matter with its properties, bound together by what we call the elementary physical forces. There seems to be no foundation in any observed fact for suggesting that the wonderful property which we call life appertains to the combinations of elementary substances in association with which it is exclusively found, otherwise than as all other properties appertain to the particular forms or combinations of matter with which they are associated. It is no more possible to say how originated or operates the tendency of some sorts of matter to take the form of vapours, or fluids, or solid bodies, in all their various shapes, or for the various sorts of matter to attract one another or combine, than it is to explain the origin in certain forms of matter of the property we call life, or the mode of its action. For the present, at least, we must be content to accept such facts as the foundation of positive knowledge, and from them to rise to the apprehension of the means by which nature has reached its present state, and is advancing into an unknown future.

These conceptions of the relations of animal and vegetable forms to the earth in its successive stages lead to views of the significance of type (*i.e.* the general system of structure running through various groups of organised beings) very different from those under which it was held to be an indication of some occult power directing the successive appearance of living creatures on the earth. In the light of evolution, type is nothing more than the direction given to the actual development of life by the surface conditions of the earth, which have supplied the forces that controlled the course of the successive generations leading from the past to the present. There is no indication of any adherent or pre-arranged disposition towards the development of life in any particular direction. It would rather appear that the actual face of nature is the result of a succession of apparently trivial incidents, which by some very slight alteration of local circumstances might often, it would seem, have been turned in a different direction. Some otherwise unimportant difference in the constitution or sequence of the substrata at any locality might have determined the elevation of mountains where a hollow filled by the sea was actually formed, and thereby the whole of the climatal and other conditions of a large area would have been changed, and an entirely different impulse given to the development of life locally, which might have impressed a new character on the whole face of nature.

But further, all that we see or know to have existed upon the earth has been controlled to its most minute details by the

original constitution of the matter which was drawn together to form our planet. The actual character of all inorganic substances, as of all living creatures, is only consistent with the actual constitution and proportions of the various substances of which the earth is composed. Other proportions than the actual ones in the constituents of the atmosphere would have required an entirely different organisation in all air-breathing animals, and probably in all plants. With any considerable difference in the quantity of water either in the sea or distributed as vapour, vast changes in the constitution of living creatures must have been involved. Without oxygen, hydrogen, nitrogen, or carbon, what we term life would have been impossible. But such speculations need not be extended.

The substances of which the earth is now composed are identical with those of which it has always been made up; so far as is known it has lost nothing and has gained nothing, except what has been added in extremely minute quantities by the fall of meteorites. All that is or ever has been upon the earth is part of the earth, has sprung from the earth, is sustained by the earth, and returns to the earth; taking back thither what it withdrew, making good the materials on which life depends, without which it would cease, and which are destined again to enter into new forms, and contribute to the ever onward flow of the great current of existence.

The progress of knowledge has removed all doubt as to the relation in which the human race stands to this great stream of life. It is now established that man existed on the earth at a period vastly anterior to any of which we have records in history or otherwise. He was the contemporary of many extinct mammalia at a time when the outlines of land and sea, and the conditions of climate over large parts of the earth, were wholly different from what they now are, and our race has been advancing towards its present condition during a series of ages for the extent of which ordinary conceptions of time afford no suitable measure. These facts have, in recent years, given a different direction to opinion as to the manner in which the great groups of mankind have become distributed over the areas where they are now found; and difficulties once considered insuperable become soluble when regarded in connection with those great alterations of the outlines of land and sea which are shown to have been going on up to the very latest geological periods. The ancient monuments of Egypt, which take us back perhaps 7,000 years from the present time, indicate that when they were erected the neighbouring countries were in a condition of civilisation not very greatly different from that which existed when they fell under the dominion of the Romans or Mahometans hardly 1,500 years ago; and the progress of the population towards that condition can hardly be accounted for otherwise than by prolonged gradual transformations going back to times so far distant as to require a geological rather than an historical standard of reckoning.

Man, in short, takes his place with the rest of the animate world, in the advancing front of which he occupies so conspicuous a position. Yet for this position he is indebted not to any exclusive powers of his own, but to the wonderful compelling forces of nature which have lifted him entirely without his knowledge, and almost without his participation, so far above the animals of whom he is still one, though the only one able to see or consider what he is.

For the social habits essential to his progress, which he possessed even in his most primitive state, man is without question dependent on his ancestors, as he is for his form and other physical peculiarities. In his advance to civilisation he was insensibly forced, by the pressure of external circumstances, through the more savage condition, in which his life was that of the hunter, first to pastoral and then to agricultural occupations. The requirements of a population gradually increasing in numbers could only be met by a supply of food more regular and more abundant than could be provided by the chase. But the possibility of the change from the hunter to the shepherd or herdsman rested on the antecedent existence of animals suited to supply man with food, having gregarious habits, and fitted for domestication, such as sheep, goats, and horned cattle; for their support the social grasses were a necessary preliminary, and for the growth of these in sufficient abundance land naturally suitable for pasture was required. A further evasion of man's growing difficulty in obtaining sufficient food was secured by aid of the cereal grasses, which supplied the means by which agriculture, the outcome of pastoral life, became the chief occupation of more civilised generations. Lastly, when these increased facilities for providing food were in turn overtaken by the growth of the population, new power to cope with the recurring difficulty was gained through the cultivation of mechanical arts and of thought, for which the needful leisure was for the first time obtained when the earliest steps of civilisation had removed the necessity for unremitting search after the means of supporting existence. Then was broken down the chief barrier in the way of progress, and man was carried forward to the condition in which he now is.

It is impossible not to recognise that the growth of civilisation, by aid of its instruments, pastoral and agricultural industry, was the result of the unconscious adoption of defences supplied by what was exterior to man, rather than of any truly intelligent steps taken with forethought to attain it; and in these respects man, in his struggle for existence, has not differed from the humbler animals or from plants. Neither can the marvellous ultimate growth of his knowledge, and his acquisition of the power of applying to his use all that lies without him, be viewed as differing in anything but form or degree from the earlier steps in his advance. The needful protection against the foes of his constantly increasing race—the legions of hunger and disease, infinite in number, ever changing their mode of attack or springing up in new shapes—could only be attained by some fresh adaptation of his organisation to his wants, and this has taken the form of that development of intellect which has placed all other creatures at his feet and all the powers of nature in his hand.

The picture that I have thus attempted to draw presents to us our earth carrying with it, or receiving from the sun or other external bodies, as it travels through celestial space, all the materials and all the forces by help of which are fashioned whatever we see upon it. We may liken it to a great complex living organism, having an inert substratum of inorganic matter on which are formed many separate organised centres of life, but all bound up together by a common law of existence, each individual part depending on those around it, and on the past condition of the whole. Science is the study of the relations of the several parts of this organism one to another, and of the parts to the whole. It is the task of the geographer to bring together from all places on the earth's surface the materials from which shall be deduced the scientific conception of nature. Geography supplies the rough blocks wherewith to build up that grand structure towards the completion of which science is striving. The traveller, who is the journeyman of science, collects from all quarters of the earth observations of fact, to be submitted to the research of the student, and to provide the necessary means of verifying the inductions obtained by study or the hypotheses suggested by it. If therefore travellers are to fulfil the duties put upon them by the division of scientific labour, they must maintain their knowledge of the several branches of science at such a standard as will enable them thoroughly to apprehend what are the present requirements of science, and the classes of fact on which fresh observation must be brought to bear to secure its advance. Nor does this involve any impracticable course of study. Such knowledge as will fit a traveller for usefully participating in the progress of science is now placed within the reach of everyone. The lustre of that energy and self-devotion which characterise the better class of explorers will not be dimmed by joining to it an amount of scientific training which will enable them to bring away from distant regions enlarged conceptions of other matters besides mere distance and direction. How great is the value to science of the observations of travellers endowed with a share of scientific instruction is testified by the labours of many living naturalists. In our days this is especially true; and I appeal to all who desire to promote the progress of geographical science as explorers, to prepare themselves for doing so efficiently, while they yet possess the vigour and physical powers that so much conduce to success in such pursuits.

FRENCH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE

THERE seems to have been few papers of striking importance read at the Nantes meeting of this Association, though the large number and the solid character of most of the papers show that the scientific activity of France continues to be well sustained. The following are some of the principal papers read in the various sections:—

Zoology.—M. Bureau presented some very interesting observations on the *Aquila pennata*, Brehm and Briss, which he has had the opportunity of closely observing. He is convinced that all the varieties belong to two types, which he has named the white

and the black types. Pairs belong sometimes to one type, very often to two different types; generally the young are completely black or completely white.

M. Giard gave an account of his researches on some controverted points in the embryogeny of the Ascidians, more especially *Molgula socialis*, which he has studied in the zoological laboratory of Wimereux. He has been able to supplement and correct in several respects the conclusions of previous observers. M. Giard also, after long research into the embryogeny of animals belonging to the various classes into which Cuvier divided the *Articulata* and *Mollusca*, proposed another limitation of these two groups. Another paper by the same was concerned with the embryogeny of the pectinibranchiate *Gasteropoda*.

Prof. Sirodot described in detail the results of his researches on Elephants. M. Sirodot remarked that, having had at his disposal a very large number of teeth, he had been able not only to correct the errors committed by Falconnet and De Blainville, but, moreover, to feel confident that the different species of *Elephas* hitherto described as closely allied to the Mammoth have no value whatever. There are a multitude of intermediate forms connecting the *Elephas primigenius* with *Elephas indicus*.

M. Lortet, while in Syria, made some investigations into the organisation and reproduction of fibrous sponges. He has been able to prove the presence and to follow the formation of the male and the female egg. Apart from these genital products, he did not meet, in the sponges which he examined, any other cellular element. M. Lortet did not observe, moreover, any canals running into the great canal of the ovule, canals referred to by a large number of zoologists. M. Lortet also described his observations on the very peculiar fauna of the Lake of Tiberias. This fauna appears to indicate a former communication between the waters of the lake and those of the sea.

Physics.—M. Cornu indicated a very simple process for determining with accuracy the focal distance and the principal points of lenses.

M. Merget explained the very interesting results of his researches on the thermo-diffusion of porous and humid pulverulent bodies. A thermo-diffuser is generally a porous vessel, filled with an inert powder, in the middle of which is a glass tube or a metallic tube riddled with holes. On heating such an apparatus, after having moistened it, steam is disengaged in abundance through the porous substance, while dry air traverses the apparatus in an inverse direction, and escapes by the tube. If this escape be prevented, there is produced a pressure which reached three atmospheres at a dull red heat. If the pulverulent mass or the porous body ceases to be moist, no gas escapes. The author did not explain the fact, but he showed that the explanation of it given by M. De la Rive cannot be accepted. M. Merget is convinced that there is here a thermo-dynamic phenomenon. Thermo-diffusion must play an important part in the gaseous exchanges of vegetable life; the author showed this by taking a leaf of *Nelumbium* as a thermo-diffuser.

M. Gripon communicated to the Section and repeated various experiments which he had performed with films of collodion. In receiving upon a Savart polariscope light polarised by a lamina of collodion, we have there systems of fringes, one normal, the other due to phenomena of secondary interference. By illuminating a film of collodion with the light reflected by a second film, we easily obtain fringes of interference, as in the experiment of Brewster. Collodion films are very diathermanous for luminous heat; they are less so for dark heat.

M. Mascart showed some very curious experiments on the condensation resulting from the expansion of moist air. If a little water is placed in the bottom of a perfectly clean flask, closed by a glass tube terminated by an indiarubber syphon bag, we have a closed space, which soon becomes saturated with moisture. By pressing on the bag the temperature rises, and there can be no condensation. But by allowing the bag to resume, by its elasticity, its original form, the air expands, is consequently cooled, and, contrary to what is usually observed, no condensation takes place. To produce the condensation ordinarily observed, it is sufficient to introduce into the flask some unfiltered air, while filtered air produces no effect. In the same way very beautiful clouds are obtained by introducing a little tobacco smoke, or gases resulting from any kind of combustion. These experiments may be of some use in explaining the formation of clouds.

M. Deprez presented an ingenious electric chronograph, intended to estimate by the graphic method intervals of time extremely small, as the duration of a shock.

M. Cornu explained his experiments on the rate of light, by the method of M. Fizeau. (See NATURE, vol. xi. p. 274).

Dr. Moreau explained some points in his investigations on the swim-bladder of fishes, and showed particularly that in proportion as a fish sinks the effort which it must make diminishes.

M. Dufet read a paper on his researches into the electric conductibility of pyrites.

In the Section of *Geology* and *Mineralogy*, most of the papers referred to local topics. Of those of general interest we mention the following:—M. Henry Dufet described his experiments on the thermic conductibility of certain schistose rocks, from which he drew some interesting conclusions regarding the deformations of the fossils contained in such rocks. M. Charles Vélain read a paper on his exploration of the islands of St. Paul and Amsterdam, while on the expedition for observing the Transit of Venus. M. Lory presented some considerations on the dislocation of rocks in mountainous countries.

Botany.—In this section M. Sirodot gave an account of his researches on the classification and development of *Batrachospermum*, and M. de Lanessan spoke on the floral organogeny of *Zostera*.

M. J. Chatin described the results of his histological and histogenic researches on the interior leaf glands and some analogous productions. After having studied the mode of formation of the structure of these various organs in many families, he draws the following conclusions:—1. The interior leaf glands originate always in the mesophyll. 2. These glands are formed by differentiation from a cellule in which multiplication by division is rapidly produced, so that except in some Lauraceæ the gland is always formed, in its perfect state, from a cellular mass, more or less considerable. 3. The products of secretion are constantly forming in the cellules proper of the gland. 4. The elements of the latter are re-absorbed from the centre to the circumference, and thus form a reservoir where the product of secretion is amassed. 5. In certain plants, and by an analogous phenomenon, there may be formed in the leaf true secreting canals. 6. The leaf-glands are almost constantly situated in the vicinity of the fibro-muscular bundles. 7. In many plants there exist at different points of the stalk, of the branches, and of the petioles, certain productions on the whole comparable to the interior leaf-glands.

M. Merget gave the result of his researches on the interchange of gases between plants and the atmosphere. He concluded with the following statements:—1. The means by which the interchange of gases is effected in plants are the stomata and accidental openings; it is by diffusion in the stomata, and not by dialysis through the cuticle, that exterior gases penetrate into the interior of a plant, and that internal gases escape. 2. The entry of atmospheric gases is due to the action of the physical force produced by the phenomena of gaseous thermo-diffusion. M. Merget concluded by some interesting details on the function of chlorophyll.

M. Baillon read a very interesting communication on the Amentaceæ.

In the Section of *Anthropology*, we note the following papers:—Dr. Lagneau read a careful and elaborate memoir on the ethnogeny of the populations of the N. W. of France, in which he reviewed the various peoples which have contributed to the formation of the former and present population of the region comprised between the sea, the Saône, and the Loire.—M. Chauvet read a report relative to the excavations undertaken by the Archæological Society of Charente, in the tumuli on a woody plateau near a Roman road, and entered into details of a nature to clear up certain controverted points of prehistoric archæology. From the objects found in these explorations, M. Chauvet develops a doctrine according to which there was no gap between the various civilisations from an industrial point of view.

As usual, a very large number of papers belong to the Section of Medical Sciences; some of these are of more than merely technical interest, but our space prevents us from referring to them in detail. A full report of the proceedings will be found in the *Revue Scientifique* for August 28 and following weeks.

THE AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.—DETROIT MEETING

THE American Association for the Advancement of Science held its twenty-fourth annual meeting at Detroit, Mass., from Aug. 11 to 17 inclusive. Some of

its previous meetings have surpassed this one in respect to the number of members present, but none can be regarded as superior to it in the general excellence of the communications presented. The causes of the slight falling off in attendance may be briefly mentioned. The cities of the Atlantic sea-board where local scientific societies have been longest in existence, and where a large proportion of the membership of the Association is resident, are 750 to 1,000 miles, chiefly eastward, from Detroit. That city, on the boundary line between the United States and Canada, is also considerably to the northward of the larger centres of population in the Western States. Thus, then, the assembling at Detroit required, in the great majority of instances, a long, tedious, and rather expensive journey. It need not be concealed that, owing to the widespread effects of the depression in all branches of business in the United States—extending even to the learned professions—the pecuniary means of members were in many cases more restricted than usual; and this fact in many cases decided adversely the question of attendance at the meeting.

A protracted series of discussions in that and previous years resulted at the meeting of 1874 in the Association's adopting a new constitution, which first displayed its general effects at Detroit. The two prominent features of change were modelled upon the system of the British Association. A division was made between Fellows and the rest of the members, prominence or usefulness in science being required for election to the honours of Fellowship. This elective process did not, however, apply to the Fellows who became such between the meetings at Hartford and Detroit, and consequently many have been admitted to the dignity who have no claim to it by scientific labours. To the Fellows rather than to the general membership, the guidance and management of the Association is confided. The effect of this change was very apparent at Detroit in the exclusion of a large number of communications which would easily have passed the ordeal of committees and been read at the meetings of previous years. The chosen remainder reached a higher average of excellence than has been hitherto attained, and in the section of Physics, Mathematics, and Chemistry, the weeding process so reduced the number of communications that the supply gave out before the close of the meeting; but this may also be accounted for by the fact that the sub-section of Chemistry, for the first time organised and separately at work, much facilitated the dispatch of business in Section A. A variety of concurrent causes presented a like result from being reached in Section B, devoted to Geology and Biology. The geologists are always largely in force when the Association meets west of the Alleghanies, the development of the mining resources of the newer States and Territories rendering their labours of immediate economic interest and value. There was an extraordinary accession of ethnological papers, prompted chiefly by numerous discoveries recently made in new and very thorough explorations of Indian mounds. The great injuries which the food crops of the United States have suffered from insects within a year or two, called forth several papers of merit from the leading entomologists, as well as much debate and some action on the part of the Association. Besides all the foregoing subjects, there was an unusual number of papers on specific investigations in natural history. These were largely the fruit of the seed sown at the Anderson School on Penikese Island, by the lamented Agassiz. The pupils there instructed, mostly for the first time, in observing the habits of animals, dissecting their forms and studying their differences, were from all parts of the Union. Nearly all of them are teachers in high schools and the smaller colleges. Having been thus started on the path of original investigation, they already find something new to relate, and their papers had a charm of freshness, very different from those of older members who have found their own easier grooves of thought and lapsed into routine.

Another important feature introduced at this year's meeting by the new constitution, resulted from the election of two vice-presidents, who were the presiding officers respectively of Sections A and B. Following in this respect the system of the British Association, each of these officers opened his Section with an address, in which a department of science was made the subject of a broad survey. Hitherto the address of the retiring President has been the only one at each meeting of this character; the change gives two such addresses in addition, and may in future years give a greater number. At the Detroit meeting the address of Prof. John L. Le Conte, of Philadelphia, the retiring President, brought forward in a general way the aid to a knowledge of past conditions on the globe, which might be derived from a study of existing forms. Prof. Le Conte's own lines of investigation have been more especially confined to the study of insects, and from the facts thus derived he drew most of his illustrations. He regards organic life as furnishing everywhere evidences of design, and a principal portion of the address was devoted to deprecating the conflict between science and religion, and to urging patience rather than controversy. Prof. H. A. Newton, the astronomer, of Yale College, delivered the opening address of Section A. He urged the study of pure mathematics as a basis for work in all the sciences; adducing, through a wide range of illustration, the evidences of its value in advancing knowledge. The want of a thorough knowledge of the higher mathematics he regarded as a frequent defect among American men of science, while their dependence upon mathematical methods in all branches of investigation was every day becoming more absolute.

The address of Prof. J. W. Dawson, Principal of McGill College, Montreal, before Section B, was one of the most important given at the meeting. He is well known as the most able and prominent anti-Darwinian in America. His address took the form of a discussion of the question, "What do we know of the origin and history of life on our planet?" Space will not permit an analysis of this address, which reviewed the evidence furnished by the Silurian fossils at great length, regarding it as inconclusive when applied to the support of evolution theories. Prof. Dawson vigorously opposed the hypothesis that organic life is a product of mere physical forces.

Thus the weight of utterance in two of the addresses is adverse to Darwinian theories, but this is no index to the general sentiment of the leading students of biology in the Association. The officers chosen for next year include names noted in connection with the advocacy of the most advanced evolutionary doctrines. The venerable President-elect, Prof. Wm. B. Rogers, of Boston, was, in years gone by, the most successful antagonist, in discussions of the new theories, that Prof. Agassiz encountered in America. Prof. Edward S. Morse, Vice-president-elect, of Section B, has attained prominence in the expression of strong Darwinian views before large popular audiences in almost every city of the United States. Prof. Charles A. Young, of Dartmouth College, well known by his spectroscopic researches on the sun's chromosphere, was elected Vice-president to preside over Section A. It is a somewhat remarkable circumstance that six out of eight of the officers for next year are residents of the New England States, the three highest positions falling to their share. The citizens of Detroit did everything in their power to make the visit of the Association pleasant. Several social entertainments and excursions by boat and rail were provided, and the Detroit Scientific Association aided materially in these hospitalities. The next meeting will be held August 23, 1876, at Buffalo.* W. C. W.

* Next week we shall refer to some of the principal papers in detail.

NOTES

We have received from the Central Meteorological Institute of Sweden the Daily Weather Charts published by the Office for the months of January, February, March, and April last. These charts, constructed from data supplied from nine stations in Sweden, nine in the British Isles, four in Norway, two in Denmark, and four in Russia, including Arkangel, are valuable additions to the daily weather literature of Europe, and supply important data, showing more particularly the influence of the Scandinavian mountains and of the Baltic at different seasons on European storms, and the influence of the systems of high and low pressures over the Baltic and neighbouring regions on the weather of Great Britain at the time.

In the *Bulletin Hebdomadaire* of the Scientific Association of France for September 5, Prof. V. Raulin, after referring in strong, but not too strong, terms to the practical neglect with which the investigation of inundations has been treated in the south-west of France, energetically urges the organising of Hydrometric Commissions similar to that of Lyons, to collect together observations of the rainfall and heights of the rivers, and compare and discuss them with the view of deducing therefrom the laws which rule the commencement, development, and progress down the several river basins, of ordinary floods, but more particularly of those great inundations which prove so disastrous to life and property. He recommends the formation of Hydrometric Commissions at Bordeaux for the basin of the Gironde; at Libourne, for the basin of the Adour; and at Carcassonne or Narbonne, for the basin of the Aude. When the enormous saving to life and property which would have been effected through such organisations, had they existed, is considered, during the late deplorable inundation, we cannot for a moment doubt that Hydrometric Commissions similar to that of Lyons will at once be organised in the basins of the Garonne and its affluents.

The annual Provincial Congress of the Iron and Steel Institute was opened in the Owens College, Manchester, on Tuesday, Mr. William Menelaus, the President of the Institute, in the chair. The Mayors of Manchester and Salford and the Bishop of Manchester were present by invitation, at the opening proceedings, and the more distinguished members of the Institute present included Mr. Henry Bessemer, Sir Joseph Whitworth, Mr. J. Lowthian Bell, and Mr. Crawshay. The Bishop of Manchester gave a very happy address. Referring to the fact that the Duke of Devonshire is an ordinary member of the Institute, one indication among others that the Duke is a man of high scientific attainments in the department of science with which the Institute is connected, the Bishop said that what struck him was how the old order had changed, "giving place to the new," and he was rather inclined to think the new order perhaps somewhat better than the old. The local authorities and the leading industrial firms in Manchester and the surrounding districts have done their part towards rendering the meeting a success. On Tuesday evening the Reception Committee received the members of the Institute at a *conversazione* in the Town Hall, and last evening the members dined at Hulme Town Hall. A large part of the time of the meeting will be spent in visits to places of industrial interest in Manchester and neighbourhood.

The proposed University College for Bristol received some impulse from the members of the British Association at a meeting held last week. Sir John Hawkshaw said foreign industrial competition with England was a very real thing, and would soon be much greater unless scientific education was fostered. Sir W. Thomson begged the promoters not to starve the literary department, and Prof. Balfour Stewart said that would not be any departure from science, for there was now a science of culture and literature. Prof. Jowett said that the appointment of the first professors would be the most critical event in the history of the College, for on their force of character depended the creation of the College out of nothing. Although not more than about 20,000*l.* has been already promised, it is intended to commence operations soon, in the belief that practical successful working will eventually bring in all the funds that are required.

Last Saturday evening the Brothers Henry, the great French asteroid finders, visited the equatorial buildings of the Paris Observatory, under the guidance of M. Leverrier. Along with them was Mr. Watson, the celebrated American astronomer, who has himself discovered no fewer than nineteen small planets. Mr. Watson was the head of the American Transit Expedition to Pekin.

The death of M. de Rémusat renders almost certain the election of M. Dumas to fill the place vacated by the demise of M. Guizot in the French Academy. It is not only that M. Rémusat voted for M. Jules Simon and that the votes were equal, when the election was postponed for six months, but M. Jules Simon has desisted from his candidature, and intends come forward for the seat of his friend Rémusat.

At the Radcliffe Observatory, Oxford, on Sept. 3, 9h. 55m. Greenwich mean time, a meteor was observed about three times the apparent magnitude of Jupiter, proceeding from Saturn downwards about twelve degrees, in the direction of δ Piscis Australis. Colour, blue to green; time visible, five seconds. At disappearance it threw off a piece about the apparent size of Saturn.

The Geological Society of France held a congress at Geneva last week, and visited some of the places most interesting to geologists in that part of Switzerland.

Baron Ferdinand von Mueller, of Melbourne, has just published a second supplement to his previous lists of "Select Plants readily eligible for Victorian Industrial Culture." These lists of Baron Mueller's are useful to a certain extent, many economic plants being thus brought together, arranged alphabetically under their scientific names, and short descriptions given of their uses. Whether many of them are worth the trouble of cultivation as industrial or economic plants, is a question which the cultivator can only know by experience, but which the botanist will be able to decide upon by a mere glance at the list. Thus we find included *Aloe dichotoma*, the Tree Aloe of Damara and Namaqualand, referred to in Nature, vol. xi. p. 89; scarcely an industrial plant, we should say. A peculiar and interesting addition to this second supplement is a geographic index, the plants being alphabetically arranged under distinct heads, such as "Northern and Middle Europe," "Countries at or near the Mediterranean Sea," "Middle and Temperate Eastern Asia," &c.

The coffee plant has been grown in Queensland for some years, but it is only of late that its cultivation has been attempted with a view to its exportation as a commercial article, and we now learn that the plants have become attacked by blight, or fungus, which has given rise to some anxiety and inquiry as to whether the disease is identical with the *Hemileia vastatrix*, which has proved so destructive to coffee plants in Ceylon. We shall probably soon hear more about this, as the subject of the extension of coffee culture in Queensland is about to be taken up by Mr. L. A. Bernays, F.L.S., Clerk of the Legislative Assembly of Queensland, and a vice-president of the Queensland Acclimatisation Society, and who moreover is known as the author of a little work on the cultivation and propagation of the olive in Australia.

The Literary and Natural History Society of Keswick has

commenced the formation, in a small room in the Town Hall, of a collection to illustrate the natural history of the district. They have already got together a considerable number of birds, birds' eggs, fishes, and insects, as well as the commencement of a herbarium; also a collection of the rocks and ores and of the scanty fossil fauna of the neighbourhood. A few very interesting celts and other prehistoric remains have been found in the district, some of them close to the celebrated "Druids' Circle" in the immediate vicinity of Keswick. There is evidently here a rich field for the zeal and energy of the local naturalists and archæologists.

THE *Quarterly Journal of the Meteorological Society*, No. 15, has just been published, containing among other matters papers on a Universal System of Meteorography, by Prof. F. Van Rysselberghe; Results of Meteorological Observations at Patras, Greece, during 1873, by the Rev. H. A. Boys; and Notes on Sea Temperature Observations on the British coasts, by R. H. Scott, F.R.S.

A ZOOLOGICAL collection of remarkable interest, the *Times* states, more particularly to Londoners, has been added during the present year to the British Museum. It consists of the Thames Valley series of remains of British elephants, rhinoceri, deer, ox, &c., which have been discovered in the Ilford Marshes, near Stratford, during the last thirty years, and has hitherto formed the unique private collection of Sir Antonio Brady, of Stratford-le-Point. The nature and value of this collection, as now exhibited at the British Museum, will appear from the following facts:—It contains remains of no less than 100 elephants, all of which have been obtained from Ilford. These are referable to two species, viz., *Elephas primigenius*, the mammoth, and *E. antiquus*, a more southern form. The skeletons of each species are represented by many fine examples, and the collection of teeth and jaws represents elephants of every age and size, from the sucking calf, with milk molars, to the patriarch of the herd, whose last molars are so worn that they must have become useless for grinding his food. One characteristic of the Ilford elephants is the number of the plates in the last molar tooth, which has never been found to exceed nineteen or twenty, as against the twenty-four and sometimes twenty-eight in other species. The largest tooth is ten inches in length. The rhinoceri of the Thames Valley are represented by eighty-six remains, of three species, distinguished by the character or the absence of the bony nasal septum—viz., *Rhinoceros megarhinus*, *R. leptorhinus*, and *R. tichorhinus*. The British lion, which recent geology shows to have been no myth, is represented by a lower jaw and a phalanx of the left forefoot. The Brady collection also includes the Thames Valley hippopotamus, which is found at Grays, as well as at Ilford. The ruminants, such as the stag, bison, and ox, constitute fully one-half the collection, numbering more than 500 specimens. They include seven specimens of the great Irish Elk (*Megaceros hibernicus*) and fifty of the Red Deer.

WE learn from the *Lancet* that the sanitary authorities of Leicester have determined to institute an inquiry into the causes and conditions of the high mortality in that town from diarrhœa, and Dr. Beck and Dr. Frankland have been appointed to carry out the inquiry. It was recently shown in NATURE (vol. xii. p. 281) that the average mortality in Leicester from diarrhœa, and among infants, has far exceeded that of any other large town in England, and that whereas the average highest mortality from diarrhœa in any other large town during any week of the year has not exceeded 10·5 on an annual mortality per 1,000 of the population, in Leicester the average reaches 15·8. This large mortality from diarrhœa has been a characteristic of Leicester each year since the Registrar-General began to publish the returns for Leicester in his weekly reports, the distribution of the deaths during the warm weeks and the number being plainly and directly dependent on the temperature. During the six weeks ending 14th August last the deaths from diarrhœa in Leicester have been 121; during the same six weeks of 1874 when the temperature was higher, the deaths were 156. The peculiarity of the mortality of Leicester lies in this: whilst the rate of its infant and diarrhœa mortality is enormously high, its annual death-rate for the whole population is moderately low, being only 26 per 1,000 of the population; whereas in Liverpool and Manchester it is fully thirty, or one-fifth more. Hence, in commencing a scientific inquiry into the causes and conditions of this great destroyer of the infant life of our large towns, no better beginning could have been made than with Leicester. For reasons stated by Mr. Buchan and Dr. Mitchell in their recently published paper "On the Influence of Weather on Mortality" (Jour. Scot. Met. Soc., vol. iv. p. 232), a separation of the infants that die, or are attacked, into three classes—viz. (1) those nursed at the breast, (2) those fed on cows' milk, and (3) those fed on slops—is most desirable in such inquiries, particularly since facts seem at present to point to the intimate bearing, on this vitally important question, of high summer temperatures on milk exposed to them, especially on the small portion of milk which may be carelessly left in the apparatus used in the case of those infants that are fed on cows' milk.

WE have before us three contributions to American Botany:—1. Conspectus of the North American Hydrophyllaceæ, by Prof. Asa Gray. The genus *Eutoca*, well known under that name to flourish in this country, is here merged in *Phacelia*, which numbers about fifty species. 2. Revision of the genus *Ceanothus*, and descriptions of new plants, by Sereno Watson. 3. Botanical observations in Southern Utah in 1874, by Dr. C. C. Parry; a series of papers reprinted from the *American Naturalist*. The south-western portion of the vast territory of the United States has been for some years one of the most fertile portions of the surface of the earth in yielding new species of plants; very little having been done, before Dr. Parry's visit, since the working up by Torrey and Gray of the results of Col. Fremont's expedition in 1844. A very interesting sketch of the botany of the district is contained in these papers, together with notes of many new species described by Prof. Gray and others.

PROF. PALMIERI has discovered a new instrument which he calls a "diagometer," and which is constructed for the rapid examination of oils and textures by means of electricity. What the apparatus will do, Prof. Palmieri details thus:—1. It will show the quality of olive oil. 2. It will distinguish olive oil from seed oil. 3. It will indicate whether olive oil, although of the best appearance, has been mixed with seed oil. 4. It will show the quality of seed oils. 5. Finally, it will indicate the presence of cotton in silken or woollen textures. The professor has been complimented for this invention by the Chamber of Arts and Commerce at Naples, who have published a full description of the apparatus, with instructions for use.

THE additions to the Zoological Society's Gardens during the past week include an Indian Leopard (*Felis pardus*) from India, presented by Mr. G. Jasper Nicholls; an Arctic Fox (*Cani lagopus*) from the Arctic Regions, presented by Mr. C. R. Wood; a Montagu's Harrier (*Circus cineraceus*), European, presented by Capt. Hadfield; a Lesser Sulphur-crested Cockatoo (*Cacatua sulphurea*) from Moluccas, presented by Mrs. H. M. Smith; a Wrinkled Terrapin (*Clemmys rugosa*) and five American Box Tortoises (*Terrapene carinata*) from Nicaragua, presented by Mr. Edmond Isaacson; a West African Tantalus (*Tantalus ibis*) from West Africa; two Brazilian Tortoises (*Testudo tabulata*) from South America, an Abyssinian Pentonyx (*Pelomedusa gehafi*) from Abyssinia, deposited; an Indian Fruit Bat (*Pteropus medius*) from India, purchased; a Wapiti Deer (*Cervus canadensis*) born in the Gardens.

SCIENTIFIC SERIALS

THE first fascicule of this year's *Bulletin de la Société d'Anthropologie de Paris* gives the new president, M. Dallas' inaugural address, in which he draws attention, amongst other points, to the importance in reference to anthropology of the study of "demography," or that branch of sociology which treats of the influence of prosperity on populations in determining the maxima and minima of births and deaths. After speaking with just pride of the merit due to the Paris Society of having inaugurated the systematic study of anthropology, and of having served as the model for similar institutions in all the great cities of the old and new Continent, the President announced that in consequence of the appointment of two new secretaries, MM. Astézat and Gerard de Rialle, and of a general-assistant secretary, M. Magitot, as well as through the adoption of different rules for the transmission of papers, the publication of the *Bulletins* would no longer be subject to the delay which had of late years marked their appearance. In the discussion which followed M. de Mortillet's paper on the circles drawn on a fragment of a human skull found in the dolmens of Lozère, M. de Leguay took occasion to express his conviction that the men who constructed these megalithic monuments must have been possessed of tools of metal, and provided with textile fabrics such as strong ropes, capable of being used to lift and pull heavy weights. He does not venture to give an opinion as to the probable antiquity of these remains, but he believes that no one acquainted with practical mechanics can attach faith to the commonly accepted theory that these stones have been conveyed from distances and elevated to their present positions by slides or rollers. The speaker, moreover, pointed to the fact that a bronze bracelet of indisputable Gallic fabrication was found below one of the Lozère dolmens; and he is of opinion that the men who erected the latter used iron as well as bronze.—In discussing the human remains belonging to upwards of 200 individuals found by M. de Baye in the Baye caverns on the Marne, among which were skulls having circular lines and perforations similar to those of the Lozère fragment, M. Broca drew attention to the two distinct cranial types which they presented, the one being dolicephalic, while the other was sub-brachycephalic.—Those interested in abnormal types of humanity will find much suggestive matter in several papers referring to the so-called Aztecs introduced into Europe twenty-five years ago, in whom microcephalism—whatever its cause may be—is more strikingly exhibited than in any other known case.—M. Hamy's learned paper on artificially produced microcephalism among the sacerdotal classes of Central America, gave rise to an animated discussion in which Dr. Broca and Madame Royer took part.—Dr. Mondières has laid an interesting report before the society, in which he supplies much hitherto unknown information in regard to the prevalent diseases of the natives of Cochin China, the remedies applied, and the practices resorted to by the bonzes for working pretended miracles. The author describes the physical characteristics of the two distinct races, the Ming-huongs and true Cambodians.—M. Broca exhibited the skeleton of a Peruvian mummy-fœtus which had been taken from an ancient cemetery near Callao, laid bare by an earthquake. It was found in the portion of the ground appropriated to infants, and where each little body was tied tightly into a cloth and had enclosed with it a number of minute toy-like vessels, utensils, and arms. The fœtal mummy was examined with special reference to the existence of the supernumary cranial bone, which some Spanish writers affirm to be a characteristic of the Inca race. No such bone could, however, be detected in the Peruvian mummy, whose skull was precisely similar to those of Europeans at the same period of fœtal existence.

THE *Journal de Physique théorique et appliquée* for July contains the following original papers:—On the acoustic theory of beats, by Terguem and Boussinesq.—On the use of collodion films in Physics, by E. Gripon.—On the interior double reflexion of uniaxal crystals, by M. Abria.—A note by M. Henri Becquerel, on the action of magnetism upon the induction spark.—On a new method to produce sonorous vibrations and interferences on mercury, by C. Decharme.—On the channelled space spectra of MM. Fizeau and Foucault, by M. Nodot.

Gazzetta Chimica Italiana (fasc. vi. 1875.)—This number contains the following papers:—Defence of the old theory of electrostatic induction, by G. Pisati.—Chemical dissociation as applied to the interpretation of some volcanic phenomena; analysis and synthesis of a new mineral from Mount Etna, which is of common origin in volcanoes, by Prof. O. Silvestri—Experimental researches by Dr. L. Pesci, on peroxide of iron as generator of nitric acid, and on the origin of nitre in some experiments of Cloëz.—Chemical and toxicological researches by Dr. C. Bettelli, on oleandrine and so-called pseudocurarine.—On albumen assisting the solution of the tricalcic phosphate of the blood, by M. Mercadante.—On the presence of leucine in vetches, by A. Cossa.

THE *Notizblatt des Vereins für Erdkunde zu Darmstadt*, series iii. heft xiii. contains but one paper of scientific interest, all the rest of the contents being devoted to statistical reports from the central station for statistics of the Grand Duchy of Hessen, and to tables relating to these reports. The paper referred to records the meteorological observations of the Kataster Office at Darmstadt during the whole of the year 1873, and is accompanied by a very elaborate table.

THE *Journal de Physique théorique et appliquée* for August contains the following original treatises:—On double spectra, by M. G. Salet.—Exposition of some experiments relating to the theory of induction, by M. Felici.—On a new method to determine quickly the refractive index of liquids, by MM. Terquem and Trannin.—On a new form of electro-magnet, by M. A. Camacho.—On elliptic polarisation, by L. Mouton.—The remainder of the journal contains extracts and translations from *Poggendorff's Annalen* and from the *American Journal of Science and Arts.*

SOCIETIES AND ACADEMIES

PARIS

Academy of Sciences, August 30.—M. Frémy in the chair.—The following papers were read:—A note by M. Leverrier on Jupiter's mass and on some new researches on Saturn.—On the formation of hail, by M. Faye.—Tenth note on the electric conductibility of bodies known to be bad conductors, by M. Th. du Moncel.—Report by a commission appointed to examine a memoir by M. Haton de la Goupillière, entitled, Direct and Inverse "developpoids" of successive Orders.—A note by M. J. Künckel, on Lepidoptera with perforating proboscis as destroyers of oranges (Ophidera).—Remarks on the granitic diluvium of plateaus; lithological composition of the caolinic sand of Montainville (Seine et Oise), by M. Stan. Meunier.—On the germination of Chevalier barley, by M. A. Leclerc.—Researches on the ferments contained in plants, by M. C. Kossmann.—A number of communications of minor interest.—On the formation of aniline black, obtained by the electrolysis of its salts, by J. J. Coquillion.—On the development of unfertilised ova of frogs, by M. G. Moquin Tandon.

THURSDAY, SEPTEMBER 16, 1875

*THE SCIENCE COMMISSION REPORT ON THE ADVANCEMENT OF SCIENCE**

WE pass now to the fourth and last head, which deals with

The Central Organisation which is best calculated to enable the Government to determine its action in all questions affecting Science.

The Commissioners discuss two questions separately under this head. (1) The appointing of a Minister of Science. (2) The establishing of a Council of Science.

Extracts from the Evidence relating to the Appointment of a Minister of Science.

The Commissioners observe—

"We have received a large amount of evidence in favour of the appointment of a Minister of Science. There has been almost complete unanimity among the witnesses on this point."

Indeed, the necessity for such a minister is the one theme never lost sight of throughout the bulky volume of evidence. Scarcely a proposal is made which does not either involve or imply this necessity. Expunge all the recommendations that a Minister of Science should be appointed, and there will scarcely remain a recommendation that can be practically carried out, or that is not, on its face, almost a confessed absurdity.

The extracts which we append from evidence on this question form but a very small portion of the representations submitted to the Royal Commission, of which they must be considered only samples.

Prof. Owen :—

"I conceive that the recommendation by Bentham in the last century of such a minister can hardly fail to be practically adopted before the close of the present century, and that the necessity of having a minister for such a purpose will be recognised."

Sir W. Thomson :—

"Would you contemplate that a new department of the State should be constituted for directing the scientific work of the Government?—It would be quite necessary to have a Minister of Science; it is indeed, I think, generally felt that a Minister of Science and scientific instruction is a necessity."

"Not a minister of other instruction?—Specially of scientific instruction, and not under any national education board, but a minister of science and scientific instruction. The minister would necessarily be in Parliament and a political man, but it would be very rare that he could also be a scientific man, and perhaps not desirable that he should be a scientific man, but he must have able scientific advisers always at hand."

"Could any such duties be well assigned to any existing department of the State?—I believe not."

"You spoke of the necessity for having a Minister of Science; do you conceive that it would be requisite to have a cabinet minister for education and a second cabinet minister for science, or would you contemplate that the minister for education should be the minister for science?—I do not wish absolutely to fix it beforehand; on the whole I think, however, that the title of Minister of Education would not suffice. If there is to be a minister it must be a minister of science and education. There might be a minister of science and education, with a chief secretary or under minister for national and elementary education, and another for the advancement of science and for the higher scientific instruction. But naturally the minister of education must act for the masses; that must be his great duty, and however much he might wish to act for science, he has still a great duty to the masses. On the whole I think it would be preferable to have a distinct minister of science and scientific instruction. A minister of science and scientific instruction, as a subordinate to a chief minister of science and education, might probably be a very good arrangement.

"The Minister of Science administers knowledge to the whole country."

Col. Strange :—

"It seems to me that in the first place there should be some means of bringing science fully before the nation through Parliament. I know of no means of doing this that is in accordance with our constitutional procedure, except through a minister of State; and therefore assuming science to be a matter of enormous national importance, I think it is essential that it should be all brought under one minister of State, who should be responsible to Parliament for everything which is done in the name of the nation to further science, and who should frame his own estimates and keep them distinct from those of departments which have little or nothing to do with science. . . . I think that there should be an estimate for science just as there is an estimate for the army and for the navy. . . .

"What I should be glad to see would be a minister for science; but I dare say that if proper assistance were given to such a minister, he might superintend other departments as well; for instance, as on the Continent, he might superintend education and the fine arts. I think it would be preferable that he should be for science only. I think there is quite enough for him to do in England, for it to be done thoroughly; but rather than have no minister I would assign to him also education and the fine arts."

"There would be a difficulty, would there not, in defining the boundaries between the duties of the minister for science and the minister for education?—I think not. I think one would relate to education, which is quite a distinct thing from national research, and I think that they should be kept as distinct as possible. I think one great evil now existing is the mixing up of those two things. Throughout my evidence I have here and there expressed the same opinion that they should be kept distinct, one being the means, the other the end; instruction I conceive to be the mode of growing a certain number of persons fit to investigate."

Mr. De la Rue :—

"I think that science ought to be recognised in the Ministry by the appointment of a Science Minister, in order that all matters relating to science might come properly under the cognisance of the Government, and that whenever the Government sought the aid of scientific men it should be through the intervention of the Science Minister. . . ."

Mr. John Ball :—

". . . . If science is to be aided effectually, and at the same time controlled effectually, there should be some permanent officer in the department of the Government that has its relation with science, whose duty it should be and who should be responsible for making himself generally aware of the state of science and the doings of its cultivators, and who should be the proper person to advise the Government, not as to the best mode of deciding a strictly scientific question, but as to where the means for solving it are to be had. I look upon it at present as being a wholly haphazard matter how questions of science or connected with science and affecting the progress of science are decided in the public offices, and I speak from

* Continued from p. 392.

some slight personal acquaintance with the matter during the short time that I was in the public service in Parliament."

"You stated, did you not, that you thought it desirable that there should be some permanent official to represent and advise the Government in its relations to science?—Decidedly."

General Strachey :—

"The first conclusion that I arrive at is that all questions relating to scientific matters that arise in the operations of the Government should be dealt with by one of the chief ministers of the Crown, and the officer at the head of the Education Department seems to be the most suitable of such officers. It has been, I know, suggested by some persons that it would be better if there were a separate department for science. That I venture to doubt. . . . .

"Under such an education and science department there would be a natural division of the duties, which would probably lead to the appointment of some permanent officer in the position of an under secretary of State, who would have specific charge of the scientific duties of the department as distinguished from the educational duties, which constitute a distinct branch of administrative work. . . . .

"The principal officers in the proposed scientific branch of the department should be, by their scientific qualifications, capable of disposing of the ordinary current business under their charge. . . . ."

Dr. Sclater :—

"Do you agree with [Col. Strange's] views as to the creation of a Minister of Science and a Council of Science?—Yes, I agree generally with his views; I think that it would be very desirable for the interest of science."

"Do you think it would be desirable that the existing State scientific institutions should be removed from the control of the Admiralty, the Office of Works, and other departments under which they are now placed?—I think it would be a very great advantage that they should be removed from those departments and placed under one minister."

"Have you any opinion as to whether the work could be done by a Minister of Education, supposing such a minister were appointed?—I think it would hardly be expected that a minister should be appointed only for science; and as I believe it is the case in continental countries that that department is given to the Minister of Education, I think that we could not follow a better example here."

Prof. Balfour Stewart :—

"I think it [the Ministry of Science] might form a division, perhaps, of the Ministry of Education."

Mr. Farrer :—

"I dislike very much the idea of establishing new departments of the Government. If it were possible that this business could be placed upon the Minister of Education, who is becoming more and more important, I think that would be much better than establishing a separate department for the purpose."

Sir George Airy is perhaps the only witness of authority who does not seem able to perceive that any advantages would follow the creation of a Science Minister. The following is his evidence on the question :—

"Do you see any inconvenience arising from the several scientific institutions that are more or less connected with the Government being under different departments?—Not that I am aware of."

"You are content that the Royal Observatory at Greenwich should remain under the Board of Admiralty. You do not require to have a Minister of Science, or a Minister of Education?—No; we are naturally connected in these respects with the Admiralty. . . ."

The Astronomer Royal appears to have confined his attention to the wants of the great Observatory of which he has so long been the distinguished director. It is to be regretted that he abstained from enunciating his views on the larger question of the administration which an extension and systematisation of national science would render necessary.

The Proposal to establish a Council of Science.

A proposal to establish a Council of Science was brought before the Government by the Royal Society in 1857, upon a Report from the Government Grant Committee of that society.

The object of the Committee was (evidence of Sir E. Sabine, qu. 11,117) to determine "whether any measure could be adopted by the Government which would improve the position of science or its cultivators in this country."

This Report, after enumerating the various matters connected with science which should properly come under the supervision of the Government, concludes by naming two bodies under whose advice that supervision might be conducted. They say :—

"11. Assuming that the above proposal should meet with the approval of her Majesty's Government, it will be desirable to ascertain what mode of constituting such a board would inspire them with most confidence in its recommendations. Two modes may be suggested in which such a board might be organised. First, the Government might formally recognise the President and Council of the Royal Society as its official adviser, imposing the whole responsibility on that body, and leaving it to them to seek advice when necessary in such quarters as it may best be found, according to the method now pursued in the disposal of the Parliamentary grant of 1,000*l*. The second method would be to create an entirely new board, somewhat after the model of the old Board of Longitude, but with improvements. The question as to which alternative shall be adopted is properly a subject for the consideration of the Government."

Upon this the Commissioners state as follows :—

"The proposal to establish a Council of Science has recently been revived by Col. Strange.

"Amongst the witnesses who recommend the appointment of a Council, there is a great diversity of opinion as to its constitution and limits of action. As regards its constitution, it will be seen from the summary of evidence which we shall give subsequently, that while some of the witnesses are in favour of a Council very limited in numbers, others would desire to have it sufficiently numerous to include representatives of nearly every branch of science, as well as men of known administrative ability.

"In regard to its limits of action, the main difference arises on the two questions, whether the Council should or should not have the power of initiating inquiries, either directly or by suggestion to the Minister, and whether or not it should itself undertake the actual work of investigation required for State purposes.

"As to the mode of remuneration, the opinions vary between those which advocate annual payments to permanent officials, and those which are in favour of payments for attendance at meetings.

"The opinions of the witnesses who are opposed to any such Council are based, in the main, upon one or more of the following objections :—

"1. That Government can get the best advice without it.

"2. That it would be liable to come into collision with Ministers.

"3. That it would not work harmoniously with our general system of administration.

"The evidence of three eminent statesmen possessing great administrative experience—Lord Derby, Lord Salisbury, and Sir Stafford Northcote—is in strong contrast (so far as the proposal to establish a Council of Science is concerned) with that which we have received from many persons holding official positions in various branches of the public service. The opinions of these latter, as to the inefficiency of the organisation of their respective services in regard to questions affecting science, we have already quoted in the first part of this Report, and it will be seen from the quotations we are now about to give, that they in general consider the creation of a Council to be the proper remedy."

The Commissioners preface their extracts from the evidence laid before them on this subject by saying:—

"We fear that no mere extracts from the evidence of Col. Strange would represent in an adequate manner the views which have led him to recommend the formation of a large and highly-paid Council of Science. It would scarcely be fair to him, as the most prominent advocate of the proposed measure, to do otherwise than refer to his evidence at length, pp. 75 to 92, and 125 to 135, vol. ii. of Evidence."

When we say that Col. Strange's evidence constitutes a complete and carefully arranged scheme for the scientific administration of the country, it will be readily understood why the Commissioners refer to it as a whole, rather than cite detached portions of it from which no conception of its systematic and comprehensive character could be formed. With respect to the Council, Col. Strange first points out its necessity and then defines its functions. His next step is to so construct it as to fit it for performing these functions satisfactorily. And finally, he enters fully into the mode of its election, its remuneration, and its relation to the Minister of Science and to the various departments and institutions concerned with scientific questions.

Though, like the Commissioners, we find it impossible to give a just idea of this scheme by means of extracts, we think that as the composition of the Council suggested by Col. Strange was made by the Commission the foundation of their examination of almost every witness who spoke on that subject, it is desirable that the sketch of Col. Strange's Council should precede the short extracts from evidence on the subject which we shall lay before our readers. It stands thus:—

Sketch of Proposed Council.

Pure Mathematician (the Professor of Mathematics at Oxford and Cambridge alternately. These should be "Regius Professorships")	1
Mixed ditto (Astronomer Royal for the time being)	1
Chemists (one to be the Director of the proposed Chemical Laboratory)	2
Meteorologist (Director of Meteorological Department)	1
Physical Astronomer (Director of proposed Physical Observatory)	1
Metallurgist (Director of proposed Metallurgical Laboratory)	1
Geologist (Director of Geological Survey)	1
Physicists (one to be an Electrician)	2
Naturalist (Head of Natural History Department of British Museum)	1
Physician (Medical Officer of the Privy Council)	1
Surgeon	1
Physiologist	1
Naval Architect	1

Civil Engineer	1
Mechanical ditto	1
Mining ditto	1
Statist	1
Royal Engineer Officers	2
Royal Artillery ditto (one for Field Artillery, the other for heavy Ordnance)	2
Royal Navy ditto (one for Navigation, the other for Gunnery)	2
Infantry Officers	2
Merchants (one a shipowner)	2
Agriculturist	1
	30

Colonel Strange remarks on the above:—

"Of course I give that sketch of the Council as a mere indication of the sort of Council that I think is desirable. It is something that I put before the Commission in order to be torn to pieces and put into shape; it is a mere sketch of a possible Council. I have given it a great deal of thought, and it does not appear to me that there are any superfluous members in it, nor do I know of any that have been omitted. I may say generally that one of my great objects was to place in this Council the heads of institutions, in order that they might be concerned in the directions given to their various institutions. I think it would hardly do (in a former part of my evidence this matter was alluded to) to have a separate body directing men of eminence as heads of institutions; it would be felt to be an interference, but if those heads were part of the governing body, then the interference would not be felt."

Though Colonel Strange's sketch was freely discussed and criticised, no witness pointed out specifically its omissions or redundancies, nor was any definite counter-proposal submitted to the Commission.

Sir W. Thomson's evidence with reference to the establishment of a Council of Science contains the following:—

"Do you think that a single body would be better than a number of small committees for advising the Government on the great variety of questions which from time to time would be likely to arise? Yes, certainly."

"The questions which might be referred to such a Council would differ very much from one another, and extend over a wide range, would they not? Yes, but there would be an unity of design and action, with a multiplicity of knowledge and skill at command, secured by a single Council, and those conditions cannot, in my opinion, be secured at all by occasional committees, or committees working separately and independently of each other. . . .

"A scientific Council would relieve the Government of all responsibility in such matters, and would be responsible itself in a general way for all its proceedings to a political chief and to Parliament. . . ."

"Would you be so good as to inform us whether you have formed any opinions as to the best system of appointing such a Council?—The Council ought to represent the different branches of science and the practical applications of science. Pure mathematics ought to be represented in the Council; mixed or applied mathematics, according to the old-fashioned nomenclature as generally understood, ought also to be represented; chemistry cannot be shut out; physics must of course be represented, and ought to be represented separately; astronomy, both what was formerly called physical astronomy and of course the new science of astronomical physics, ought to be represented. I do not believe that astronomy could be properly represented under one head; astronomical physics must, in my opinion, be separately represented. Geology should be separately represented, and also the various branches of natural history; physiology also, and medical practice in general, should be

represented. I have spoken of applied mathematics, I meant rather mathematical dynamics than applications to art and mechanical operations. Then practical applications should be represented, mechanics and mechanical engineering; then again civil engineering and geodesy, mining engineering, statistical inquiries, and the scientific branches of her Majesty's service ought to be thoroughly represented. Engineer and Artillery officers and the navy should be represented both in its navigation department and in the department of seamanship, and the department of gunnery. The mercantile interests of the country and the agriculture of the country ought certainly to be represented. The universities ought to be represented amply—the English universities, the Scotch universities, and the Irish universities. Also practical telegraphy, which is a very distinct branch of engineering, civil engineering or mechanical engineering would not sufficiently represent it."

"Do you think that the functions which are proposed to be assigned to the scientific Council would not interfere in any way with the existing scientific departments of the Government; for example, the Medical Department of the Privy Council, or some of the other Government scientific departments?—I think it would relieve the departments from pieces of scientific work at present given to them, because there is no other body to whom they can be given, and for which they are by their organisation and *personnel* almost necessarily ill fitted and insufficiently competent."

"You would leave to these departments their administrative functions, but give them the advantage of consulting with the Council upon higher questions of science on which they desired information?—Yes, certainly; every question of science that falls under the notice of any department of the Government would naturally be referred to the scientific Council."

Dr. Frankland thus deals with Col. Strange's proposal:—

"Are you acquainted with Col. Strange's proposal for the establishment of a consultative council of science?—Yes, I have heard from him some of the chief ideas that he entertains on that subject."

"Are you disposed to consider that such a Council would be desirable?—I think so. I am not prepared to say that it should be constituted exactly in the way that Col. Strange mentioned, but a Council of that description would be exceedingly desirable, on many grounds, for furnishing the Government with trustworthy scientific opinions in cases requiring them. . . ."

"Are you of opinion that the advice of such a Council, even on matters to which the larger proportion of the members of the Council had not paid special attention, would be valuable?—Yes, I think it would, because those members of the Council who were thoroughly acquainted with the subjects would be expressing their opinion to men conversant with scientific methods, and they would be able to convince their colleagues with respect to the opinion that the Council generally ought to give upon the matter. It would be a very different thing from that of convincing a Parliamentary Committee, for instance, upon a scientific point, because all the men upon the Council would have received a scientific training and would understand the bearing of scientific arguments."

"Have you considered at all how such a Council could best be appointed, whether would you leave it to one of the Ministers to appoint and select the proper persons to serve on the Council?—I should think that it must ultimately fall upon the Minister, but he might be assisted by the presidents of different learned societies or by the Council of the Royal Society, in whom I think everyone would have confidence."

(*To be continued.*)

THE IRON AND STEEL INSTITUTE

EVERY friend of science and true patriot must heartily welcome the sound and steady progress of the Iron and Steel Institute. The proceedings at the Manchester meeting last week, as also its Journal, just received, containing the papers read at the last London meeting, show that it is doing exactly the kind of work which is now becoming quite necessary for the maintenance of the dignity and prosperity of British industry. It also displays a very important feature of industrial progress. One need not be grey-headed to be able to remember when iron-workers and iron-masters, in common with other artificers, were nearly unanimous in believing that their trade interests were best served by each man hugging up to himself every bit of newly acquired trade information, and keeping his competitors as much as possible in the dark respecting it. Indentures of apprenticeship still describe our common trades as "mysteries," and bind the pupil to abstain from revealing the secrets of the craft which his master solemnly agrees to communicate in return for the premium and seven years' servitude. The ceremonials, secrets, and degrees of freemasonry are based on the old practice of hoarding the arcana of a "craft" and communicating them in various degrees of profundity to certain privileged individuals, who were bound under dreadful penalties to reveal these sacred mysteries to none but the initiated.

Contrasted with these lingering shadows, these penumbral fringes of the old passing darkness, the meetings of the Iron and Steel Institute are full of hopeful suggestion, by displaying the magnitude of the revolution which modern science is gradually effecting. In the still older and still darker times all knowledge was made a mystery and a craft, and was selfishly held by the initiated few who used it for the oppression of their fellow-men. Abstract or pure science was first thrown open; learned societies were formed for the discovery and diffusion of natural truth by the open and world-wide co-operation of philosophers; their discoveries threw new light into the dark mysteries of trade, and now we see the craftsmen themselves emulating the philosophers, and offering freely to all the world the best results of their technical knowledge, their laborious investigations, and hard-earned technical experience. This is the true chivalry of trade, that only needs its full development in order to place industry fairly upon the throne of its natural and proper dignity.

The Manchester meeting, under the presidency of Mr. W. Menelaus, has been as successful as could possibly have been wished. Although the papers read were too purely technical to be referred to at length in NATURE, still they are all evidences that the iron and steel industries are being more and more rigidly conducted on scientific methods. The papers read were few, but they were all of a thoroughly practical kind, and along with the discussions which generally followed, were well calculated to promote the objects for which the Institute has been established. The first paper read, and which gave rise to a warm discussion, was by Mr. Daniel Adamson on "The Application of High-pressure Steam to Quadruple Engines." Mr. I. Lowthian Bell's paper on "The use of Caustic Lime in Blast Furnaces" is likely to prove of great value to

those interested in the subject. The object of the paper was to show that for high furnaces it was unnecessary to calcine the limestone before using it.

Mr. W. Hackney read a paper on the designing of ingot moulds for steel rail ingots. Mr. Hackney has designed a mould in which the outside is rounded, the thickness of the metal being so adjusted at different parts of the circumference that the expansion under heat should be equal all round. This form has given satisfactory results, one proof of its correctness being that when it becomes heated to redness by an ingot of steel cast in it, the temperature of the outside is apparently equal all round.

Mr. Charles Wood described some improvements made by him in the hearths of blast furnaces. Another paper by Mr. Lowthian Bell described Mr. W. Price's retort furnace. In Mr. Price's furnace the temperature of the air, as well as that of the gaseous and fixed constituents of the coal, is raised by the waste heat before it enters the chimney. Mr. Price cannot compete with the Siemens furnace as regards intensity of temperature, but he avoids the loss which occurs in the gas-producers of the regenerative furnaces.

A paper by Mr. C. J. Horner, on the North Staffordshire Coalfields, had to be considerably curtailed, and two other papers had to be taken as read, in order that the excursion programme might be carried out. Indeed, one of the chief objects of the autumn meeting of the Institute is to visit places of interest from an industrial point of view, and hence the number of papers read is generally limited. This year the visits and excursions were very numerous indeed to industrial establishments in and around Manchester, and all of them seem to have been completely successful. Our space does not permit us to give a detailed account of these excursions, although many of the processes witnessed by the visitors were of considerable scientific interest. The meeting was brought to a successful termination on Friday by a visit, which formed, indeed, a hard day's work, to the North Staffordshire iron and coal district. From first to last the members of the Institute have good reason to be satisfied with the Manchester meeting.

In conclusion, we must express a hope that ere long our other great industries will follow the example of the iron and steel trade in forming their own special technological Institutes and holding meetings and publishing records of similar character and value to those of the Iron and Steel Institute.

RUTHERFORD'S "PRACTICAL HISTOLOGY"

Outlines of Practical Histology. By William Rutherford, M.D. (London: J. and A. Churchill, 1875.)

OF the different methods whereby the standard of scientific education is capable of being elevated, few will not place foremost the extension of theoretical studies into first principles and collateral branches which have a bearing, ever so little as it may appear to be, on the main subject. How much, for instance, does physiology suffer from a deficiency in mathematical and physical knowledge on the part of many of its most enthusiastic devotees. A wider general acquaintance with chemistry would, also, not be out of place. Practical aptitude and experience no doubt stand next in importance. A mastery of the methods by which what is already known has been arrived at cannot but be one of the best trainings for original investigation. How many a valuable suggestion has been allowed to drop undeveloped, simply because of a want of manipulatory skill on the part of the deviser, whose love for the conception of his own brain is the only sufficient stimulus towards the realisation of its importance, and the working out of its details. All attempts to raise the standard and develop facilities for practical education deserve special attention. The work before us is one of the best of these.

The Notes on Practical Histology were published originally in the *Quarterly Microscopical Journal* for January 1872. Several additions have been made, and various fresh methods have been introduced. As it stands, the work contains all the information on the subject necessary for the student of medicine; and we are certain that anyone who has mastered its details will be in a fit position to undertake high special investigation under favourable auspices. It is evident in every page that Prof. Rutherford is thoroughly master of every method he explains, as much from the minuteness of the detail into which he enters, as from the manner in which matter the least irrelevant is omitted. This is nowhere better seen than in the sections devoted to the "preparation of tissues previous to their examination," which, within a few pages, states exactly what is to be done in the way of preparation and preservation with the body of an animal, such as a guinea-pig, in order that all its tissues and organs, extending to such minutiæ as the structure of the cochlea, shall be in a condition most favourable for detailed investigation.

The book is divided into two parts. The first of these treats of the microscope itself, together with the method of using it; which account is followed by a series of histological demonstrations, explaining the manner in which each tissue and organ of the body must be manipulated in order to show its minute anatomical features. The following is an example under the head of *Nerve Tissue*. "The fibrillar structure of the processes of nerve-cells may be shown as follows. Cut the fresh spinal cord of a calf into pieces about a quarter of an inch in length. Place these for a month in a one per cent. potass. bichrom. solution. Remove a thin slice of the grey matter of the anterior horn with scissors, tease with needles, stain with carmine, and mount in glycerine." Among other special processes described, we find a novel one devised by Dr. William Stirling for exhibiting the structure of skin, which consists in partly digesting it, when stretched, in an artificial peptic fluid, and then staining. By so doing "the white fibrous-tissue swells up and becomes extremely transparent, thus permitting of a clear view of the other tissues." Dr. Urban Pritchard's method of exhibiting the structure of the organ of Corti is also fully explained.

The second part of the book consists of general considerations regarding histological methods. In it the relations of the tissues to surrounding media, the methods of hardening tissues (including the employment of the excellent freezing microtome introduced by the author) and of softening them, are fully explained; as well as are the composition of the best staining fluids, and the most efficient means of preserving microscopic preparations.

One of the most important novel points of manipulatory detail which we notice, is the value of mucilage as an imbedding agent when the microtome is employed for freezing, as suggested by Dr. Pritchard. It depends on the fact that "frozen mucilage can be sliced as readily as a piece of cheese," a most valuable property, as all who have had any experience will acknowledge.

Prof. Rutherford has supplied a deficiency. He has given us a manual which will meet the requirements of a large class of students who will never find it necessary to enter into the details of practical histology so minutely as they are discussed in larger works, such as the "Handbook for the Physiological Laboratory," or the still deeper manual of Stricker.

OUR BOOK SHELF

A Yachting Cruise in the South Seas. By C. F. Wood. With six photographic illustrations. (London: King and Co., 1875.)

MR. WOOD'S narrative is so interesting that we wish it had been very much longer. He has made several voyages among the Pacific Islands during the last eight years, and, judging from this and what he tells us in the work before us, he must possess much valuable information concerning these islands, and especially with regard to their puzzling populations, which he would do well to publish in detail, and which would be welcomed especially by ethnologists. Mr. Wood is evidently a careful observer, and has the power of describing what he observes interestingly and clearly.

The present volume contains a narrative of a cruise which the author made, starting from New Zealand, from May to December 1873, among some of the most interesting groups of the Pacific Islands. Among the islands visited during this time were Rotumah, to the N.E. of Fiji, Futuna, Savaii, and Upolu, in the Samoan group; Niuafu, some of the islands in the Fiji group, the New Hebrides, the Solomon Islands, the Caroline Islands, Oualan, the Mulgrave Islands, and the Ellice group. Concerning every island which he visited, Mr. Wood has some interesting and valuable information to give, either about its physical condition, its products, its people, its history, or its antiquities. One of the main objects of his cruise was the collection of native implements and weapons, and in this he seems to have succeeded to his heart's content. His observations concerning the people seem to us especially valuable; he has gathered many traditions as to their migrations, and gives some specimens of folk-lore. In many of the islands the natives seem restless and discontented, and Mr. Wood was frequently petitioned to give them a passage from one island to another. Like many other Pacific voyagers, he has but a poor opinion of the results of the attempts which have been made to Christianise the natives. Not that he disapproves of attempting to civilise them and to raise them in the scale of humanity, but he thinks the methods which are generally adopted are quite abortive. The unmodified European garment of civilisation evidently cramps and enervates the Pacific Islander.

The information which Mr. Wood gives concerning the Rotumans, their traditions as to their predecessors in the island, their migrations, customs, superstitions, folk-lore, &c., is especially valuable. He refers briefly to the remarkable mounds among the hills in Bonabi, or Ascension Island, in the Caroline group, about which them have no tradition, but which would be likely to repay a careful examination. Quite as interesting, and still more wonderful, are the remains of large buildings of stone in the same island, some of the blocks of which are of immense size, and concerning which also the natives seem to have no traditions. Mr. Wood believes these ruins to be the work of a people that have passed away, and it is very unlikely that the original buildings were the work of passing Spaniards, as has been supposed. We have certainly much yet to learn concerning the history and relationships of the Pacific Island populations, and it is a subject well worth careful investigation. Mr. Wood's modest volume is a valuable, though small, contribution to our knowledge of the subject; he must, we should think, have a great deal more to tell as the result of his long intercourse with these islands. The few autotype illustrations are appropriate and well executed.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*]

Living Birds of Paradise in Europe

WE have just received at the Zoological Gardens of Dresden two living Birds of Paradise, viz., *Paradisea papuana*, from New Guinea, and *Paradisea apoda*, from the Aru Islands, both males, in excellent health and fine condition. Mr. von Below, Assistant-Resident of Makassar, in Celebes, brought them home in a three-months' passage from Makassar, *viâ* Java, Suez, Gibraltar, London, and Hamburg to Dresden, where he intends to spend the winter, and has deposited the birds in the Zoological Gardens. They have already been about three years in captivity with him at Makassar, where I saw them when passing through that place to New Guinea in 1873. The birds, therefore, are accustomed to cage-life, and as the conditions under which we have placed them are most favourable—consisting chiefly in a large space to allow free movement, and in an equal temperature of about 20° Réaumur—there is some hope of our being able to keep them alive. Mr. von Below got these birds through native traders who have their home at Makassar and trade to New Guinea and the Aru Islands. He fed the birds in India with grasshoppers, bananas, and rice, and on board the steamers with the same, cockroaches being substituted for grasshoppers. In Dresden we try to feed them with bread, rice, and worms (*Mehlwürmer*). Both are very active, and cry their well-known "wôk, wôk" with much force; the specimen of *Paradisea apoda* especially is not the least shy, and takes the worms out of one's hands. Their fine plumage suffered, of course, on the voyage, but I was astonished to see that it was not damaged more. As they probably will moult from about November till April, the plumage will not be at its finest condition till the month of May, and, supposing that the readers of NATURE will be interested in the further fate of these Birds of Paradise, I shall report in time how they are getting on.

I believe I am not mistaken in saying that a living specimen of *Paradisea apoda* has never before been alive in Europe. The two Birds of Paradise which Mr. Wallace brought home, which he had bought at Singapore, were *Paradisea papuana* (if I remember correctly, having no books at hand here); Mr. Cerrutti, some years ago, brought over a specimen of *Seleucides alba*, but I did not hear how long it lived in Europe. No other species of Birds of Paradise have yet been brought alive to Europe, so far as I know, and we may therefore felicitate Mr. von Below on having increased the number of these at least to three.

The inhabitants of those parts of New Guinea which I visited in 1873 are not accustomed to catch *Paradisea papuana* alive, as Mr. Wallace states is the case with *Paradisea apoda* from the Aru Islands; they only know how to kill the bird with the arrow, and I did not succeed in teaching them otherwise, but I suppose that the Papooas of the south-west coast of New Guinea know how to catch the Birds of Paradise alive, and that Mr. von Below's specimen is from that part of New Guinea.

Wildbad Gastein, Sept. 11 A. B. MEYER

Source of Volcanic Energy

MR. W. S. GREEN, like others of Mr. Mallet's supporters, takes wider ground than he did himself in his original paper. It is obvious that he regarded his experiments conclusive as to the amount of heat that could be produced by rock crushing

His advocates, however, and he himself in his later papers, appeal to pressures within the earth enormously greater than those obtained by the mechanical contrivances used, and consider that proportionately greater heat may be evolved.

My "Remarks" at the Geological Society, now published in *The Journal*, were primarily framed with reference to Mr. Mallet's paper as it stood, although I think they are a tolerably satisfactory reply even to the theory as now extended. I have, however, lately gone into the question on first principles, and have satisfied myself that, accepting the conditions lately assumed by Mr. Mallet as a basis, the theory can be shown to be untenable. I hope that a paper containing the grounds of my conclusion will shortly appear.

I am unable to understand how Mr. Green proposes to account for the development of forces as productive of heat through means of "the gravitation of the whole mass" (of the earth) "to itself," otherwise than by "the gravitation of the surface upon a retreating nucleus;" because, unless room be given by a retreating nucleus for the parts to descend, there can be no motion, and consequently no heat. O. FISHER

P.S.—Upon further consideration of Mr. Green's letter, it strikes me that he has misunderstood my meaning in a way that I did not at first perceive. He says that I "object to the possibility of assuming high *local* temperatures to be produced by the transformation of tangential forces into heat within the earth's crust;" as if I objected to any localisation. What I did object to was, not a localisation of work and heat, but a localisation within a localisation, such that the heat of crushing a certain localised volume should fuse a further localised portion of the crushed volume.

Harlton, Cambridge, Sept. 11

Important Discovery of Remains of *Cervus megaceros* in Ireland

DURING 1847, when draining a bog at Kellegar among the Dublin mountains, as many as thirty heads of *C. megaceros*, together with a perfect head and antlers of a Reindeer, were discovered in a cutting of about 100 yards, by 3 yards in breadth. They were found as usual in the marl and clay under the bog. I visited this locality in March last, and from the aspect of the ground and evidence of a farmer who remembered the spot where the above were dug up, it seemed probable that by running a series of trenches parallel with the original ditch made in 1847, fresh exuviæ might be discovered. The subject was accordingly brought to the notice of the Royal Irish Academy, and a grant of 25*l*. obtained. The result has been the finding of about thirty additional heads of *Cervus megaceros*, besides numerous detached bones not yet fully determined.

Mr. R. J. Moss, Keeper of Minerals in the museum of the Royal Dublin Society, who volunteered to conduct the explorations, writes to me that he found the remains embedded in about two to three feet of clay, and often either lying on or impacted between blocks of granite as if they had been drifted into the above situation. A log of oak three feet in length was discovered among the bones in the same stratum of clay. In this instance, as generally obtains in Ireland, the cervine exuviæ are met with around the margins of the bogs, and not in the middle, as if the animals were mired in shallow water, or else their carcases had drifted with the winds or currents to the sides and outlets of the lake. Mr. Moss had to stop excavations in consequence of the grant having become expended, so that doubtless many more remains await further explorations.

This is not the only case known to me of the accumulation of carcases in a small space. I just lately examined a large assortment of skulls and bones of *C. megaceros* dug out of a bog on the property of Mr. R. Usher, of Cappagh, near Dungarvan. These were collected in a space of about 100 yards in length and 70 yards in breadth. They include heads and cast antlers of no less than fifteen individuals of the great horned deer (*i.e.* thirteen male and two female skulls), besides the cast antler of a Red Deer. The above were likewise found more towards the side than the centre of the marsh.

It seems difficult to account for these accumulations of deers' carcases, unless we suppose that a herd was mired on attempting to cross the lake. The fully developed burr of the antler so generally observed on this deer's horns discovered in the mud of ancient lakes might indicate that their owners perished in autumn during the rutting season, when doubtless many far grander scenes than those depicted in the "Challenge" and Wolf's "Race for Life" occurred along Irish lakes. The Bear and Wolf being the only large carnivores in Ireland during the Pleistocene period may account for the abundance of *C. megaceros*; moreover, we have it on historical evidence that the Wolf was extremely common during the seventeenth century, and it is probable, having neither the Hyæna nor the large Felidæ to compete with, that it might have hunted the great horned Deer into the lakes, where many would have got mired in the deepening mud along their margins. A. LEITH ADAMS

Magnus's "Elementary Mechanics"

WITH reference to the favourable notice of my "Elementary Mechanics" which appeared in last week's NATURE, I shall be glad if you will permit me to state that the second edition of my book is already in the printers' hands, and that the few errors, chiefly clerical, in the answers to the examples, which you were good enough to point out, are therein corrected.

London PHILIP MAGNUS

Sanitary State of Bristol and Portsmouth

YOUR correspondent, Dr. Black, in accounting for the uniformly low death-rate of Portsmouth, has, I venture to suggest, omitted two somewhat important coefficients. The one is a thorough and well-planned system of drainage and outfall, completed some few years since at a cost of about 150,000*l*.; the other is the presence of a floating population of several thousand healthy adult males in the shape of the garrison and the sailors.

E. J. E.

Lancaster Gate, W., Sept. 11

OUR ASTRONOMICAL COLUMN

BINARY STARS.—Mr. J. M. Wilson has communicated measures of Σ 2107, 44 Bootis, and ζ Aquarii, made at the Temple Observatory, Rugby, in 1871-75, from which the following are selected:—

Σ 2107	1872·49	Pos.	210°·0	Dist.	0″·77	
	1873·48	,,	207 ·5	,,	0 ·7	est.
	1874·65	,,	208 ·4	,,	0 ·7	est.
	1875·58	,,	215 ·5	,,	0 ·5	est.
44 Bootis	1873·25	,,	240 ·6	,,	5 ·3	
ζ Aquarii	1873·79	,,	335 ·1	,,	3 ·58	

The binary character of the first of these stars is well supported by Mr. Wilson's measures; the angular velocity appears to have regularly increased since about the year 1850, due allowance being made for the difficulty of the object. Struve's first epoch (a correction being made to the time as printed in "Mensuræ Micr.") is

1829·01 Pos. 148°·6 Dist. 1″·127

A discussion of the elements of the orbits of σ Coronæ, τ Ophiuchi, γ Leonis, ζ Aquarii, and 36 Andromedæ, by Dr. Doberck, of Col. Cooper's Observatory, Markree, forms Part 19 of volume xxv. of the *Transactions of the Royal Irish Academy*. Dr. Doberck employs the graphical method proposed by Sir John Herschel, which has been so generally applied, at least in the earlier part of the work. Correction of the approximate elements thus obtained by equations of condition will lead to satisfactory results where there are reliable single epochs, or a sufficient number of contiguous ones, to enable us to form normals. It may be questioned whether the additional labour of calculation which some of the methods of calculating double-star orbits that have been proposed necessarily involve, is rewarded by more satisfactory results than can be obtained by the application of Herschel's graphical process in the first instance, following up by equations of condition.

THE ZODIACAL LIGHT.—During the past week has appeared *Zodiacallicht-Beobachtungen in der letzten 29 Jahren* 1847-1875, by Prof. Heis, forming the first special publication of the Royal Observatory of Münster. It contains in considerable detail, but on a systematic plan, the particulars of the numerous observations made by

Heis himself, with a large number by Eylert, Weber, and others, and is a most valuable addition to the observational results bearing upon this, as yet, little-understood phenomenon. We may remind the reader who is desirous of fully acquainting himself with the literature of the subject, that Dr. Julius Schmidt, now Director of the Observatory at Athens, published in similar detail his observations of the zodiacal light in the years 1843-55 (*Das Zodiacallicht*, Braunschweig, 1856).

THE NEXT RETURN OF ENCKE'S COMET.—The appearances of this comet at nearly ten-year intervals in 1819, 1829, 1838, 1848, 1858, and 1868 took place under circumstances which were more or less favourable for observation in this hemisphere; these conditions, however, will not attend the ensuing return to perihelion, which, with the mean motion found by Dr. von Asten for 1875, neglecting the small effect of perturbation, would occur about the 27th of July, 1878; and if the path in the heavens be calculated on this assumption, it will appear that observations will hardly be practicable except in the southern hemisphere in August. The nearest approach to this track is that which the comet followed in 1845, when a few observations only were obtained with difficulty at Rome, Washington, and Philadelphia. With regard to the effect of perturbation upon the length of this comet's period since the year 1819, when its periodicity was first detected, it may be remarked that the longest revolution was that from 1842-45, which extended to 1215·6 days, and the shortest, that from 1868-71, 1200·2 days; difference of extremes, 15½ days.

COMET 1874 (III.), COGGIA.—A third computation of the orbit of this fine comet, founded upon observations between April 20 and July 16, by Herr Geelmuyden, of Lund, has resulted in an ellipse with a period of 10,445 years, confirming the great length of the revolution which resulted from the calculations of Prof. Tietjen and Herr Schulhof. There appears to be no probability of the comet having previously visited these parts of space within historical times.

THE LATE PROF. ARGELANDER.—The last part of the *Vierteljahrsschrift der Astronomischen Gesellschaft*, x. Jahrgang, Drittes Heft, contains an interesting memoir of this distinguished astronomer by his successor, Prof. Schönfeld. As an authoritative summary of his long and laborious services to sidereal astronomy in particular, this memoir will be found a useful reminder. Argelander was born at Memel on March 22, 1799, and died at Bonn on February 17, 1875. His first astronomical observation is stated to have been one of the occultation of the Pleiades on August 29, 1820.

NOTES ON A SUPPOSED MARRIAGE EMBLEM OF AMERICAN INDIAN ORIGIN

A REMARKABLE form of "Indian relic," varying somewhat in details, but having much in common, and never approaching any other stone implement or ornament, is occasionally met with in the "finds" of the Atlantic coast States and westward to the Mississippi. In New Jersey they are less abundant, I believe, than in the States west and south, but a sufficient number of them have been gathered by myself and others to indicate their having been, at one time, a marked feature in the dress of our aborigines.

This "relic," however varied in its outline, always suggests a brooding bird, especially when in the position in which it is placed in Fig. 1. So far as I have made examination of these specimens, and met with notices of them in various publications, they are all manufactured from comparatively soft stone, are accurately outlined, highly polished, and drilled diagonally at the lower corners.

Of the many suggestions made as to their significance, as knife-handles, corn-huskers, idols, &c., I have met with but one that seemed at all probable; and this, I think, is rendered the more probable from circumstances connected with the discovery of various specimens, and certain peculiarities of the fragment of one here figured (Fig. 2).

Writing of one of these relics, Mr. Henry Gillman, in the Smithsonian Annual Report for 1873, p. 371, states: "I have learned, through an aged Indian, that in olden

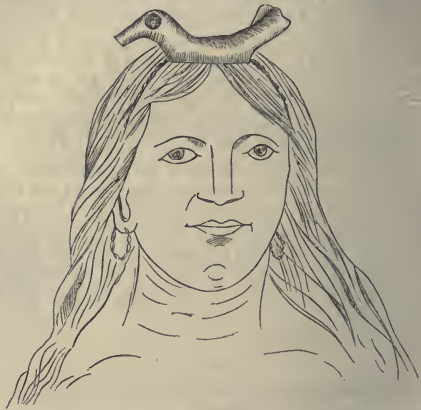

FIG. 1.

time these ornaments were worn on the heads of Indian women, but only after marriage. I have thought that these peculiar objects, which are always made of some choice material, resemble the figure of a brooding bird; a familiar sight to the 'children of the forest;' that thus they are emblematic of maternity, and as such were designed and worn."

Fig. 2 represents the "tail end" of one of these "brooding birds." Probably broken by accident, whether the head was lost or both halves preserved, it will be seen that the specimen has been considered of considerable value, inasmuch as this half has been carefully squared and polished at the point of fracture, and a hole drilled through it, to enable its owner to suspend her rude bracelet or her necklace. Surely, had the unbroken implement (?) been a knife-handle or corn-husker, the fragment such as is here figured would not subsequently have been utilised as an ornament. If put to so commonplace a use in its entirety, a half of one would have no beauty in it, even in

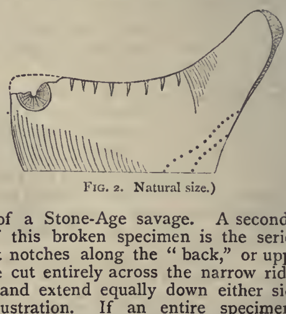

FIG. 2. Natural size.)

the eyes of a Stone-Age savage. A second noticeable feature of this broken specimen is the series of eight deeply cut notches along the "back," or upper margin. These are cut entirely across the narrow ridge forming the back, and extend equally down either side, as seen in the illustration. If an entire specimen, such as is represented on the woman's head (Fig. 1), is or was worn on the head of an Indian woman, but only after marriage, and so emblematic of maternity, then is it not

reasonable to presume that these marks are records, not merely ornamental lines, and if records, of children born? Such a carved stone, once proudly worn by an Indian of high rank, if broken, as this has been, would naturally be preserved; and that it is but the half of such an one, as seen in Fig 1, is proved by the fact of a hole being drilled in the lower corners, as shown by the dotted lines; a hole that became of no use when the specimen was broken, or at least was less well placed than that subsequently drilled in order to suspend the relic as an ornament, as an ear-ring, or addition to a necklace, as previously suggested.

The traces, as they really are now, of the graves of our aborigines occasionally contain a single specimen of the above-figured relic. So far as I have been able to examine these graves, such relics are never associated with the stone axes and spear-heads characterising the graves of adult males, but simply with other forms of stone ornaments, and a single small mortar and pestle, or earthenware vase. In one instance the "brooding bird" was so placed with reference to the narrow strip of discoloured earth that marked where the body had been laid, as to show conclusively that the relic was attached to the hair, as shown in Fig. 1.

If we examine a series of these relics, it will be at once seen that every one has holes drilled at the lower corners. Such specimens could only be worn upon the top of the head, without being upside down, as would necessarily be the case had they been suspended. It must, too, be borne in mind that these relics are nowhere very abundant, but on the other hand, nowhere unknown north of Mexico. Had they been knife-handles, as suggested by Schoolcraft, or corn-huskers, as suggested by various writers, certainly they would be much more abundant than they really are. Indeed, in considering them as ornaments for married women, I am forced, in consideration of the scanty number that have been collected, to restrict them to women prominent in their tribes, the wives of kings, chiefs, and eminent warriors. If this be true, then the eight birth-records on Fig. 2 are those of "Indian princes," it may be. I must admit, however, that this broken specimen is the only one that I have seen having like marks cut upon it; but such record marks, as I believe them to be, are quite common upon other forms of stone ornaments, particularly those stone tablets and crescents that I have elsewhere (Smithson. Ann. Rep. for 1874) called "breast-plates."

These facts considered, I think that the suggestion of Mr. Gillman, based upon information received from an aged Indian, truly explains what this much-discussed relic truly is—an ornament for married women, an emblem of maternity. CHARLES C. ABBOTT

Trenton, New Jersey, U.S.A.

THE BRITISH ASSOCIATION
REPORTS.

Report of the Committee on Luminous Meteors, by Mr. James Glaisher.—The report related, as usual, to meteors doubly observed, and to aërolites, the portion having reference to the latter being the more interesting, as the falls of aërolites which have been placed on record since the last report were more than ordinarily numerous and interesting. A mass of meteoric iron fell on Aug. 24, 1873, at Maysville, California, and is one of the very few metallic irons the actual descent of which has been witnessed. In the following month a number of meteorites fell near Khairpur, in the Punjaub; and it is also related that in the month of December, when the British army halted on the banks of the Prah, an aërolite fell in the market-place of Coomassie, and was regarded by the native population as a portent of evil. On the 14th and 20th of May, 1874, aërolites fell at Castalia, in North Carolina. The last stone-fall of the past year took place near Iowa city on the 12th of February, 1875, and of this meteorite also special analyses were made in the United States, of which some unforeseen results were lately announced by their author, Mr. A. W. Wright. In England no detonating meteor has been observed this year; and the brightest meteor recorded since the last report occurred on the 1st of September last, taking its course over the north of England, or Scotland, where clouded skies must have prevailed, as its flash was like that of lightning. Other bright meteors occurred on the 2nd and 16th of September, 11th of October, 17th of December, 9th of March, 12th of April, and 2nd and 4th of May in this year. A meteor burst with a loud detonation over Paris and its neighbourhood on the 10th of February; it was of great size and brilliancy, and left a cloud-like streak of light on its track for more than half an hour. No duplicate observation of it was obtained in England. Another fireball fell at Orleans on the 9th of March, and of this two good observations appeared to have been obtained in England, which may assist to determine its real height. During the annual meteor showers of the past year very unfavourable weather generally prevailed for recording meteor tracks, and few meteors were seen on those nights when the usual expectations of their appearance were entertained. A thorough examination of all the observations collected by the committee since the publication of the Meteor Atlas in 1867, with the view of extending and correcting the list of general and occasional meteoric showers which it embraced, has been continued with satisfactory results under the direction of Mr. Greg. The report also contained a *résumé* of the contents of the recent publications on the subject of meteoric astronomy. Mr. Glaisher remarked that the report was the result of considerable labour performed by Prof. A. S. Herschel, but he pointed out that the work of properly treating meteor observations had now become so great as to be beyond the power of the Association to grapple with, and alluded with satisfaction to the arrangements being carried out by M. Leverrier. A discussion took place on the connection of comets and meteors, in the course of which Sir William Thomson said that there was nothing to justify the assertion that the mass of comets was so small as was sometimes supposed, and he considered there was good evidence for believing that the comet's tail was really a train of meteors.

The Report of the Committee on British Rainfall, by Mr. G. J. Symons, began by giving an epitome of the rainfall work done in connection with the British Association during the last fourteen years. It then referred to the steps taken after the meeting at Belfast to obtain additional stations in Ireland, which were so successful that the committee received 190 offers of assistance. The acceptance of all these offers would have involved an expenditure far beyond the funds at the disposal of the committee, and they were therefore reluctantly compelled to make a careful selection, resulting, however, in the establishment of sixty-six stations, many of them in localities of extreme importance. In the past fifteen years the number of stations had been raised from 241 to nearly 2,000. The influence of size and shape on the indications of rain gauges had been experimentally examined, and also the effect of height above ground. The laws which regulate the seasonal distribution of rainfall had been to a certain extent ascertained. The secular variation of annual fall had been approximately determined. A code of rules had been drawn up for observers. Nearly 250 stations have been started at the cost of the Association, and 629 stations have been visited, and the gauges examined by the secretary. They had obtained and supported observations on mountain tops, and places difficult of access where no observations had been made, in Cumberland, Westmoreland, Wales, and Scotland, and also an extensive series in Ireland. When the works actually in hand are completed, they will furnish an index to all the observations hitherto made.

The committee appointed to examine and report upon the reflective powers of silver, gold, platinum, and speculum metal did not present any report, but was reappointed at its own request, with the addition of Prof. Ball.

Owing to the absence of Col. Babbage in India, the committee for estimating the cost of Mr. Babbage's analytical engine had not met, but it requested to be reappointed. No report was received from the committee for the determination of the mechanical equivalent of heat, but it was stated that Prof. Joule's experiments were making good progress. The committee on teaching physics in schools was reappointed. Also the committee for considering the possibility of improving the methods of instruction in elementary geometry was reappointed, with the addition of Prof. Henrici and Mr. J. W. L. Glaisher, and requested to consider the syllabus of the Association for the improvement of geometrical teaching, and to report thereon.

Mr. W. C. Roberts read a note from the committee which had

been appointed to investigate *the methods of making gold assays and stating the results.* It stated that the standard gold plate had now been finished, and that portions of it had been forwarded to different mints for the purpose of being assayed. The reports read were very satisfactory, as was shown by the fact of M. Stas, of Brussels obtaining 999·95 parts of pure gold out of 1,000 as the result of an analysis. The same plate had also been examined by Mr. Lockyer by means of the spectroscope, and the lines having been compared with the solar lines, it had been shown that silver, copper, and iron were absent, and that therefore the purification of the metal had been very great.

Mr. A. H. Allen read the *Report of the committee appointed for the purpose of examining and reporting upon the methods employed in the estimation of potash and phosphoric acid in commercial products, and on the mode of stating the results*, in which he stated the object of this committee was to examine all the known methods of analysis of manures and potassium salts. They had hoped to be able now to present to the Section some practical and easy process as a neutral standard of reference by which the present discrepancies might be avoided. The plan adopted by the committee was to draw up a printed list of queries which were sent round to all the members of the Chemical Society, with the request that they would send back answers; this plan had been found to work well with very few exceptions, who declined to give up the processes which they alone employed. The report ended by the committee desiring to be re-appointed, and expressing a confident expectation that by the end of another year some really good results would be obtained.—The President remarked, at the conclusion, that the estimation of potash seemed to present much less difficulty than that of phosphoric acid.

Second Report of a Committee, consisting of Prof. A. S. Herschel and G. A. Lebour, on Experiments to determine the Thermal Conductivities of certain Rocks, showing especially the Geological Aspects of the Investigation.—The experiments during the past year were directed chiefly to a re-examination, with improved apparatus (fully described in the report), of the rocks observed last year. With the exception of Kenton sandstone, which was misplaced in the last table, all the rocks have, under the new mode of treatment, kept the same *relative* positions, and the absolute conductivities given in the present report are believed to leave little or nothing to be desired on the score of accuracy. Quartz has been added to the list, and proves to have less resistance to the passage of heat than any of the other substances examined. Slate has been tried both in the line of cleavage and across it, showing *less* resistance in the latter position than in the former. Some rocks have been experimented on wet as well as dry, the addition of the water giving an increased conductivity of a tolerably constant value. It is intended to continue the experiments in the direction foreshadowed by these results. A full table of absolute conductivities and resistances, with the results of both series of experiments compared, forms part of the report. Coal still maintains its position with the greatest resistance yet found.

SECTIONAL PROCEEDINGS

SECTION A—MATHEMATICS AND PHYSICS

Captain Abney read a paper *On the Increase of Actinism due to difference of Motive Power in the Electric Light*, in which he stated that having been called upon by the War Office to undertake the photometric measurements of certain magneto-electric lights, he had determined to carry out actinic measurements of their value at the same time, believing that the eye observations would be closely checked by such an independent method. In the first comparison of the results obtained by both kinds of measurement, a considerable discrepancy was found to occur in the values given to the different lights. The photographic records could not err except through gross carelessness in the chemical preparations, and against this every precaution had been taken. At first it seemed likely that the eye observations were in fault, but a more critical examination convinced Captain Abney that both were correct; and that though the curves obtained for the values of the lights did not coincide, yet that they did act as a check, the one on the other. In all there were six different machines to examine, each of which was driven by a ten-horse power engine. Several were driven at varying speeds that the difference in the light caused by the variation might be tested.

The eye observations were made by a little instrument called by Captain Abney the Diaphanometer, and described in the *Monthly Notices* of the Astronomical Society for last June. The method adopted for registering the actinic power of the light was by exposing uniformly sensitive chloride of silver paper to the action of its rays. Two registrations were carried out with each light: first, paper was exposed to the naked light at a fixed distance from the carbon points for three minutes; and secondly, a strip of the same paper was exposed beneath black wedges of slight taper for sixteen minutes. The eye observations were carried on simultaneously with the latter exposure of the sensitive paper, in both cases obtaining an integration, as it were, of the light during that period. Between ten and twenty observations were taken for each light at the beginning, middle, and end of each trial. Diagrams of the steam pressure were taken in the usual manner, and diagrams were also taken of the steam pressure when driving the machine without exciting a current, at the same speed as that at which the light was produced. They were also taken in many cases when the machines were what may be called short circuited. The data were thus obtained for calculating the power necessary to produce a light of a certain value.

Diagrams were exhibited showing the mean of the results of a series of experiments with one instrument; one curve, deduced from eighty readings, giving what may be called the optical value; another, deduced from 450 readings, giving the actinic value; whilst a third showed the ratio of the actinic to the optic value—the abscissæ being in all these cases measures of the horse power. The curves are interesting as showing the rapid decrease of the optical value, and still more of the actinic value, of the light when worked with a low motive power. They also show that each machine has a point beyond which the increase in motive power is not compensated for by increase in light, the curves apparently becoming asymptotic.

Captain Abney stated that he was not at all prepared for the great diminution of the value of actinic power in the lights, though he expected it in a smaller degree. The early experiments of Draper and others had shown that with increase of temperature the more refrangible portions of the spectrum appear after the least refrangible, but there seemed to be no measurements which would have been applicable to the present set of experiments. The curves must evidently be some function of the wave-lengths, and the author hoped to carry out other experiments in fixed portions of the spectrum in order to ascertain if the formula which he thought should hold good could be employed.

SECTION B.

CHEMICAL SCIENCE.

OPENING ADDRESS BY A. G. VERNON HARCOURT, M.A., F.R.S., F.C.S., PRESIDENT.

To the privilege of presiding over this Section custom has added the duty of offering some preliminary remarks upon the branch of science for whose advancement we are met.

In discharge of this duty some of my predecessors have reviewed the progress of chemistry during the previous year; and until a few years ago there was no more needful service that your President could render, though the task of selection and abstraction was one of ever-increasing difficulty. But a few years ago the wisdom and energy of Dr. Williamson transformed the Journal of the Chemical Society into a complete record of chemical research, and this Association materially promoted the advancement of science when it helped the Chemical Society in an undertaking which seemed at one time hopelessly beyond its means. The excellent abstracts contributed to the Journal err, if at all, on the side of brevity, and yet the yearly volume seems to defy the bookbinder's press. I shall not venture to attempt further abstraction, nor to put before you in any way so vast and miscellaneous an aggregate of facts as the yearly increment of chemistry has become. The advancement of our science—to borrow again the well-chosen language of the founders of this Association—is of two kinds. The first consists in the discovery and co-ordination of new facts; the second in the diffusion of existing knowledge and the creation of an interest in the objects and methods and results of scientific research. For the advance of science is not to be measured only by the annual growth of a scientific library, but by the living interest it excites and the number and ardour of its votaries. The remarks I have to offer you relate to the advancement of chemistry in both aspects.

One fact has been brought into unpleasant prominence by the Journal of the Chemical Society in its present form, namely, the small proportion of original work in chemistry which is done in

Great Britain. All who are ambitious that our country should bear a prominent part in contributing to the common stock of knowledge, and all who know the effect upon individual character and happiness of the habit and occupation of scientific inquiry, must regret our backwardness in this respect. The immediate cause is easily found. It is not that English workers are less inventive or industrious than their fellows across the Channel, but that their number is exceedingly small. How comes it that in a country which abounds in rich and leisurely men and women—for neither the reason of the case, nor the jealousy of the dominant sex, nor partial legislation excludes women from sharing this pursuit with men—there are so few who seek the excitement and delights of chemical inquiry? Moralists tell us that the reason why some men are content with the pleasures of eating and drinking and the like is, that they have never had experience of the greater pleasure which the exercise of the intelligence affords. I am not about to represent it as the moral duty of those who have means and leisure to cultivate chemistry or any branch of science; but no taste for a pursuit can be developed in the absence of any knowledge of its nature. A taste for chemistry is often spoken of as a peculiar bias with which certain men are born. No doubt there are differences in natural aptitudes and tastes, but the chief reason why it is so rare for men of leisure to addict themselves to scientific pursuits is, that so few boys and young men have had experience of the pleasure which they bring. Much has been done during the last twenty years, both at the Universities and at the Public Schools, to provide for the teaching of science. To speak of what I know best, the University of Oxford has made liberal provision for the teaching of science, and for its recognition among the studies requisite for a degree; nor have the several colleges been backward in allotting scholarships and fellowships as soon as and whenever they had reason to believe that those elected for proficiency in science would be men equal in intellectual calibre to those elected for proficiency in classics or mathematics. But the result is somewhat disappointing, and under a free-trade system science has failed to attract more than a small percentage of University students. Excellent lectures are delivered by the professors to scanty audiences, and the great bulk of those educated at the University receive no more tincture of science than their predecessors did twenty years ago.

The recognition of science among the subjects of University examinations is by no means an unmixed advantage to those concerned. Examinations have played and will continue to play a useful part in directing and stimulating study, and in securing the distribution of rewards according to merit; but they produce in the student, as has often been pointed out, a habit of looking to success in examination as the end of his studies. This habit of mind is peculiarly alien to the true spirit of scientific work. Only such knowledge is valued as is likely to be producible at the appointed time. Whether a theory is consistent or true is immaterial, provided it is *probable*, that is to say, advanced by some author whose authority an examiner would recognise. All incidental observations and experimental inquiry lying outside the regular laboratory course, which are the natural beginnings of original work, must be eschewed as trespassing on the time needed for preparation. The examination comes; the University career is at an end; and the student departs, perhaps with a considerable knowledge of scientific facts and theories, but without having experienced the pleasure, still so easily gained in our young science of chemistry, of adding one new fact to the pile of knowledge, and, it may be, with little more inclination to engage in such pursuit than have most of his contemporaries to continue the study of Aristotle or Livy.

However, examinations have their strong side, to which I have referred, as well as their weak side; and although it is the natural desire of a teacher to see his more promising pupils contributing to the science with whose principles and methods they have laboured to become acquainted, the younger, like the elder branches of knowledge, must be content to serve as instruments for developing men's minds. Chemistry can only claim a place in general education if its study serves, not to make men chemists, but to help in making them intelligent and well-informed. If it is found to serve this purpose well, the number of chemical students at the Universities ought to increase; and if the number increases, no rigour of the examination system will prevent one or two, perhaps, in every year adopting chemistry as the pursuit of their lives. But the Universities have little power to determine what number of students shall follow any particular line of study. With certain reserves in favour of classics and mathematics, their system is that of free-trade. Young men of eighteen or nineteen have tastes already formed, some for the studies which were put before them at school, in which, perhaps, they are already proficient and have been already successful, some for games and good fellowship. It is, from the nature of the case, with the masters of schools that the responsibility rests of fixing the position of science in education. During the last ten years provision has been made at most of the larger schools for the teaching of some branches of science; and those who recall the conservatism of schoolboys, and their consequent prejudice in favour of the older studies, will understand a part of the difficulties which have had to be encountered. The main and insurmountable difficulty is what I may call the impenetrability of studies. A new subject cannot be brought in without displacing in part those to which the school-hours have been allotted. It is the same difficulty which occurs again and again in human life. There are so many things which it would be well to know and well to follow; but life, like school-time, is too short for all. From the educational phase of this difficulty the natural difference of tastes and aptitudes provides in some degree a way of escape. I think that wherever a school can afford appliances for the teaching of chemistry, all the boys should pass through the hands of the teacher of this subject. Two or three hours a week during one school-year would be sufficient to enable the teacher to judge what pupils were most promising. There may be instances to the contrary, but I no not think it likely that any boy who attended chemical lectures for a year without becoming interested in the subject would ever pursue it afterwards with success. Suppose that out of one hundred boys who have gone through this course, five are selected as having shown more intelligence or interest than the rest; they should be permitted to give a considerable part of their time, while still at school, to studying science without suffering loss of position in the school, or forfeiting the chance of scholarships or prizes. If any such system is possible and were generally adopted, each school sending annually to the Universities, or other institutions for the education of young men, its small contribution of scientific students, the professor's lecture-rooms and laboratories would be filled with young men who had already learnt the rudiments of science. Laboratories of research as well as of elementary instruction would find a place at the English Universities, and the reproach of barrenness would be rolled away.

Some of the defects or difficulties to which I have adverted are perhaps peculiar to our older schools and universities. The introduction of the study of natural science has borne earlier fruit in schools whose celebrity is of more recent date, such as the excellent college in this neighbourhood. Oxford and Cambridge ought to possess, but are far from possessing, such laboratories as have lately been built at the Owens College, Manchester. It is proposed to constitute in this city a College of Science and Literature, similar to Owens College and in connection with two of the Oxford colleges. The scheme set forth by its promoters appears thoroughly wise and well-considered, and all who are interested in scientific education must wish it success.

I have placed first among the modes in which science, and in particular chemical science, may be advanced, the assignment to it of a more prominent and honoured place in education; but owing, as I do, my own scientific calling and opportunities of work to a bequest made to Christ Church by Dr. Matthew Lee more than a hundred years ago, I cannot forget or disbelieve in the influence of endowments.

I have spoken of the leisurely class in this country as that to which scientific chemistry must look for its votaries. In our social conditions and in the absence of endowments it is hard to see where else they can be found. Men who have their livelihood to make cannot afford to spend money, and still less to bestow their time and energy, on the luxury of scientific inquiry. Even if they have the opportunity of earning their livelihood by scientific teaching, and with it the command of laboratory and apparatus, no leisure may remain to them for original work, and the impulse to such work (often, it must be admitted, of a feeble constitution) is starved in the midst of plenty. The application of endowments to the promotion of original research is a difficult question. I am inclined to think that posts, constituted chiefly with this object, should be attached in every case to some educational body, and should have light educational duties assigned to them. The multiplication of such posts in connection with the many colleges and schools in this country, where there is some small demand for chemical teaching, with the provision in each case of a sufficient laboratory and means of work, would probably

do more than any centralised scheme for the promotion of chemical research.

To the advancement of chemistry by the formation of public opinion on the questions of scientific education and the endowment of original research, the Chemical Section of the British Association may reasonably hope to contribute. But doubts have been expressed as to the serviceableness of this or any such organisation for the direct advancement of our science itself. No doubt we cannot accomplish much. Chemical inquirers at the present time may be compared to a party of children picking wild flowers in a large field: at first all were near together, but as they advanced they separated, till now they are widely scattered, singly, or in groups, each busy upon some little spot, while for every flower that is gathered ten thousand others remain untouched.

That the science of chemistry would advance more rapidly if it were possible to organise chemists into working parties, having each a definite region to explore, cannot, I think, be doubted. Is such organisation in any degree possible?

The experiments of which Bacon has left a record, though curious historically, have no scientific value. But in one respect his "Physiological Remains" furnish an example which we might follow with profit. "Furthermore," he writes, "we propose *wishes* of such things as are hitherto only desired and not had, together with those things which border on them, for the exciting the industry of man's mind." I will quote further, as an example, a part of one of his "wishes," which has very recently been fulfilled. "Upon glass four things would be put in proof. The first, means to make the glass more crystalline. The second, to make it more strong for falls and for fire, though it come not to the degree to be malleable."

I do not know that the industry of M. de la Bastie's mind was excited by Bacon's mention of glass more strong for falls and for fire among things hitherto only desired and not had; but the conception of such an enumeration seems to me worthy of its author. Much fruitless and discouraging labour might be saved, a stimulus might be given to experimental inquiry, and chemical research might become more systematic and thus more productive, if Bacon's example were followed by the leaders of chemistry at the present day.

The Council of the Pharmaceutical Conference, whose meeting has just preceded our own, has published a list of subjects for research which they commend to the attention of chemists. Where one of these subjects has been undertaken by any chemist his name is appended to it. Might not the representatives of scientific chemistry issue a similar list?

Perhaps two or three of the distinguished English chemists who are members of this Association might be willing to serve on a committee which should put itself into communication with the leaders of chemical inquiry abroad, and should make and obtain and publish suggestions of subjects for research. Such a list so got together would, I think, find a welcome place in all scientific journals, and would thus be widely known and easily accessible to every student.

That which chiefly makes the organisation of chemical inquiry desirable is the boundless extent of the field upon which we have entered. Not every fact, however laboriously attained and rigorously proved, is an important fact, in chemistry any more than in other branches of knowledge. Our aim is to discover the laws which govern the transformations of matter; and we are occupied in amassing a vast collection of receipts for the preparation of different substances, and facts as to their composition and properties, which may be of no more service to the generalisations of the science, whenever our Newton arises, than were, I conceive, the bulk of the stars to the conception of gravitation.

It may, however, be urged that the growth of chemical theory keeps pace with the accumulation of chemical facts. It is so, if the elaboration of constitutional formulæ is leading us up to such a theory. But at present, however useful and ingenious this mode of summarising chemical facts may be, it does not amount to a theory of chemistry.

Two objections to regarding such formulæ as anything more than a chemical short-hand, as it has been termed, seem worth recalling. The first is mentioned at the outset in most text-books in which these formulæ are employed, but sometimes, I venture to think, lost sight of afterwards. The arrangement of the atoms of a molecule in one plane is equally convenient in diagrams, and improbable as a natural fact. But is not this arrangement used as though it were a natural fact when the possible number of isomeric bodies is inferred from the number of different groupings of the atoms which can be effected on a plane surface? The conceptions of plane geometry are much simpler than those of solid geometry (which is another recommendation of the present system of formulæ); but so far as I am able to follow the similar theories which have recently been propounded independently by MM. Le Bel and van't Hoff, the consideration of the possible isomerisms of *solid* molecules leads to new conclusions.* Wislicenus has found that paralactic acid undergoes the same transformations as ordinary lactic acid when heated and when oxidised. The two acids differ in their action on polarised light. His conclusion is that paralactic acid does not differ in its atomic structure from the lactic acid of fermentation, and that the kind of isomerism which exists between the two acids is not connected with the difference in the reciprocal arrangement of the atoms, but rather with a difference in the geometric structure of the molecule. To this difference he gives the name of "geometric isomerism."† The authors named above agree in supposing that the action of substances in solution on polarised light results from an unsymmetrical arrangement of atoms and radicles in three dimensions around a nucleus-atom of carbon.

The second objection relates to the statical character of the account which "developed" formulæ give of the differences between different kinds of matter. The modern theory of heat supposes, not only that the molecules which constitute any portion of matter are in constant rapid motion, but that the atoms which constitute each molecule are similarly moving to and fro. Such movement might be an oscillation about the position assigned to the several atoms in the constitutional formula of the molecule. Since, however, the modes of formation and decomposition of substances are the principal facts upon which the formulæ are based, it is to be considered whether these facts may not depend altogether upon the nature or average nature of the motion impressed upon the atoms—that is, upon dynamical and not upon statical differences.

Many substances are known whose existence is contrary to the theory of valency and saturation, such as nitric oxide and carbonic oxide; others, which transgress the theory of isomerism, such as chloride of dichlordibromethane (C^2 Cl^2 Br^2, Cl^2) and bromide of tetrachlorethane (C^2 Cl^4, Br^2), which should be identical, but are isomeric:‡ yet these theories are simply an expression of the statement that certain substances can exist or can differ, while others cannot. It is true that in the vast majority of cases the theoretical limitation seems to hold good. But just as the absence of any fossil remains of the connecting links between species is only significant if the geologic search has been sufficiently thorough, so it is with chemical theories depending upon the non-existence of certain classes of bodies. Indeed, in our case, where investigation is guided by theory, and, as a rule, only those things which are looked for are found, the limitation may be partly of our own making. A chemist who should depart from the general course, and set himself to prepare substances whose existence is not indicated by theory, would perhaps obtain results of more than the usual interest.

Among chemical inquiries, if ever such a list as I have ventured to suggest should be drawn out, I hope that many would be included relating to the most familiar substances and the simplest cases of chemical change. The thorough study of a few reactions might perhaps bring in more knowledge of the laws of chemistry than the preparation of many new substances.

I believe that if any chemist not content with a process giving a good yield of some product examines minutely the nature of the reaction, observing its course as well as its final result, he will find much more for study than the chemical equation represents. He will probably also find that the reaction and its conditions are of a formidable complexity, and will be driven back towards the beginnings of chemistry for cases sufficiently simple for profitable study.

In concluding my remarks, I desire briefly to refer to another branch of chemical science, to the advancement of which this Association seeks to contribute, I mean applied or technical chemistry. One of the principal differences between the papers read before this Section, as a class, and those which the Chemical Society receives, is the larger proportion in our list of papers on technical subjects. Whatever chemists may hold, there can be no doubt that the estimation of our science by the outside world rests largely on the well-founded belief that chemistry is useful. Indeed, though scientific chemists are justly eager to vindicate the value of investigations remote from any application to the arts, they cannot feel a livelier sense of triumph when the suc-

* Bull. de la Soc. Chem. de Paris, t. xxii. p. 337, and t. xxiii. p. 295.
† Ann. Chim. et Phys., 5me série, t. l. p. 122.
‡ Bull. de la Soc. Chim. de Paris, t. xxiv. p. 197.

cessful synthesis of a vegetable principle yields at the same time a product of great technical value, as in the case of the production of artificial alizarin.

By visiting in turn the principal centres of British industry, this Association brings together men engaged on pure and on applied chemistry. We who come as visitors may hope that our papers and discussions here may bring fresh interest in the science, if not actual hints for practice, to those whose art or manufacture is based on chemistry. In return, the most interesting communications the Section has received have not unfrequently been the descriptions of local industries; and there is no part of our hospitable reception more welcome and more instructive to us than the opportunities which are provided of seeing chemical transformations on a large scale, effected by processes which observation and inventiveness have gradually brought to perfection and with the surprising familiarity and skill which are engendered by daily use.

SECTION D.—BIOLOGY.

Department of Zoology and Botany.

Dr. Hector, chief of the New Zealand Survey, gave a most interesting account of the modes of occurrence of the Moa bones in New Zealand. He used the term Moa in preference to that of Dinornis, because the bones of the New Zealand birds were now divided among so many genera. He demonstrated most conclusively that the knowledge of their former existence was not communicated to the Maoris by the Europeans, who deduced their structure from their remains, but, on the contrary, was imparted to the latter by the former. Up to recent times there had been a constant fulfilment of the statements made by the Maoris concerning the localities in which the bones would be found. He believed there was no hope of ever finding the birds alive, for he himself had been over the whole of the islands very thoroughly without seeing them. Dr. Hector exhibited a map of New Zealand on which were denoted all the areas in which Moa bones had been found, and all the localities in which considerable finds of bones had been made, with indications of their condition or surroundings. He found that the country occupied by primeval forests before the advent of Europeans was that in which Moa bones did *not* occur. His deduction was that they lived in the open and low scrub, in which they could walk. In all this region, within his own memory, the Moa bones were extremely abundant in the South Island, all over the ground; but these bones were very rarely found in collections, for they were usually decomposed and split and warped. In the enormous extent of Sub-Alpine country in the South Island, which was covered by only a light vegetation, large quantities of well-preserved Moa remains had been recently found, associated with remains or reliques of natives. It appeared to him that the natives had pressed up the country for the purpose of capturing, killing, and eating the Moas; and as the natives could not follow them through the sharp bayonet-grass and other underscrub, they seemed to have got at them by setting portions of it on fire, which collected the animals together, often killed them, and accounted for so many of their bones being accumulated in particular spots. And in some of these localities where the Moas were destroyed by fire, little heaps of chalcedonic quartz pebbles, which were their crop-stones, were found, each heap associated with the remains of one bird. And this fact, of their being the crop-stones, had been conclusively proved by the discovery of a carcase crushed and decayed so as to be unfit for anatomical purposes, but containing within the thorax just such a little heap of pebbles as had been described. The second chief mode of occurrence of Moa bones was in the turbary deposits and desiccated swamps, occurring in almost all the valleys leading to the east coast. One notable deposit was at Glenmark, where the remains of a terrace at a higher level had been cut through by the stream, leaving a large turbary deposit on the shoulders of the hill on both sides. Here were found a great number of Moa bones, without any associated Maori implements. Out of this place had been got bones sufficient to cover twice the area of the Section Room. They occurred mixed together, and above, below, and among great accumulations of drift-wood, which were ten or twelve feet deep over many acres. The bones got out of that deposit indicated at least 1,700 individuals, which had either been carried down and smothered in floods or which had died naturally and been carried down by the water. Similar deposits occurred in caves, and in turbary deposits on the coast, which were exposed below high-water mark, showing that there had been comparatively modern submersion; but there were no marine deposits above, and they rested on a denuded surface of the latest Tertiary beds. There seemed to have been an uninterrupted submergence of New Zealand since the time when the Moas were first developed in such large numbers; and there had been no considerable re-emergence of the land since then. Another mode of occurrence of Moa bones was wherever the country was favourable for Maori camps, on the sheltered grassy plots and links, or among the sand-hills near. They were associated with their cooking-hollows, and with stone implements, which, however Neolithic in aspect, were similar to those used now by Maoris. It had been said that the oldest Moa remains were those associated with the ancient moraines of the upper valleys, but these were the great natural roads up which it was very likely that some Moas would travel and leave their remains there. In caves the Moa bones were found resting on the stalactitic shelves, perhaps cemented by a little carbonate of lime. They were hardly ever found on the lower surfaces of the caves; and he believed they had mostly gained access to the caves by falling through the upper chasms. He had evidence that sheep in modern days fell through in the same way, and their bones were found similarly situated in the caves. The earliest traces of the Moas that had been found were footprints at Poverty Bay, occurring in a soft pumice sandstone, within six or eight inches of the upper surface. Many blocks had been procured with these undoubted footprints. The lower surface of each depression was formed of very fine micaceous sand, but it was filled up with much coarser green quartzose sand. After the birds had passed, the impression had been filled up by blown sand. Undoubtedly a true bird-bone had been found in Tertiary deposits in New Zealand, but he was inclined to think it belonged to a gigantic extinct Penguin.—The President testified to the value of Dr. Hector's address by saying that he had never till that time really understood the modes of occurrence of Moa bones.—Prof. W. C. Williamson said that scientific workers who had advice and sympathy readily accessible to them could know little of the energy and enthusiasm required to sustain the solitary individual who had to labour without meeting a scientific or even an educated man for weeks and months. Dr. Hector was a conspicuous example in this respect, and deserved all the honour his fellow-workers in England could give him.

Dr. Carpenter gave a summary of the results of his investigations into the nervous and generative systems of comatula. He described as a nervous cord the cord existing in the axial hole of the skeletal segments, which Müller had described as a vessel. No cavity was to be found in it, and in a favourable plane of section branches from it to the tentacular muscles were detected. Although this cord was destitute of the ordinary structure and insulating material of nerves, that was explicable by the fact that only one kind of muscle had to be affected, and that all the muscles acted simultaneously, in flexion of the arm. The cord to each arm came off from the curious five-lobed organ in the calyx below the perivisceral cavity. This was determined to be the central nervous mass by the following experiment. A living comatula was taken, and the visceral mass was turned out. A needle was thrust into the supposed nervous organ, and instantly all the arms were coiled up to their full extent, and were gradually relaxed. This was repeated several times. A curious generative axis had also been discovered in the shape of a cord passing through the middle of the nervous centre, and through the visceral mass to spread into a plexus around the mouth. Thence branches were given off to the arms and pinnules, and the ovaries and testes were directly connected with these cords as axes. Dr. Carpenter said that these facts were such as to necessitate the separation of the crinoids much further from the rest of the echinoderms than hitherto. In fact, he considered they had little in common beyond the calcareous network of the skeleton. In conclusion he said that he had learnt from a trustworthy observer that after a recent hurricane in the West Indies a vast number of Pentacrini had strewed the shore of Barbadoes, in all stages of growth, from one inch to eighteen inches in length; but unfortunately no naturalist was at hand to reap the rich harvest.

Dr. I. Bayley Balfour read a paper *On the Flora and Geological Structure of the Mascarene Islands*. He said that in Bourbon there was a great contrast between the flora of the older north-western portion and that of the south-eastern district within the area formed by the volcano now acting. Here the soil was very barren, with only a few composites and other plants that flourished in a dry soil. The flora was not most closely allied to that of Africa, but rather to that of India and the Indian Archipelago.

There was a great profusion of ferns, mosses, and lower cryptogams; and evergreens were abundant. The species were few in proportion to the genera, and the genera in proportion to the orders. The proportion of indigenous plants and of species to any area was generally small; but in Bourbon there was the great number of 1,700 species. The most remarkable genus in the group, perhaps, was Pandanus, the screw-pine, which had species peculiar to each island, though the commonest, *P. utilis*, occurred on all three islands. Certain genera were found to be endemic to the group, especially in the Rubiaceæ and Compositæ. In addition, in each island there were certain genera endemic to that island alone. In North-western Bourbon, although, as in Mauritius, settlers had produced much alteration by cutting down trees, &c., there was still an abundance of plants which flourished in a moist climate. The flora of Mauritius exhibited affinities with that of N. W. Bourbon, although possessing endemic genera. Perhaps no place in the world had had its flora so much altered by settlers, especially by means of fires through carelessness. The original flora had been almost exterminated. The few plants now remaining included one new genus; and there were certain peculiar Pandani, but the general type was allied to that of Mauritius. In many of the small volcanic and coral islands which surround Mauritius and Rodriguez, very often little more than rocks, there were genera which were peculiar to those islands, or else species that were representatives of other species existing on the main islands. Round Island, a mere cone near Mauritius, had three genera of palms represented by different species, which were found nowhere else; and exhibited many other peculiarities in its flora. Dr. Balfour reserved his opinion on the vexed question of the origin of these islands by independent volcanic action or by the submergence of an ancient continent connected with Africa; but stated that soundings taken between Mauritius and Rodriguez, about fifty miles west from the latter, gave a depth of 2,000 fathoms; while 100 miles S.W. of Mauritius the depth was 2,700 fathoms.—Prof. Williamson remarked on the parallel between these facts and those first brought to light by Mr. Darwin relative to Galapagos. It appeared that these modifications of species and genera were such as must necessarily have resulted from modifications in a long course of time; and they compelled naturalists to accept Mr. Darwin's views whether they liked them or not. Coupled with the facts derived by Mr. Wallace from the Indian Archipelago, he thought considerable probability was given to the submergence theory.—Prof. Dickson could not see that the occurrence of representative forms on different oceanic islands was any stronger proof of evolution than the facts relating to the grouping of plants about geographical centres; but Prof. Williamson maintained that the occurrence of distinct yet analogous species on contiguous islands of very recent geological age was a striking evidence of modification produced by new physical conditions, unless indeed distinct new creative acts were admitted within a comparatively modern period.

Prof. Williamson gave an account of his recent discoveries among the fossil seeds of the coal measures, and partly confirmed and partly controverted Brogniart's views on some of the same seeds. He (Prof. Williamson) gave the name Lagenostoma to a form of seed larger and more bulky than a grain of rice, which had a flask-shaped cavity above the nucleus, between it and the micropyle. This cavity was surrounded by a membrane quite distinct from that investing the nucleus. Prof. Williamson believed that he had found pollen grains in this cavity, and that the only difference between this and an ordinary coniferous seed consisted in the presence of this chamber, which protected the pollen and brought it into contact with the nucleus. Another seed of the same general type had the upper part of the nucleus contracted, forming a sort of mammilla: thus the cavity above became of a different shape. He named it Physostoma. Another type he called Æthiotesta. All these were from the Lancashire coal-field. A specimen from Burntisland showed a transition from the extremely small and narrow micropyle of ordinary angiospermous seeds, and the large chamber of Lagenostoma. Prof. Williamson also referred to Cardiocarpum, which he found to have the nucleus thickened, and to have a prolonged spur containing the micropyle. Antholithes and Cardiocarpum were but portions of the same flowering plant. He found that Trigonocarpum had really a long projection at the end, of a similar nature, but from some Newcastle specimens he inferred that it had a large investing sarcocarp. The type was not at all dissimilar to Cardiocarpum.

Prof. Balfour, in a *Notice of Rare Plants from Scotland*, drew attention to the discovery of *Naias flexilis* in Perthshire, hitherto only found in Ireland. He exhibited the original specimen of *Salix sadleri* and *Carex frigida*, discovered in Scotland last year by Mr. Sadler.—Dr. I. Bayley Balfour contributed some notes on Turneriaceæ from Rodriguez, especially referring to one new form.—Prof. A. Dickson exhibited a *Primula vulgaris* with interpetaline lobes, and pointed out its relations to Soldenella and other Primulaceæ; he also described a monstrosity in *Saxifraga stellaris*, in which there occurred a calyx, no corolla, many stamens, and many carpels. Two specimens were found, each with a single terminal monstrous flower.

It is to be regretted that there was a paucity in the attendance of distinguished zoologists and botanists, and that the number and importance of the papers read was not so great as to furnish any idea of a widespread existence or encouragement of research in natural history. It might be well for naturalists to put themselves in evidence a little more strongly, and to show the value of their results more prominently, if they desire to be aided in their researches by public funds, or to win general sympathy, especially when geologists and anthropologists make such vigorous displays of their conquests.

Department of Anatomy and Physiology.

Prof. Rolleston, in moving a vote of thanks to Prof. Cleland for his presidential address to the department, said he had rarely spent an hour with more pleasure than in listening to that address. He would show the value he set upon it by saying that Prof. Cleland's old master, the great John Goodsir, would have been glad to hear it. He believed much of what the President had said would take its date from that meeting as of permanent authority and value.

Dr. McKendrick read the important report *On the Physiological Action of Light*, by himself and Prof. Dewar. We hope to publish it in full in an early number.

Mr. W. J. Cooper, in a paper *On the Physiological Effects of various Drinking Waters*, referred to the experiments of M. Papillon on various animals, described before the French Academy of Science in 1870–73, by which it was shown that not only the ash of the food eaten affects the composition of the bones, but also that mineral matter in dilute solution is capable of being assimilated. Consequently, alterations in the composition of the water supply of a community might be of very great importance to the organic structure of the human body, if the very composition of the bones is affected by the quality of the water. The inorganic impurities of water had been too much overlooked, notwithstanding the serious consequences which sometimes follow. Mr. Cooper insisted that one of the first conditions in the inauguration of a water-supply should be to ensure perfect freedom from excess of any mineral except those comparatively harmless ingredients, chloride of sodium and carbonate of lime.

Mr. T. G. P. Hallett read a paper *On the Conservation of Forces*, devoted to a long argument against this principle being extended to vital phenomena. He endeavoured to prove that life, whether tested by its origin or its effects, was a force, and that the laws of that force were not such as the conservation principle required and declared. Dr. Allen Thomson, at the close of the discussion which followed, thought it best to suspend judgment on the points that had been mooted, and to continue the quiet investigation of physical phenomena; his impression, derived from long observation, being that the more the phenomena of life were attended to, the more fully they were explained by known laws.

Among other papers may be mentioned Messrs. L. C. Miall and F. Greenwood's, *On Vascular Plexuses in the Elephant and some other Animals;* and Mr. Greenwood's *On the Preservation of the Larger Animals for Anatomical Examination.*

If the papers read before the Department of Anatomy and Physiology had to be taken as an index of the activity of research and thought concerning these subjects in Great Britain, we should have to confess ourselves to be at a low ebb. The department only sat on three days out of five, and those three days were certainly not crowded with valuable papers. The physiological investigations of Drs. McKendrick, Lauder Brunton, and Pye-Smith, and Prof. Dewar, were of high interest and great value; but the subjects they referred to cover only a very small part of the wide domain of Physiology. Morphology was represented most worthily by the President's address, but there was a plentiful lack of memoirs on descriptive anatomy, morphology, embryology, and histology. It is of course difficult to make the details of morphological investigation interesting in a spoken narration, but expositions of new or improved principles,

and results of research in all departments, could be usefully brought forward at these meetings and receive illumination from discussion by those in authority. Are our anatomists and physiologists less willing to make such efforts than other scientific men, or have they a greater fondness for remaining in their own special haunts without emerging on any common ground?

Department of Anthropology.

Miss A. W. Buckland, of Bath, read a paper *On Rhabdomancy and Belomancy*, in which she endeavoured to show that rhabdomancy, or divination by means of a rod, still practised in England in some localities, was a survival of a very ancient superstition, originating in the use of rods as symbols of power.

Mr. John Evans described fully the proposed code of symbols for archæological maps which has been drawn up by a committee of leading archæologists on the continent of Europe, and will probably be extensively used. Suggestive crude symbols are adopted for the leading varieties of ancient remains, and a series of modifications of each chief form is to be used, to denote as far as possible the exact nature of the remains.

Mr. Hyde Clarke furnished a notice of the prehistoric names of weapons, in continuation of a note laid before the British Association in 1873, which showed that there was a community of aboriginal names of weapons in the prehistoric epoch. He now added that further research had confirmed these views.

Mr. Hyde Clarke also read a paper *On Prehistoric Culture in India and Africa.* After referring to his investigations as to the evidence of the successive migration and distribution of languages in Asia, Africa, North, Central, and South America, and in some cases in Australia, he proceeded to give the result of later special investigations as to the community of culture in India and Africa. The philology of the aboriginal languages of India could only be effectually studied from those of Africa, and Mr. Hyde Clarke suggested that it would be a great advantage if some of the missionaries of the two regions could interchange stations.—Prof. Rolleston remarked upon the desirableness of a complete work being prepared on the present ethnology of India, under the superintendence and at the cost of the Indian Government.

Dr. Phené, in his paper *On the Works, Manners, and Customs of the Prehistoric Inhabitants of the Mendip Hills*, adopted the theory of a similarity of race in the people who formerly occupied the caves on the Atlantic seaboard of Europe and of Britain; and identified the inhabitants of the Mendips with them.

Mr. D. Mackintosh read a paper *On Anthropology, Sociology, and Nationality*, which referred especially to distinctions of race in the British Isles, and defended his previously expressed views. He believed that the various colonising tribes had either continued in certain localities with little interblending, or that the process of amalgamation had not been sufficient to prevent the persistence of the more hardened characteristics. He tried to show that between the north-east and south-west the difference in the character of the people, irrespectively of circumstances, is so great as to give a semi-nationality to each division—restless activity, ambition, and commercial speculation predominating in the north-east, and contentment and leisurely reflection in the south-west.

THE AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.—DETROIT MEETING.

LAST week we gave a general account of the meeting of the American Association, from an American correspondent. The following are brief notices of some of the principal papers read.

We have already referred to the presidential address of Prof. Le Conte, and to the address of Prof. Dawson, both of which were anti-evolutionary, the latter more distinctly so than the former. Prof. Dawson's views are so well known that we need not refer at length to his Association address.

Prof. Augustus R. Grote, Director of the Museum of the Buffalo Academy of Sciences, undertook the task of throwing light upon past geological eras by showing the present distribution of certain North American insects. He described the glacial epoch as occurring at the close of the Tertiary by a continuous loss of heat. The winters gradually lengthened, the summers shortened. The tops of mountains that now bear foliage were then covered with snow, which, in time consolidating, formed glacial ice that flowed into the valleys. Gradually an icy sea extending from the north spread southward, even over the Southern States and down the Valley of the Mississippi. Existing insects of the Pliocene, no matter how gradually they were affected by the change, must have eventually left their haunts, and doubtless many species were exterminated. At the present day there are found in the tops of the White Mountains, and in the lofty ranges of Colorado, certain species of butterflies and moths which are completely isolated. To find others of the same kinds we must explore the Plains of Labrador and the northern portions of our continent; there and there only do we find similar or analogous species. A White Mountain butterfly, *Oeneis Semidea*, was cited as an instance in point, and other butterflies and moths were mentioned, whose isolated habitats served to prove the general proposition. The retirement of the glacial seas at the close of the epoch was then considered. Then the summers were lengthening, while the winters were shortened. Then ice-loving insects, such as the White Mountain butterfly, hung on the edge of the ice sheet which supplied their food, and followed its retreat—not all, but some of their forms surviving. Straying upon the local glaciers of the mountain ranges, they were left behind in some instances, while the main body followed the retiring ice sheet to the far north. Those that were left behind still find the conditions of their existence in the snow-covered summits of the present day. As the valleys became warmer and glaciers fewer, the chances of their escape from their isolated positions gradually diminished till their removal became impossible.

Prof. E. S. Morse, of Salem, Mass., has for a long time made a study of the bones of embryo birds. At this meeting he recalled briefly the evidence he had shown last year regarding the existence of the intermedium in birds by citing the embryo tern, in which he had distinctly found it. This year he made a visit to Grand Menan expressly to study the embryology of the lower birds, and was fortunate in finding the occurrence of this bone in the petrel, sea-pigeon, and eider duck. This additional evidence showed beyond question the existence of four tarsal bones in birds, as well as four carpal ones. In these investigations he had also discovered embryo claws on two of the fingers of the wing—the index and middle finger. Heretofore in the adult bird a single claw only had occurred in a few species, such as the Syrian blackbird, spur-winged goose, knob-winged dove, jacana, mound bird, and a few others, and in these cases it occurred either on the index or middle finger or on the radial side of the metacarpus. All these facts lent additional proof of the reptilian affinities of birds.

Prof. S. P. Langley, of Alleghany Observatory, detailed some of the conclusions at which he had arrived after years of study of the solar surface. Prof. Langley first showed by comparative experiments that an absorptive atmosphere surrounds the sun. Little attention has in recent years been paid to the study of this atmosphere. The earlier efforts to tabulate its absorptive power, produced with different observers, though men of eminence, strangely discordant results. Their methods and deductions were given in detail. Secchi's results, making the neighbourhood of the edge of the sun about half the brightness of the centre, are probably near the fact. Prof. Langley applied well-known photometric methods to the problem. By attaching a circle of cardboard to the equatorial telescope, a solar image is received on the board, plainly showing spots, penumbræ, &c., if the image be one foot in diameter. From holes in this cardboard, pencils of rays issue, which being caught on a screen give a second series of images. If these images are caught upon separate mirrors, instead of a screen, their relative light can be made the subject of comparison with that of a disc of flame from Bunsen's apparatus, and thereby their relative intensity determined. Between each aperture and its respective mirror a lens was interposed which concentrated the pencil of rays. By suitable additions this apparatus can be converted to a Rumford photometer, and in this form it proved most available in Prof. Langley's hands. He found a value for the brilliancy of the umbra in sun-spots, considerably higher than that hitherto computed. The blackest umbra, he finds, is betweeen 5,000 and 10,000 times as bright as the full moon. The light of the sun is absorbed by its atmosphere not in the same, bu in a greater proportion than its heat. A long series of experiments shows that not much more or less than one-half of the radiant heat of the sun is absorbed or suffers internal reflection by the atmosphere of the sun itself. Observations indicate that this atmosphere is (speaking comparatively) extremely thin; Prof. Langley is inclined to regard it as identical with the "reversing layer" observed by Dr. Young,

of Dartmouth, at the base of the chromosphere, though the chromospheric shadow should perhaps be taken into the account. The importance of a study of this absorbent atmosphere becomes evident if we admit that the greater part of the 500° which separate the temperature of the temperate zone from absolute zero is principally due to the sun's radiation. To this atmosphere new matter is constantly being added and taken away by the continual changes of the interior surface. Any alteration in the capacity for absorption—say a difference of 25 per cent., which could hardly be recognised by observation—would alter the temperature of our globe by 100°. The existence of life on the earth is clearly dependent on the constancy of the depth and absorption of this solar envelope. Hitherto we have chiefly confined calculations to the diminution of solar heat by contraction of the sun's mass—an operation likely to go on with great uniformity. But here is an element of far more rapid variation. If changes in the depth of this solar envelope are cyclical, they would be accompanied by cyclical alterations of earth's temperature. This may serve alike to explain the characteristics of variable stars and the vast secular changes on earth indicated by geology. If the law of alterations in that envelope can be ascertained, new light may be shed on the history of the globe and the near future of life upon it.

Prof. Thomas Meehan, of Germantown, Penn., made an attack on Darwinian theories in a paper which disputed the assumption that insects are a material aid in the fertilisation of plants. He drew the following conclusions: (1) That the great bulk of coloured flowering plants are self-fertilisers. (2) That only to a limited extent do insects aid fertilisation. (3) Self-fertilisers are in every way as healthy and vigorous, and are immensely more productive, than those dependent on insect aid. (4) That when plants are so dependent they are the worse fitted to engage in the struggle for life—the great underlying principle in natural selection.

Prof. Morse described the evident characteristics of insects which seemed not only fitted for fertilisation, but were found actually engaged in the process. He was not prepared to abandon the vast mass of facts already obtained on account of the few and doubtful experiments detailed by Prof. Meehan. Prof. Riley thought that the fact that insects were absolutely essential to the existence and perpetuation of many plants, had been proved by experiments and observations so numerous and convincing that it could no longer be denied. He mentioned his own experiments with the *Yucca;* and he met and combated the theory that self-fertilisation, like interbreeding, did not tend to deterioration. Prof. Meehan, in explanation of his views, stated that he regarded the present dependence of plants upon insects as an evidence of weakness and accident, or of deformation in the plant. Prof. Riley said that it was a mistake to suppose that insect life was scarce in the Rocky Mountains.

A paper was presented *On some New Fossil Fishes and their Zoological Relations*, by Prof. J. S. Newberry, of Columbia College, giving brief descriptions of interesting fish remains found during the past year in the Devonian and Carboniferous rocks of Ohio. Of these, the most important "find" was that of nearly the entire bony structure of a single individual of *Dinichthys Terrellii*, the hugest of all the old armour-plated Ganoids. Life-size drawings of most of these bones were exhibited to the Association, and copies of them will appear in the second volume of the "Geology of Ohio," now going through the press. Drawings of another species of *Dinichthys* was shown (*D. Hertzeri*) in which the maxillaries and mandibles are set with teeth instead of being sharp-edged. The remains of both these monsters have been found only in the upper Devonian rocks of Ohio. Prof. Newberry also exhibited to the Association teeth of *Dipterus Glenodus*, and those of a new genus belonging to the same family.

Prof. E. D. Cope, of Philadelphia, made a communication *On the Indications of Descent exhibited by North American Tertiary Mammalia.* The gradual development from one form to another by changes in the foot bones was traced through a long series from extinct Tertiary animals to those of the present day. A similar process of change was traced in the teeth of animals, the simpler forms of teeth in the Eocene being a crown with four tubercles. The human skeleton, Prof. Cope declared, retained many more ancient types than other Mammalia.

A paper from Prof. Daniel Kirkwood, of Bloomington, Ind., *On the Distribution of the Asteroids*, was read by Prof. Langley. Prof. Kirkwood stated that twenty years ago, when the number of known asteroids did not exceed fifty, it was inferred from purely physical considerations that there must be great irregularity in their distribution, and that gaps would be found in their zone where their periods were commensurable with those of the planet Jupiter. In 1866, when the number of asteroids amounted to eighty-eight, the agreement of theory and observation in this matter was the subject of a paper from Prof. Kirkwood, read at the Buffalo meeting of the Association, and the evidence was again summed up in a paper at Indianapolis in 1871. Since then thirty-one asteroids have been added to the group. It is now proposed to show that the truth of the theory advanced in 1866 is now more than ever determined. The Professor proceeds to divide the space between the asteroids into six zones by orbits whose periods would be commensurate with those of Jupiter. Then taking the members of the group in the order of their mean distances, it is found that the widest intervals between them are at these gaps where orbits would coincide with certain multiples of Jupiter's revolution. He remarks that it is a notable fact in the development of the solar system that the largest planet, Jupiter, should be succeeded by a space so nearly destitute of matter as the zone of the asteroids, the ratio of masses being as 1 to 5180. An explanation of the disproportion was given in a paper read in 1870; but it may be asked what might have been the result if the density of the asteroidal group had been equal to that of the other planetary rings. For reasons which he assigns, Prof. Kirkwood believes that if the asteroidal group had possessed a total density half that of Jupiter, they would when nebulous have been brought so closely into contact by the great planet's attraction as to fuse into one, instead of remaining as separate bodies. A similar result he regards as having taken place in the case of Uranus. A formation of the same kind would result where the period of a planet was one-third that of Jupiter; corresponding to the ratio between the periods of Jupiter and Saturn. The rare instances of great inclination among asteroids' orbits he is inclined to believe may have been occasioned by comets, when the minor planets were themselves in a cometary or nebulous condition.

The Hon. L. H. Morgan, of Rochester, read papers *On Ethnical Periods and the Arts of Subsistence.* The discussion of ethnology would be much facilitated by the use of a certain number of ethnical periods representing conditions in the advance of man from his earliest to his higher conditions. Mr. Morgan proposes the following:—

1. A period of savagery.
2. The opening period or lower status of barbarism.
3. The middle period of barbarism.
4. The closing or upper period of barbarism.
5. The period of civilisation.

The ages of stone, bronze, and iron have served a useful purpose in archæology, but the progress of knowledge has rendered more definite subdivisions necessary. The use of stone implements began far back in savagery, which extended even to the introduction of tools of iron. The successive arts of subsistence offer distinctions of more value. The period of savagery begins with the human race. The invention or practice of the art of pottery may enable us to draw the line between savagery and barbarism.

The transition from the lower to the middle stages of barbarism is marked in the eastern hemisphere by the domestication of animals; in the western by the cultivation of maize and succulent plants by irrigation, together with the use of adobe and stone in house architecture. The upper status of barbarism is cut off from civilisation by the invention and use in the latter of a phonetic alphabet and the art of writing.

In respect to the effect of arts of subsistence in modifying the improvement of mankind, Mr. Morgan takes very broad views. He is of the opinion that success in multiplying the sources and amount of food decided the question of man's supremacy on earth. His advance has been identified with improvement in this particular.

Prof. Burt G. Wilder, of Cornell University, read papers on the following natural history subjects:—Notes on the American Ganoids (*Amia*, *Lepidosteus*, *Acipenser*, and *Polyodon*); The Use and Morphological Significance of the Caudal Filament of the young *Lepidosteus*; The Embryology of Bats; The Affinities and Ancestry of the existing Sirenia. This paper was based upon three specimens which were exhibited. First, a fœtal Dugong, 2½ feet long, obtained from Australia through Prof. H. A. Ward. Second, a fœtal Manatee, between three and four inches long (as if extended), obtained from South America through Prof. James Orton. Third, a fœtal Cetacean (probably

Porpoise), three inches long (as if extended), lent to Prof. Wilder by Mr. Alex. Agassiz, Curator of the Museum of Comp. Zoology at Cambridge. The last two specimens are believed to be the smallest of their kind hitherto recorded.

Prof. Wm. S. Barnard, of Canton, Ill., read a paper *On the Development of the Opossum, Didelphys virginiana.*—Prof. Barnard read another paper, in which he compared the muscles of man with those of the higher apes, showing the points of similarity as well as of difference. An interesting point made in this paper was the statement that one of the buttock muscles supposed to be peculiar to the higher apes, distinguishing them from man, really existed in the human body and in a similar position. It was shown that the muscle thus described by Traill, and afterwards by Wilder as in the chimpanzee, and by Owen and Bischoff as in the orang, and by Coues as in the opossum, is also found in man, and offers no distinction in this respect. Three new muscles about the hip-joint, found in the orang and some other apes, were also made the subject of description; these muscles have no homologues in man. Two of these act to rotate the leg and draw it inward; the other seems too small to have any functional value and is probably a rudiment, but is interesting as occurring also in some of the lower apes and the opossum. The other muscles in this region of the body were like those of man, but in the case of an orang the short head of the biceps of the thigh was found entirely separated. This is only occasionally the case with the orang, and this peculiarity is not known to exist in any other animal. The two large external muscles of the calf do not unite with each other to form a single tendon Achillis, consequently in the orang this tendon is double, which sometimes occurs with marsupials. These investigations, which were explained in much technical detail, tend to prove that all the muscles possessed by man can be traced backward in the lower forms of animals, through the apes to the lemuroids.

Prof. Barnard gave a detailed account of his observations on the *Protozoa*, made in the anatomical laboratory of Cornell University, Ithaca, N.Y., where the specimens described were also seen by Prof. Wilder and others than the investigator himself.

Prof. George F. Barker, of Philadelphia, read a paper *On the Cause of the Relative Intensity of the Broken Lines of Metallic Spectra.* The purpose of this paper is to give the general result of a series of measurements made to ascertain, by Vierordt's method, the relative intensity of these various lines, and to compare these with their lengths measured micrometrically. Vierordt's method consists in measuring the intensity of a coloured light by the amount of white light necessary to extinguish it. By means of a third telescope attached to the spectroscope, a bright slit of light may be thrown upon any portion of the spectrum, and by varying the distance of the source of this light, until it extinguished the various spectrum lines in the order of their brightness, a series of numbers was obtained which, by the law of the inverse squares, gave the relative intensity of the different spectrum lines. The metals experimented upon were copper, gold, silver, antimony, bismuth, and magnesium. The general result is, that in no case does the length of the spectrum line follow the law of brightness. Hence some other hypothesis must be suggested to account for the phenomena. The author suggested one which seemed to him to be at least possible, and to be sustained by the prevalent views on molecular and atomic physics. The constitution of a gas is simple; the molecules composing it move in straight lines, and encounter each other and the walls of the containing vessel in so complex a way that Prof. Maxwell doubts if mathematics can follow their paths. The oscillations of the atoms within the molecule, are, however, less complex; they either are simple harmonic motions themselves, or they may be resolved into such. It is these harmonic vibrations which, communicated to the ether, cause the spectrum lines; the number of the different forms of oscillation constituting the number of lines in the spectrum, the period of any one oscillation determining the wave length of the corresponding line, and the amplitude fixing the brilliancy of that line. These things being granted, we have only to suppose what is perfectly conceivable, that the amplitude of the vibration, the only point we are now concerned with, varies with the temperature differently for each of the different kinds of vibration in the molecule, or, what is the same thing, with the wave length. If, for example, the peculiar harmonic vibration of the atoms of a copper molecule which gave the longest line in the green, diminished the amplitude of its oscillation less rapidly than the one in the blue, then this is a sufficient reason why it should be the longest. We may, therefore, by inspection of a broken spectrum, conclude at once on the rapidity with which the amplitude of the different harmonic vibrations of the atoms within the molecule decreases with decreasing temperatures, this being simply in the order in which the lines are arranged as to their length. This is offered as a working hypothesis to be proved or disproved by special investigation. From the facts already known it may be regarded as antecedently probable. It seems to be a step taken into the great field lying between chemistry and physics, at present a great and unexplored gulf. Work done here cannot be thrown away even if done to test an untenable hypothesis. It must bear fruit, though it may be very different in kind from that anticipated.

REPORT ON THE PROGRESS AND CONDITION OF THE ROYAL GARDENS AT KEW DURING THE YEAR 1874

FROM Dr. Hooker's recently issued report on the progress and condition of the Royal Gardens, Kew, for 1874, we learn that a series of lectures, or, as they are called in the report, "practical lessons," have been given to the gardeners during the evenings, after working hours. These "lessons" embrace the elements of structural, systematic, and physiological botany; of chemistry, physical geography, and meteorology, in their application to horticulture; of economic botany, forestry, &c. They are given, some in the young men's Library, others in the Garden or Museum. Notes of these lessons have to be taken by those attending them, which, after being fairly written out in note-books, are examined periodically by the teacher and corrected, or more explicit instruction given if necessary. The attendance at these lessons is voluntary, but the fact of "good attendance" is recorded in every gardener's certificate of conduct and proficiency on his leaving the service of the establishment.

These lessons have been instituted with the view of the better education of the gardeners in subjects bearing upon their profession, so as to qualify them for "Government and other situations in the Colonies and India, where a scientific knowledge of gardening, arboriculture, &c-, is required." Most of the colonial gardens and Government plantations are at the present time under the superintendence of able men, who received at some time or another instruction at Kew.

The liability of *Coffea arabica* to the attack of both insects and fungi have been abundantly proved of late by the visitation of the so-called blights in Dominica, Southern India, and more recently in Ceylon. In consequence of this a good deal of interest is attached to the prosperity of the Liberian Coffee, which has been distributed from Kew. On this subject Dr. Hooker says: "A large stock of true Liberian Coffee has been obtained through the kind efforts of Messrs. Irvine and Woodward, of Liverpool. This is a larger and perhaps different variety from that received from Cape Coast. . . . Large quantities of both have been sent to the coffee-growing British possessions, and have arrived in excellent condition. Dr. Thwaites states that the Cape Coast Coffee, the safe arrival of which in Ceylon I mentioned in the report of last year, is, notwithstanding that it was immediately attacked by the leaf disease, doing well. He also remarks that 'the Cape Coast and Liberian Coffees, although they would seem to differ much as regards size of their respective seeds, yet in the matter of foliage there is great resemblance between them. In this latter respect they differ considerably from the ordinary coffee plant of Ceylon, their leaves being a good deal larger, more firm in texture, and tapering more gradually to the base.'"

The increased cultivation of coffee, and the introduction of varieties better suited to resist the attacks of disease, has, it appears, attracted the attention not only of the British Government, but also of the Colonial Governments, so that a good deal of correspondence has arisen with Kew on the subject. Dr. Hooker says: "My attention has in consequence been directed (1) to obtaining accurate reports as to the nature of the disease, of which several are confounded under one common epithet; (2) to recommending measures for the cultivation of coffee in colonies once famous for its production where it has been almost abandoned, as well as in others where the cultivation has been scarcely attempted; and (3) to the cultivation of new and improved varieties."

The Blue Gum Tree (*Eucalyptus globulus*), which has now become so popular that plants some twelve or fourteen feet high may be seen growing in the open air in some of our London parks, is recommended for planting by Dr. Hooker, simply on

account of its quick growth and its value as a timber tree, the wood being exceedingly hard and durable. With regard to its supposed beneficial effects in malarious districts, Dr. Hooker says he is "still unable to endorse the views of those who regard the tree as capable of cultivation in tropical swamps and as a prophylactic against ague and fever."

The prospects of the Ipecacuanha cultivation in India is, we are told, not very encouraging, owing rather to the slow growth and small yield of the underground root stock from which the drug is obtained, than to the want of success in growing and propagating the plants. "Nevertheless the cultivation must be persevered in. The causes that retard the progress of this valuable herb under cultivation are those that raise the price of it in its native country. Were it a plant that increased rapidly, it would be with difficulty eradicated from the forests which it inhabits."

One very important matter mentioned in the report is that referring to the new Herbarium, the site for which is not yet, however, determined upon. It is, moreover, satisfactory to learn that when erected it will, through the liberality of Thomas Philip Jodrell, Esq., M.A., the founder of the Jodrell Professorship (of Physiology) in University College, London, be associated with a laboratory for physiological botany. The contributions to the Gardens of living plants and seeds, to the Herbarium of dried plants, and to the museums of economic specimens, have been exceedingly numerous and interesting.

NOTES

M. JANSSEN'S appointment as the head of a new French Physical Observatory, which we intimated some time ago, has been gazetted. The French Government, we believe, wishes to give M. Janssen the choice of having the Observatory built at Fontenay, as was originally decided upon, or at Vincennes, which is at a less distance from Paris.

MR. WATSON, at Monday's sitting of the French Academy, read a long and interesting paper on the observations of the Transit of Venus made at Peking station, of which he was the chief. The question of the atmosphere of Venus and the difficulty of determining the exact time of real contact were examined at full length. M. Leverrier expressed his decided opinion that the determination of the parallax of the sun by this method was useless unless some unexpected service should be rendered by photography for solving the difficulty raised by Mr. Watson. Mr. Watson tried to discover to what height the atmosphere of Venus was liable to cause optical disturbances by its illumination by the sun, and he found it to be fifty-five miles, about 1-70th the diameter of the planet.

THE Kirtland Summer School of Natural History (named in honour of Dr. Jared P. Kirtland) was inaugurated July 6, 1875, in Cleveland, Ohio (U.S.) The session this year extended through five weeks, closing August 9, with appropriate exercises. The school was founded on behalf of the Kirtland Society of Natural Sciences, by Prof. Theo. B. Comstock and Dr. Wm. K. Brooks. Instruction was given in botany and entomology by Prof. Theo. B. Comstock, of Cleveland; in general invertebrate zoology by Dr. Wm. K. Brooks, of Cambridge, Mass.; in microscopy and protozoa by Prof. Albert H. Tuttle, of the Ohio Agricultural and Mechanical College, Columbus, Ohio; and a short course of lectures on geology was given by Dr. J. S. Newberry, of Columbia College, New York City, Director of the Ohio Geological Survey. The work was all done in the laboratory and in the field, text-books being wholly discarded. Twenty-five enthusiastic pupils, many of them lady teachers, availed themselves of the advantages afforded for the small fee of ten dollars. The expenses were paid by a subscription fund, the instructors receiving but slight compensation by a division of the small balance in hand. The session was very profitable, and it is hoped that the school will be continued year after year.

THE French Department of the International Maritime Exhibition contains a large number of apparatus intended for the raising of wrecks from the bottom of the sea. Working models of these have been sent in by M. Bazin, an engineer. This inventor has organised an immense submarine observatory which enables the bottom of the sea to be inspected with perfect security. M. Roselli, an Italian engineer, exhibited a self-moving gigantic grapnel, which being worked by steam could render great service to raise even such heavy weights as the *Vanguard*. M. Bazin has also invented a ship for dredging at small depths when it is necessary to open a channel for a port. Several ships of this kind have been constructed for the Russian Government, and are now at work in Russian waters. The principle involves the use of syphons, which are let down to the bottom and are so worked as to send mud, sand, and water into the main hold of the vessel, from which they are taken out by powerful steam-engines.

A UNIVERSITY is to be founded at Tomsk, one of the chief towns of Siberia. The new establishment will have only two faculties, one of Law and the other of Medicine. The want of doctors in Siberia may be inferred from the fact that there are only fifty-five of them in a country which is as large as the whole of Europe, and whose population amounts to more than 6,000,000 inhabitants. The Russian Minister of Finance has granted a credit of 40,000*l.* on the revenue of the State for the new establishment, which will raise the number of Russian Universities to eight, seven others being already in existence, viz., St. Petersburg, Moscow, Kiew, Kazan, Kharkow, Odessa, Varsovie, besides two foreign Universities—a German one in Dorpat, and a Swedish one in Helsingfors. A new University is also to be established in Vilna.

CAPTAIN WATERHOUSE writes that he has verified Dr. Vogel's discovery of the influence of certain dyes in increasing the sensitiveness of bromide of silver to the less refrangible rays of the spectrum.

AN examination will begin at Merton College on Tuesday, October 12, for the purpose of electing to one Mathematical and one Physical Science Postmastership. The postmasterships are of the annual value of 80*l.*, and are tenable for five years from election, or so long as the holder does not accept any appointment incompatible with the pursuance of the full course of University studies. After two years of residence the College will raise by a sum not exceeding 20*l.* per annum the postmasterships of such postmasters as shall be recommended by the tutors for their character, industry, and ability. Further information may be obtained from the Mathematical and Physical Science Tutors.

MR. E. J. MILLS, D.Sc., F.R.S., has been appointed Young Professor of Technical Chemistry in Anderson's College, Glasgow, on the resignation of Prof. Gustav Bischof.

WE would direct the attention of zoologists to a sketch and description by Prof. Wilder, of Cornell University, in the *American Journal of Science and Art* for last month, of a fœtal Manatee whose total length is 3·7 inches. "The head (which is somewhat pig-like) is strongly flexed upon the chest, and the tail forms a right angle with the trunk;" a contour very different from the adult animal being the result. The specimen was obtained at Pebos, Peru, upon the Marañon, a tributary of the Amazons, by Prof. James Orton.

IN a letter to yesterday's *Times*, Mr. W. L. Watts gives a long description of a volcanic eruption which he witnessed last month on the Myvatns Orœfi, in Iceland.

THE Berlin Geographical Society has received a telegram from Lisbon, dated the 11th inst., announcing that Dr. Pogge and Lieut. Lux, with their African Exploring Expedition, were on their way from Cassandje to Lunda. Major von Homeyer was still on the coast.

SOME of our readers may be glad to learn that the *Philosophical Magazine* for the present month contains, in full, Mr Croll's paper on "The *Challenger* Crucial Test of the Wind and Gravitation Theories of Oceanic Circulation," read before the British Association.

THE second number of Mr. Flemming's *Veterinary Journal* maintains its promised standard of excellence. The original articles are instructive, and the manner in which the most recent home and foreign investigations are placed before the reader will add greatly to the facilities for acquiring advanced information. We would direct special attention to the translation, from the German, of Prof. Siedamgrotzky's observations on the Thermometry of the Domesticated Animals.

A NEW American fossil Crustacean from the Water Lime Group, named by its discoverers, Mr. A. R. Grote and Mr. W. H. Pitt, *Eusarcus scorpionis*, is described and illustrated by an excellent photograph in the last number of the *Bulletin of the Buffalo Society of Natural Science*. It is allied to *Eurypterus* and *Pterogotus*, but is peculiar in the narrowness of the cephalo-thoracic portion, and the sudden constriction of the terminal segments.

MR. WILLIAM LONGMAN has reprinted in a separate form his interesting article in the August number of *Fraser's Magazine*, "Impressions of Madeira," containing some interesting notes on the natural history, scenery, climate, and life of the island. A good map accompanies the paper.

THE Report of the Council of the Leicester Literary and Philosophical Society speaks hopefully of its position and prospects. The Society is now in its fortieth year, has more than 250 members, and is regarded as "the leading institution for the cultivation of literary and scientific tastes" in the town and county. The Society has resolved to commence the publication of Transactions by bringing out gradually a brief but complete history of the proceedings of the Society from the date of its formation. In speaking of the decreasing attendance on the lectures by eminent outsiders, the Report gives a hint to scientific lecturers which we reproduce here for the sake of those whom it may concern:—"It must be acknowledged that the professors have sometimes relied too much upon their reputation, and given to a critical audience mere badly arranged notes, or information which any handbook would supply. And it is not too much to say that the quality of the lectures delivered gratuitously by the Society's own members and friends is of such a character that the advantage on the side of the professors is not always very striking." We hope the Society will go on with increased vigour when it enters upon its new premises, and especially that the various sections will set themselves to organise really valuable practical work.

FROM the Third Report of the Leicester Town Museum, we notice that several important additions have been made during the year, and that the Committee are in earnest to make the collection serve a really educational purpose. We hope that when the new premises are ready and the Museum transferred, that it, like the Leicester Society, will take a decided step forward. We are glad to see that the gratuitous lectures in connection with the Museum have been fairly well attended.

WE have received the Fifty-fourth Annual Report of the Board of Direction of the Mercantile Library Association of New York. This library is the fourth largest in the United States, and contains upwards of 155,000 volumes, with a membership of upwards of 8,000. The library seems to be well administered and to serve a very useful purpose, and, to judge from the report of books added during the past year, contains a fair amount of scientific literature.

FROM the Forty-first Annual Report of the York School Natural History, Literary, and Polytechnic Society, we are glad to see that the first-named branch obtains a fair amount of attention.

THE night of July 7–8, 1875, will be long remembered in Switzerland for the thunderstorms, several of them of almost unexampled severity, which occurred in Val de Travers, Liestal, Lucerne, Argovie, Zurich, and St. Gall (Rapperswyl), Langenthal, Grisons, Valais, Fribourg, and Geneva. Of these, the thunderstorm which broke over Geneva was unprecedentedly severe and disastrous. A detailed account of the phenomenon has been sent us under the title "L'Orage du 7 au 8 Juillet, 1875. Extrait du *Journal de Genève*, du 9 au 12 Juillet." It appears to have originated to westward in the department of Ain, and took an easterly course up the valley of the Rhone to Geneva, on reaching which it spread over a wider area, and thence directed its course over Savoy. As midnight came on, though the heat was suffocating and not a breath of wind stirred below on the streets, light objects on the roofs of the houses began to be whirled about and carried off as by a tempest of wind. At the same time a dull rumbling sound, resembling neither that of wind nor that of thunder, announced the approach of the thunderstorm, and at 12 midnight exactly it burst over Geneva in all its fury. An avalanche of enormous hailstones with no trace of rain was precipitated from the sky, and shot against opposing objects by a tempest of wind from the south-west. In a moment the street lamps were extinguished, and in a brief interval incredible damage was inflicted, the glass and tiles of houses smashed to powder, trees stripped of their bark on the side facing the west, and crops of every sort were in many places all but totally destroyed. The smallest of the hailstones were the size of hazel-nuts, many were as large as walnuts and chestnuts, and some even as large as a hen's egg. Some of the hailstones measured four inches in diameter, and six hours after they fell weighed upwards of 300 grammes. For the most part the hailstones were of a flattish or lenticular form, with a central nucleus of 0·16 to 0·40 inch diameter, enveloped in several concentric layers of ice, generally from 6 to 8, alternately transparent and opaque. An interesting map accompanies the description, showing the districts where the storm was felt as well as the degree of its intensity in each locality. The electrical phenomena were very remarkable; the flashes of lightning succeeded each with so great rapidity from midnight till a few minutes after 1 o'clock in the morning, that a mean of from 2 to 3 were counted each second, or from 8,000 to 10,000 per hour. Electrical phosphorescence was remarkably intense before and during the hail. The ground, animals, prominent objects, as well as the hailstones, were strongly phosphorescent. Immediately after the hail, ozone was greatly developed, the smell being so pronounced as to be compared by nearly all observers to garlic. The incessant electrical discharges passed from cloud to cloud over a central point from which the hail fell, but thunder was very rarely heard.

THE additions to the Zoological Society's Gardens during the past week include a Syrian Fennec Fox (*Canis famelicus*) from Persia, presented by Mr. Edwyn Sandy Dawes; two Glaucous Gulls (*Larus glaucus*) from Greenland, presented by Capt. Loftus F. Jones; two Fork-tailed Jungle Fowl (*Gallus varius*) from Java, presented by Mr. W. Fraser; a Royal Python (*Python regius*) from West Africa, presented by Capt. H. T. M. Cooper; a Dotterell (*Charadrius morinellus*), European, presented by Dr. C. R. Bree; a Weeper Capuchin (*Cebus capucinus*), a Golden-crowned Conure (*Conurus aureus*) from South-East Brazil, eleven Blackish Sternotheres (*Sternothœrus subniger*) from Madagascar, deposited; a Malabar Parrakeet (*Palæornis columboides*) from South India, a Blue-crowned Conure (*Conurus hæmorrhous*) from Brazil, two Burrowing Owls (*Pholeöptynx cuniculata*) from America, purchased.

SCIENTIFIC SERIALS

THE *American Journal of Science and Arts*, August.—The article on the observation of the corona and red prominences of the sun, by E. S. Holden, we have already reprinted. The other original articles are :—A note on Walker's Statistical Atlas of the United States, prepared by order of Congress. This is based on the census of 1870. Formerly the results of a census have been given in numerical form only ; now much information is set forth in ingeniously contrived maps, of which there are sixty-five. Ten of the maps are prepared from data not derived from census returns, but which are of especial interest in such a work. The work is divided into three parts, the first relating to physical features of the United States. The relations of some of these maps to each other are very instructive. For instance, the relation between woodlands and rainfall and other climatic conditions has of late been the subject of much dogmatic theorising. A comparison of these maps shows that the forests of Washington Territory are in regions having an annual rainfall of sixty inches and upward. The magnificent forests found from Minnesota to Maine are in regions of twenty-eight to forty inches, a rainfall precisely identical with that of the nearly treeless prairies which extend westward from Chicago. The northern part of the Michigan peninsula with its heavy timber is marked with precisely the same rainfall as large portions of Southern Minnesota lying in the same latitude and nearly treeless. In the second section the interesting question of the "centre of population" is discussed. In 1790 it was about twenty-three miles east of Baltimore. It has travelled westward, keeping curiously to the 39th degree of latitude, never getting more than twenty miles north nor two miles south of it. In the eighty years it has travelled only 400 miles, and is still found nearly fifty miles eastward of Cincinnati.—On the chondrodite from the Tilly-Foster Iron Mine, by E. G. Dana. The chondrodite forms the gangue of the magnetite, being everywhere disseminated through it in varying proportions ; it is identical with humite in chemical composition, and alike in crystalline form. The humite crystals are of three types, but until now the correspondence of the minerals has been known only for the second type. The Tilly-Foster mine affords crystals of all three types, and the comparisons between humite and chondrodite form the subject of this long article.—On an easy method of producing di- and tri-nitrophenetol, by P. T. Austen.—On a fœtal Manatee and Cetacean, with remarks on the affinities and ancestry of the Sirenia, by Prof. B. G. Wilder. There is added a list of writers on the subject.—On tidal waves and currents along portions of the Atlantic coast of the United States, by J. E. Hilgard.—On ancient glaciers of the Sierra Nevada, by Prof. Joseph Le Conte. The paper consists of a description of Fallen Leaf Lake Glacier, Cascade Lake Glacier, and Emerald Bay Glacier, a map of which district is given. Among the questions of a general nature discussed are :—Evidences of the existence of the great Lake Valley Glacier ; Origin of Lake Tahoe ; Passage of Slate into Granite ; Glacial Deltas ; Parallel Moraines ; and Glacial Erosion.—Certain methyl and benzyl compounds containing selenium, by C. Loring Jackson.—Description of the Nash County meteorite which fell in May 1874, by J. Lawrance Smith.

Reale Istituto Lombardo, Rendiconti (vol. 8, fasc. xv.)—From this part we note the following papers :—On a supposed reform of the theory of electrostatic induction (second paper), by G. Cantoni.—On preventative measures against Phylloxera, by V. Trevisan.—On the intersections of a cone by a plane curve of the fourth order, by G. Jung.—On the central nucleus, and on the curves of resistance to rotation, through the flexion of transversal sections of prisms, by Antonio Sayno.

THE *Archives des Sciences Physiques et Naturelles* (No. 210, June 15) contains an elaborate review of M. Becquerel's work just published, "Des Forces physico-chimiques et de leur interprétation dans la production des phénomènes naturels."—A note by M. Hermann Fol, on the first origin of sexual products. —On the viscosity of saline solutions, by M. Ad. Sprung; the author first considers the influence of temperature, and then describes the relation existing between the velocity of effluence of a salt and its chemical composition.—A letter from M. E. Liais, dated Rio Janeiro, May 1st, 1875, and relating to the next oppositions of Mars with regard to the determination of the sun's parallax ; and on the remarkable coincidence of the parallax obtained in 1860, with the new measurement of the velocity of light by M. Cornu.—On the determination of the sun's parallax by observations of the planet Flora, by M. Galle.

Poggendorff's Annalen der Physik und Chemie, No. 7 (1875). —This part contains the following papers :—On friction and conducting of heat in rarefied gases, by A. Kundt and E. Warburg.—Spectral analytical researches, by R. Bunsen (second paper.) This paper treats of spark spectra, flame spectra, and absorption spectra of elements, and is accompanied by several tables.—On the diathermancy of moist air, by J. L. Hoorweg. —On the experimental determination of the dielectricity constant of some gases, by L. Boltzmann.—On crystallisation products in ordinary glass, by Dr. Otto Schott.—On the penetration of gases through thin layers of liquids, by Dr. Franz Exner.—On a simple method to compare two sounding columns of air by means of sensitive flames, by Dr. Bresina.—An experiment on the electrodynamical effect of the current of polarisation, by N. Schiller and R. Colley, of Moscow.—On a peculiar case of magnetisation, by J. Jannin (translated from the *Comptes Rendus*).—On the magnetic properties of iron prepared by electrolysis, by W. Beetz. —Spectro-electric tube or fulgurator, an apparatus serving for the observation of spectra of metallic solutions, by MM. B. Delachanal and A. Memet.—A reply by Dr. K. Heumann to Herr R. Schneider's remarks on the decomposition of cuprous sulphide by nitrate of silver.—On the sudden breaking of glasses, by Ed. Hagenbach.

SOCIETIES AND ACADEMIES

PARIS

Academy of Sciences, Sept. 6.—M. Frémy in the chair.—The following papers were read :—On the application of a new theorem of the calculus of probability, by M. Bienaymé.—Researches on the cold bands in dark spectra, by MM. P. Desains and Aymonet.—Eleventh note on the electric conductibility of bodies which are known to be only indifferent conductors, by M. Th. du Moncel.—Results from palæontological researches at Durfort (Gard), by M. P. Cazalis de Fondouce, made for the Museum of Natural History, by M. P. Gervais.—New nautical charts of meteorology, giving both direction and intensity of probable winds, by M. Brault.—On the superficial radiations of the sun, by Mr. S. P. Langley—Observations of the August meteors in 1875 by M. C. Wolf.—A note on Bernouilli's numbers, by M. E. Catalan.—On the larva forms of Bryozoa, by M. J. Barrois.—On two thunderstorms with hail observed on July 7 and 8, in some parts of Switzerland and the South of France, by M. Colladon.

HELMHOLTZ ON TONE

On the Sensations of Tone as a Physiological Basis for the Theory of Music. By Hermann F. Helmholtz, M.D. Translated with the author's sanction by Alex. J. Ellis, F.R.S., &c. (London: Longmans and Co., 1875.)

IN the general advance of scientific knowledge which has taken place during the last half-century, the science of acoustics has hardly received its fair share of attention. Founded on principles originated by the ancients, and afterwards extended by Galileo, Newton, Taylor, Sauveur, Bernouilli, Euler, Smith, Young, and others, the first great and complete work on it was "Die Akustik," of Chladni, published in Germany in 1802, but which is chiefly known by its French translation.

It acquired a high and wide reputation, and it has ever since been a standard authority on the subject. Sir John Herschel's celebrated treatise on Sound in the "Encyclopædia Metropolitana," carried the theoretical views of the science much further, and so supplied what was deficient in Chladni's more practical work; but nothing of importance has been added to our knowledge of the science from Chladni's time till about fifteen years ago.

It was then known that one of the most eminent physicists and physiologists of Germany, Herr Helmholtz, Professor of Physiology at Heidelberg, had been devoting considerable attention to the science of acoustics, and, if we recollect aright, some of his discoveries were brought forward by himself in lectures at our Royal Institution. In 1863 appeared a work by him, entitled "Die Lehre von den Tonempfindungen als physiologische Grundlage für die Theorie der Musik," the result of eight years' investigations in acoustical science. This work not only gave much new information on acoustical subjects generally, derived almost entirely from the author's own long-continued investigations; but it published new and most important discoveries as to the nature of musical sounds, and valuable reflections on the bearing of these discoveries on the theory of music generally. The work met with high and universal appreciation among those who could understand it; it went through three editions in Germany, and was translated into French, which gave it a much wider circulation. Helmholtz's book has been followed by two popular works in English, namely, "Lectures on Sound," by Prof. Tyndall (1867), and "Sound and Music," by Mr. Sedley Taylor (1873), the chief object of both being to expound Helmholtz's discoveries and doctrines to English readers. We have now, however, a translation into English of the entire work, as mentioned at the head of our article.

In attempting to give some idea of the book, it is necessary to premise that it treats of two distinct kinds of subjects, physical and musical. In addition to being a profound and practised physicist, the author has clearly devoted much attention to the study of music, both theoretically and practically, and he has endeavoured to apply his physical discoveries and theories to the elucidation of many points connected with the art which he has found obscure. We may therefore divide our notice into these two heads.

In regard to the physical part of the subject, Helmholtz's work owes its greatest interest and its greatest fame to the entirely new light he has thrown on the nature of musical sounds, and the complete way in which he has explained and accounted for phenomena in regard to them which were previously very obscure.

A little attention will lead anyone possessing an ordinarily susceptible ear to the perception that a musical sound has three properties, each of which may be subject to a wide range of variation. These are: (1) its *pitch*, or its degree of acuteness or gravity in the musical scale; (2) its *strength*, or degree of loudness or softness; (3) the *quality*, or character of tone.

The question then naturally arises to what physical circumstances these three peculiarities are due. In regard to the two first there has been no great difficulty. It has been long known that the *pitch* of a musical sound depends on the rapidity of the vibrations which cause it, for according as the vibrations succeed each other more or less rapidly, the note produces sounds to us more acute or more grave, or, in other words, its pitch is higher or lower.

The *strength*, or degree of loudness or softness of a musical sound, has been also known to depend on the *amplitude* or extent of the vibrations, a larger amplitude giving a louder sound, and *vice versâ*.

The third property of musical sounds is their *quality* or peculiar character of tone. A violin, for example, gives a tone of a different quality from that of a clarionet, an oboe, a flute, or a trumpet, which all again differ from each other. The varieties of quality of tone that may be obtained are almost infinite; we not only possess an immense variety of musical instruments and means of producing musical sounds, all which have their individual qualities of tone, but even on the same instrument the same note may often be given several different varieties of character, independent of the mere loudness or softness. And that these infinite varieties are really objective physical differences, and not merely subjective or ideal, is proved by the facility with which educated ears can identify and distinguish between them, even sometimes to the minutest shades of difference. The stringed tribe of instruments, and still more the human voice, furnish ample examples of this.

The tone of a particular violin, or of a particular violin player, can be identified by a connoisseur among a hundred, and we all know that the varieties of quality of the human voice, even in the same register, are as easily recognised by the ear as the varieties of physiognomy are by the eye. And even in the same voice, the numerous varieties of vowel sounds producible are, when examined carefully, only varieties in quality of tone.

The nature of this property of sounds has hitherto been very obscure. Chladni, the great expounder of acoustical science in the early part of this century, says:—"Every real musical sound is capable of different modifications, whose nature is as yet entirely unknown, but which probably consist of some mixture of what is simply noise." He then explains at some length that this may arise either from peculiarities in the structure of the sounding body as regards material, &c., or from the

nature of the body with which it is struck or rubbed, to produce the sound. He further adds the suggestion that such irregularities may be due to irregular tremblings of the smaller parts of elastic bodies.

Sir John Herschel ("Encyclopædia Metropolitana"), speaking of musical sounds, says: "Of their quality and the molecular agitation on which they depend, we know too little to subject them to any distinct theoretical discussion."

To put the problem clearly, suppose we have two musical sounds of the same pitch and the same degree of loudness, but of different qualities. To what physical cause is the difference in quality due? We know that the rapidity and the amplitude of the vibrations is the same in both cases; what other element of variation can enter into the phenomenon? Helmholtz is the first who has given a complete answer to the question.

It very seldom happens that a musical sound consists of one simple note; it is generally a compound of many notes combined together. To illustrate this by a simple example, suppose a stretched string, as a violin string or pianoforte wire, sounds any particular note. This note, which is called the fundamental one, will be due to the vibrations of the string as a *whole*, and if we could prevent any other kind of vibration this sound would be a simple one. But the string has a natural tendency (for reasons too recondite to enter upon here) to take upon itself other partial vibrations, and thereby to complicate the effect produced. It will divide itself spontaneously into two, three, four, five, six, or more aliquot parts, and each of these parts will set up an independent vibration of its own, giving a new note corresponding to its length. All these will sound together, and thus by the vibration of the string we get not only the fundamental note (which is usually the loudest and most prominent), but its octave, its twelfth, its double octave, its seventeenth, nineteenth, and so on, all heard in addition, and giving a sound which is a compound of them all. All the additional notes above the fundamental have been usually called in England *harmonics*; Helmholtz calls them *overtones* (obertöne).

We have given a string as a simple example of the mode of generation of a compound sound, but such sounds are produced in many different ways. A compound sound, so far as its effect on the ear is concerned, is due to a particular form of air-wave, produced in the instance given by the superposition of different sets of vibrations of the sounding body; and such a form of wave may be equally well produced by other means, such as a reed; or it may originate in the air itself, as in a flute. In every case where a given fundamental note is found, there is the same tendency for it to be accompanied by subsidiary fractional vibrations, producing corresponding overtones.

The phenomenon of compound sounds, as found by harmonics or overtones accompanying fundamental sounds, has been long known. It was mentioned by Mersenne as early as 1636, and has since been noticed by Bernouilli, Young, Rameau, Chladni, Sir John Herschel, Woolhouse, and others; but there is great difficulty in getting practical musicians, who have not been accustomed to considerations of this nature, to admit that what, judging by the practical impression on the ear, seems only a simple and single note, can really be one compounded of a great many sounds differing much in pitch, and some absolutely discordant. Helmholtz endeavours to combat this prejudice. He shows by several analogous physical and physiological examples that the senses are apt, in the presence of prominent facts, to ignore others which may be less prominent but equally real; and he reasons that as the fundamental note is almost always stronger than any of the others, the ear is inclined to refer the whole combination to that one note, and refuses to take the trouble of separating and identifying the various elements of the sound.

An example of artificial compound sounds, purposely made, is furnished by a large organ. The pipes from which its sounds arise are in themselves but weak, and no multiplication of them would give tones of great power. Hence the long experience of organ builders has led them to form compound sounds by adding to each note pipes speaking its octave, twelfth, fifteenth, and other "overtones," the effect of which is, as is well known, to produce sounds of a most powerful and penetrating quality. Yet, if these overtones are well proportioned, they give, to an ordinary hearer, only the impression of one single loud sound.

By a little practice the ear may be educated to distinguish and separate the various notes which make up a compound sound, and when the habit of doing this is acquired, the illusion disappears. But that no proof may be wanting of this important principle, Helmholtz has contrived mechanical means by which any sound may be analysed, like a ray of light or a chemical compound, and its component parts exhibited separately. He has contrived certain instruments called resonators, each of which will, like a chemical reagent, test the presence of a particular overtone, and by submitting these in succession to the vibrating influence of the compound tone, they at once show whether the sounds they are tuned to are present or absent therein.

We have dwelt at some length on this phenomenon of the compound nature of musical sounds, because it is in reality the great fact which underlies the whole of Helmholtz's researches in this volume, and he himself has accordingly taken great pains to demonstrate and explain it, knowing that, although not a new discovery, it was yet far from being generally acknowledged. Indeed, we consider the establishment of this fact, so difficult of acceptation by practical musicians, and yet so simple and obvious when explained, is one of the most useful and important features of that portion of the complete work now under review. This establishment and explanation he afterwards uses as the basis for most of his researches, namely, the compound nature of musical sounds.

Such sounds, we have shown, consist, in almost all cases, not of a simple vibration, but of a number of vibrations of different velocities, superposed upon a fundamental one. The whole thus form a compound vibration which, though it produces on the inexperienced ear the effect of a single note, is really, when analysed, a compound of this note with a number of "overtones" harmonically related to it.

Among the many novel uses Helmholtz makes of this fact, the most important, physically, is the way in which

he deduces from it the explanation of the third property we have mentioned of musical sounds, namely, their quality or character of tone.

Chladni was perfectly aware of the complex and varied nature of the vibrations producing musical sounds, but he does not seem to have attached any importance to them in this respect; for he says (p. 48, ed. 1830): "Die Verschiedenheit der Schwingungsarten trägt meistens nur wenig zu einer verschiedenen Wirkung des Klanges bei."

Sir John Herschel (Encycl. Metrop.) appears to have doubted Chladni's assertion, for he hints clearly at the probable influence on the quality of the sound, of the *form of the air-wave* (which is only the result of the complex vibration); and we may probably consider this to be the first hint on record pointing to Helmholtz's discovery.

Mr. Woolhouse, in an admirable little "Essay on Musical Intervals, Harmonics, &c.," 1835, goes further. He says (p. 77), speaking of the complex vibrations of a string: "The various combinations of these different modes of vibration must have a considerable influence on the musical quality and expression of the musical sound," which is a still nearer anticipation of the later doctrine.

Still, however, these anticipations were only guesses; it was reserved for Helmholtz to put the matter in the shape of a scientifically demonstrated fact. He has shown, by the most elaborate and conclusive investigations, that the *quality of a musical tone depends chiefly on the number and on the comparative strength of the various harmonical notes of which the tone is compounded.*

The overtones accompanying a fundamental note may be present in greater or less number, and they may vary considerably in comparative loudness or softness, and it is on the combination of these sources of variation that the quality of the tone will depend—or, to put the explanation in another and more scientific shape; as the *pitch* of a sound depends on the length or the frequency of recurrence of the air-wave, and the *loudness* on the degree of disturbance of the particles of the air therein; the *quality* of tone depends on what is called its internal *form*, or on the varieties of arrangement of expansion and compression of the air contained within one complete periodic cycle of oscillation.

Some modification in effect is often produced by a sound being accompanied by unmusical noises, such as the escaping of imperfectly used wind in a pipe, the unskilful scratching of the bow on a violin, the beating of reeds, and so on; but these are rather impurities than varieties of tone, and may be excluded from consideration.

There are very few natural sounds which are entirely simple, consisting of the fundamental note only. They are best produced artificially by means of the "resonators." The nearest approach to them may be found in the larger stopped wood pipes of an organ, an old-fashioned (not a modern) flute, and a tuning-fork after the sharp ring has subsided. The vocal sound of the Italian U (our *oo*) is also nearly a simple one. These examples will give the idea that simple tones are soft, dull, and entirely devoid of what is called brilliancy.

The addition of overtones gives this brilliancy and at the same time adds life, richness, and variety. It is to them that we owe entirely the agreeableness and pleasurable effect of musical tones. In proportion as the higher overtones predominate, so will the sound be bright and sparkling, or if in great predominance it will become metallic, thin, and wiry. If, on the other hand, the upper tones are weakened and the lower strengthened, the tone becomes more full, rich, and mellow. All the qualities of tone most esteemed and most useful in music are rich in overtones.

Helmholtz gives many examples of musical sounds of different character, which have been analysed according to his method. The tones produced from strings are peculiarly adapted to this purpose, because the vibrations so produced admit not only of mathematical calculation, but of ocular observation, and so give direct means of comparing the new theory with the facts, the result in all cases being most satisfactory and conclusive. The overtones in strings depend largely on the kind of impulse and the place where it is applied. In an ordinary piano the first six overtones are all audible, the three first strong, the fifth and sixth weaker, but still clear. The seventh and ninth, which are inharmonious, are excluded by striking the string in a peculiar place which does not admit of their generation. To prove the dependence of the quality on the strength of the overtones, Helmholtz has calculated mathematically what the strength of the first six overtones ought to be when produced with hammers of different degrees of hardness, and finds they should be as follows:—

	1.	2.	3.	4.	5.	6.
With a very hard hammer	100	325	500	500	325	100
With a medium hammer	100	249	243	119	26	1
With a very soft hammer	100	100	9	2	1	0

Now, as everybody who knows anything about pianofortes is aware that the tone is full and rich with a soft hammer, and hard and jangling with a hard one, it will be seen how admirably the mathematical results correspond with the actual ones, and how both confirm the theory.

Again, it is easily shown, both mathematically and practically, that thin wires will vibrate in short lengths much more easily than thicker and stiffer ones, and will therefore be more liable to produce the higher overtones, and hence the well-known metallic jangling of thin wires. This is the scientific explanation of the improved tone from the use of thicker wires in modern pianos, inasmuch as they admit of a more powerful blow without the production of the high and unfavourable overtones that would result from such a powerful impulse on a thin string.

The peculiar tones of the violin tribe, wind instruments, wood and brass, organ-pipes of various kinds, and so on, are all satisfactorily investigated in this way.

Helmholtz devotes much attention to the phenomena of vowel sounds, which had been already investigated by Willis and Wheatstone. He has completed their investigations by bringing the vowel sounds within his theory, and his elegant discussion of the subject, and the important results he obtains, are among the best features of his book.

All the above results we have mentioned have depended on the *analysis* of musical sounds. But the author

has not stopped here. In chemistry, when a discovery has been made of the constitution of a compound body, by analysing it into its constituent elements, the efforts of the chemist are naturally turned to the converse process of proving the same proposition by synthesis, or by combining the single elements and showing that they will produce the compound. This proof has not been wanting in the present case, for Helmholtz has succeeded in combining simple sounds together in such a way as to produce imitations not only of vocal sounds, but of many other peculiar qualities of tone; not perfectly, from the extreme difficulty of imitating exactly all the minute shades of difference that enter into the combination, but still with enough success to demonstrate the general argument.

We have given especial prominence to Helmholtz's discoveries on the nature of musical sounds, because this is in reality the great feature of his work, by which it first acquired its fame, and by which his name will hereafter be honoured. But the physical part of the book contains much beside this that is important and interesting. His explanations on the general phenomena of acoustics are most lucid, and often very original; and his descriptions of the mechanism and action of the organs of hearing, coming from one of the highest authorities in physiology, are exceedingly instructive and valuable.

In Part II. the author enters into an investigation of what are called *beats*—a subject which has been heretofore very obscure—and also of other acoustical phenomena called "combination tones," which, though known since the time of Tartini, have not been thoroughly understood till Helmholtz gave their explanation. Into these matters we have not, however, space to follow the author: those who are interested in them can refer to the book for themselves.

Before we leave the physical part of the work it will be only just to testify to the excellence of the translation. Mr. Ellis is so well known as a philologist and a man of science, that his competence to deal with the work in a literary and scientific point of view requires no comment, and English readers may be satisfied that in this translation they have the original faithfully put before them. His work has evidently been a labour of love, and he deserves the highest credit for the trouble he has taken over it.

At the same time all men are fallible, and when a great authority condescends to do a work that could hardly be expected from him, we must not be unprepared for some little waywardness on his part, and there are a few things which we would rather have seen otherwise done. The title of the book is unfortunate; for, although no doubt "The Sensations of Tone" is a correct translation of "Tonempfindungen," yet to many English ears it will, we fear, sound strange and unintelligible from the fact that we are hardly accustomed in our language to understand the word "tone" in the sense here intended. The English title certainly does not give to the English reader anything like the same idea as the original title, "Die Lehre von den Tonempfindungen," does to an educated German. The strict rendering of a German phrase does not always correctly represent the original; for example, in speaking of the clever little tract of Hauslick, "Ueber das Musickalisch Schöne," Mr. Ellis translates it, "On the musically beautiful," whereas, as every reader of the tract well knows, the more appropriate expression in English would be "On the beautiful in music."

But the chief fault we have to find in the translation is the rendering of a term which of all others is the most important in the whole work, and in which the translator has, we conceive, taken a liberty not altogether justifiable. Helmholtz, in describing the compound nature of musical sounds, has called all the sounds above the fundamental one by the name of "obertöne," a word exceedingly appropriate, useful, and expressive, inasmuch as it at once defines and includes all these sounds in one appellation. Prof. Tyndall, in his *résumé* of Helmholtz's discoveries, has most naturally and with great propriety translated this term by the word "overtones." It exactly expresses the German in the simplest way, and it is as perfectly admissible into English as "overcoat" or "overseer."

Unluckily, Mr. Ellis is either too proud to adopt this word or has taken otherwise a dislike to it; for, on the ground that he does not consider it good English, he substitutes for it the expression "upper partial tones." This is not only clumsy and roundabout, but it is imperfect and wrong, inasmuch as it does not include, as the original expression does, the *whole* of the sounds above the fundamental, and gives no means of distinguishing higher overtones from the lower ones. As these overtones play such an exceedingly important part in Helmholtz's work, we cannot but consider, with all respect to Mr. Ellis, this rendering a blot on the translation which we very much regret.

We must reserve our notice of the musical portion of Helmholtz's work till a future opportunity.

OUR BOOK SHELF

Guide to the Geology of London and the Neighbourhood (Geological Survey of England and Wales). By William Whitaker, B.A., F.G.S. (London: Messrs. Longmans and Co., 1875.)

It is a matter of great satisfaction to geologists that the Geological Survey are again giving to the public some of the accumulated stores of information of which they are necessarily possessed, by resuming the series of large and complete memoirs which had been in abeyance for many years before the publication of "Whitaker's Geology of the London Basin," Part I., in 1872—a series now so well continued by the works of Judd and Topley. These, however, are comparatively expensive, and enter into minute details, so that although the whole of the information contained in the small book under notice has already been given at greater length in Mr. Whitaker's work mentioned above, or will be in a similar promised publication on the "Drifts of the London Basin," it will be of great use to a large number of persons who would not care for a more detailed description. A special Geological Map of London and its Environs, with all the Drift beds indicated, has lately been published, and for the last two years the Geological Model of London on a six-inch scale has been the admiration of all visitors to the Jermyn Street Museum: the pamphlet now before us is designed as a handbook to these. It commences with a description of the construction of the model, a matter of no small difficulty, considering the accuracy of the representation. The description of the various formations which enter into the London area, with their resulting features and scenery, though necessarily short, contains the cream of all the known facts, and what is better still, the reasons for all the not self-obvious determinations of the age and

relations of the beds. Another most valuable portion is the series of tables of localities where the different formations may now be studied, showing no less than 154 places worthy of a geological visit within twenty miles of London. With regard to the general structure of the district, Mr. Whitaker is careful to refute the idea that the Tertiary beds were deposited in an eroded hollow of the chalk, as is often supposed; unfortunately, however, his section gives them rather the appearance of being so. We should also notice that although, on the evidence of fragments of Ammonites and Belemnites, he prefers to refer the red beds of the Kentish Town section to the Lower Greensand, none of this formation is represented in the section as lying beneath this part of London.

This convenient little publication, so full of valuable and condensed information, for so small a sum, will be of such great use to the members of the numerous field clubs, that we fear it will soon be out of print. What are 500 copies among so many who would wish to have it?

Sniolavd; or, Iceland, its Jökulls and Fjalls. By William Lord Watts. (London: Longmans and Co., 1875.)

IN a recent number (vol. xii. p. 333) we published a letter from Mr. Watts announcing the important fact that he had succeeded in crossing the Vatna Jökull. So far as is known, this is the first time that this jökull (which means "glacier," and is probably cognate with the latter part of our word ic-*icle*) has been crossed, and the fact is creditable to Mr. Watts's determination and perseverance. The little book before us contains a narrative of an unsuccessful attempt to accomplish the same object, made by Mr. Watts in the summer of 1874. We regret to have to say that the narrative is a disappointing one. It is in the form of a rough diary, which seems to have been sent to the press in its crude form and published with little or no revision. A large portion of the book is occupied with a statement of the many difficulties, petty and serious, which Mr. Watts and his party encountered in the journey from Reykjavik, by the Geysers, Hekla, and the Myrdals Jökull to the Vatna Jökull, and there is really very little information about the region through which he passed. The entire narrative is extremely vague and unsatisfactory, and if Mr. Watts has any literary faculty, he certainly does not show it here; the reading of his narrative is a heavy task. Mr. Watts ought to know a great deal about the region with which this narrative is concerned, and especially about the jökulls in the south of Iceland, and we would advise him to put this information into a systematic form, make but little reference to the difficulties he encountered, obtain a few photographs on a much larger scale than the insignificant things which appear in the present work, and we have no doubt he would make a substantial contribution to our knowledge of Iceland. The party succeeded in getting only about half across the Vatna Jökull, when, from want of the necessary means to go further, they were compelled to turn back, after Mr. Watts had rather unnecessarily and sensationally planted the union jack at his furthest point. Mr. Watts's carelessness, to put it mildly, extends even to his use of language. The use of "laid" for "lay" might possibly be justified by eminent precedents; "peninsular of rock" may be a misprint, but "pulverent" is unjustifiable, and "molusc" is shocking.

Perhaps the most tangible piece of information conveyed by Mr. Watts is contained in the following paragraph:—

"To sum up, this hitherto untrodden Vatna Jökull is a mountainous tract, surmounted by a rolling plateau, containing numerous volcanoes, one or more of which, upon the north, appear to be in a state of pretty constant activity, while numerous others in all probability are paroxysmal, most likely exhibiting all the phenomena characteristic of (if I may be allowed the term) *bottled up volcanoes*. This tract, together with the Odatha-hraun, and the centre of Iceland with its numerous mountains, is a new volume of Nature, the first leaf of which has only just been cut, but whose secluded fastnesses will amply repay investigation."

In an appendix Mr. Watts gives some information as to equipment, which intending travellers in Iceland will find useful. The map at the end is on too small a scale to be of much use.

The main object of Mr. Watts's narrative is to attract attention to Iceland and induce travellers to co-operate in its exploration. We hope the work will serve this laudable object, as there is no doubt Iceland presents a handy and fertile field for explorers. Mr. Watts himself deserves great credit for what he has already achieved; we hope he will continue his work, and in a future publication add something of permanent value to our knowledge of the interesting island.

Report on the Neilgherry Loranthaceous Parasitical Plants destructive to Exotic Forest and Fruit Trees. By George Bidie, M.B., Madras. (Printed by E. Keys, at the Government Press, 1874.)

SURGEON-MAJOR BIDIE has in this volume presented to the Indian Government a report on the parasitical plants which prove destructive to forest and garden trees on the Neilgherries, and on the best mode of remedying the evil. The whole of these destructive parasites belong to one natural order, Loranthaceæ, represented in this country by a single species, the Mistletoe, and to two genera, *Loranthus* and *Viscum*. The fruit of the Loranthaceæ is characterised by the envelopment of the seed in a layer of a viscid substance, described by Dr. Bidie as intermediate in character between resin and india-rubber. Outside this viscid layer is a pulpy body which serves as food for birds and squirrels. After devouring this the seed is rejected, or, in the case of squirrels, passes uninjured through the body, and then adheres to the bark of any tree on which it may be cast. If the immediate conditions are unfavourable, the seed will be preserved in a state capable of germination for a very considerable time beneath its viscid covering. With regard to the mode of germination, Dr. Bidie has nothing to add to the information already furnished by Mr. Griffith and Dr. Hooker. With reference to the mode of attachment between the parasite and the host, the author states that although very firmly attached, there is no actual interlacing of the tissues; and that in some instances, after maceration in water for a few days, the parasite could be separated from the host without much difficulty. It is noteworthy that native Indian trees and shrubs do not appear to suffer nearly so much from the attacks of the Loranthaceæ as introduced, especially Australian, species. One foreigner, however, which appeared quite exempt from their ravages, was the "blue gum," the *Eucalyptus globulus*, which has already so many other useful qualities placed to its credit. Dr. Bidie asserts that the Loranthaceæ derive their nutriment not from the descending elaborated, but from the crude ascending sap of the host; hence their need for green foliage containing chlorophyll and possessing stomata, in which other parasites are deficient. The volume is embellished by fifteen large lithographs representing the different species, and illustrating the structure of the fruit and the mode of parasitism of the order.

LETTERS TO THE EDITOR

Personal Equation in the Tabulation of Thermograms, &c.

MR. PLUMMER, in his letter (NATURE, vol. xii. p. 395), has missed the point of the review of the work of the Meteorological

Office referring to the tabulation of temperatures (vol. xii. p. 101). From 1,283 estimations of tenths of seconds, as tabulated by the highly-trained and experienced observers at Greenwich, he shows that the whole seconds estimated were 15 per cent. of the whole number, and thereupon remarks that this is precisely the excess of whole seconds that is taken in the review of the work of the Meteorological Office as indisputably proving the carelessness of the tabulations at the Kew Observatory. This is a mistake. Kew was not singled out for criticism because the whole degrees tabulated there amounted to 15 per cent. of the whole number, but because of "the irregularity of the tabulations, more especially as regards the tabulations from day to day." An examination of the tabulations at Kew from day to day shows that there are first-class tabulators in that Observatory, but it also shows there are others whose work is inferior. Thus, in the first published sheet for Kew, viz., January 1874, on seventeen of the days the whole degrees tabulated amounted on each of these days to at least 25 per cent., and the average of the whole seventeen days reached 31 per cent., or nearly a third of the whole. On the remaining fourteen days of the month the average was 14 per cent. Hence the variations of the numbers of whole degrees from month to month, which, as stated in the review, were 172 for January, 87 for February, 127 for March, and 94 for April. It is this irregularity in the work of tabulation which has lowered the character of the work done at Kew.

The averages calculated from 6,696 tabulations showed that the number of whole degrees read off at the seven observatories were 8·4 per cent. of the whole at Stonyhurst, 15·0 at Kew, 19·5 at Aberdeen, 21·2 at Armagh, 23·7 at Falmouth, 24·7 at Valencia, and 24·8 at Glasgow. So far as the mere average numbers are concerned, the tabulations at Stonyhurst and Kew are satisfactory; not so, however, is the work done at the other five observatories, especially the last three, where, on an average of 6,696 tabulations, a fourth part of all the numbers tabulated were whole degrees. For particular months the percentages are sometimes very large. Thus, at Aberdeen during January 1875, the following are the percentages of the different decimal places of the dry-bulb readings as printed by the Office:—

Decimal places.	·1	·2	·3	·4	·5	·6	·7	·8	·9	·0
Percentages.	11	6	5	7	6	6	6	5	9	39

From this examination it is seen that 50 per cent. of the whole readings are assigned to two of the decimal places, viz. ·0 and ·1, of which 39 per cent. are whole degrees. The largest percentages are not, as in the cases adduced by Mr. Plummer, distributed in different parts of the decimal scale, but stand together, viz., ·9, ·0, and ·1. As regards the column for each particular hour, out of the thirty-one readings, nineteen whole degrees occur in the 5 A.M. column, eighteen in the 8 P.M. column, sixteen in the 5 P.M., fifteen in the 6 A.M., fourteen in the 4 P.M., thirteen in four of the columns, twelve in six, and so on, down to eight whole degrees in one column, and seven in another, than which no fewer whole degrees occur in any column. It is unnecessary to make any remark on these figures.

The Meteorological Office has published in their Quarterly Weather Reports the monthly extremes of temperature in two forms, viz. in figures, and in curves of temperature. These were compared and the results stated in the review, from which it was shown that as regards the first month's extremes, fourteen in number, there were twelve errors in the numbers as published by the Office; and as regards the first year's extremes, 168 in all, there occurred forty-one errors of temperature varying from 0°·4 to 9°·6, and twenty-two errors as regards the day and nine errors as regards the hour of occurrence. Altogether twenty-nine months have been examined with the general result of an average of fully four errors in stating each month's fourteen extreme temperatures. Now it is on the large proportion of errors made in stating the extreme temperatures (for the prevention of which one of the twenty-seven regulations for the Director of the Central Observatory was specially designed), taken in connection with such results as those given above for one of the observatories for January last, that the charge of inaccuracy in this very costly but vitally important part of the work of the Meteorological Office is based. This charge, Mr. Plummer's letter in no way meets. The simple course is to see that this department of the Meteorological Committee's work, including that of the outlying observatories, be brought under some sort of satisfactory control.

THE REVIEWER

Ocean Circulation

As the strength of Mr. Croll's conviction that he has completely demolished the "gravitation theory" of oceanic circulation by the "crucial test" to which he subjected it before the Geographical Section of the British Association, is not unlikely to influence the minds of some, I shall be glad to be allowed to point out (1) that I have never denied the existence of a horizontal "wind-circulation," and (2) that the doctrine to which he applied his test was not mine, but a creation of his own. For his whole argument was based on the assumption that the ocean is in a state of static equilibrium; whereas the theory I advocate, which was originally advanced by Lenz, and which Sir William Thomson (in commenting upon Mr. Croll's paper and my reply to it) pronounced to be a matter "not of argument, but of irrefragable demonstration," is, that the ocean never is and never can be in a state of equilibrium, so long as one part of it is subjected to polar cold, and another to equatorial heat; but that it is in a state of constant endeavour to recover the equilibrium which is as constantly being disturbed.

If the boiler and water-pipes of a heating apparatus be filled with water whose temperature is that of the building in which it is placed, the whole mass of fluid *is* in a state of equilibrium; but the lighting of the fire beneath the boiler disturbs that equilibrium, and produces a circulation, which will be maintained as long as the water is being alternately heated in the boiler and cooled by the atmosphere of the building.

Suppose that the elongated basin of the Mediterranean, instead of lying E. and W., were to be turned N. and S., so that its water, instead of being exposed (as at present) to a practical identity of thermal influences, should be subjected at one end to arctic cold and at the other to almost tropical heat: instead of remaining in its present state of nearly perfect equilibrium, it would have a circulation like that which I have exhibited in the trough-experiment.

The only objection raised by Mr. Croll which has even a show of validity, is based on the supposed "viscosity" of water, which he asserts to be sufficient to prevent the disturbance of thermal equilibrium from exerting the effect which the "gravitation theory" attributes to it. This assertion has now been completely disproved by the masterly investigations of Mr. Froude; who has demonstrated experimentally—what the "wave-line theory" of Stokes, Rankine, and Sir William Thomson had rendered probable—that in the resistance to the motion of a ship through the water, the viscosity of the water itself is so small an element that it may be practically thrown out, water behaving as a nearly "perfect fluid," except where it moves over solid surfaces. Mr. Froude (in conversation with me) not only sanctioned my conclusion that a constantly renewed disturbance of thermal equilibrium *must* produce an oceanic circulation, but mentioned as an instance of the very small difference of downward pressure necessary to sustain such a circulation, that he had ascertained by repeated observation at the mouths of harbours, lochs, and fiords, that wherever the water within has its salinity at all reduced by a mixture with fresh water, there is an underflow of sea-water setting inwards, precisely as in the Baltic and Black Sea Straits.

Mr. Croll attempted to draw a further disproof of the "gravitation theory" from the *Challenger* observations on the temperature of the upper strata of the Antarctic Sea, at and near the ice-border. These observations show that a stratum of water of from 32° to 29° overlies a stratum of from 34° to 32°; which is considered by Mr. Croll as a death-blow to my assumption that the coldest water sinks to the bottom. Now, since I have repeatedly pointed out that the water of melting field-ice, and *à fortiori* that of melting icebergs, will float on ordinary sea-water colder than itself, in virtue of its inferior salinity, and since Capt. Nares distinctly speaks of the cold surface-stratum as having this origin, it does seem to me not a little strange that Mr. Croll should have overlooked this consideration. It is obvious that, for the reason just stated, the descent of the cooled surface-stratum cannot take place in the polar summer *at or near the margin of the ice*: but that it takes place wherever and whenever the surface-cold is sufficient to check surface-liquefaction, and to cool down water of ordinary salinity to a temperature below that of the subjacent stratum, it will be hard for Mr. Croll to disprove.

I cannot but greatly regret that Mr. Croll abstains from subjecting his conclusions on this subject to the test of *personal discussion*. For if he would bring them (as I have brought my own) under the criticism of the Mathematicians and Physicists of Section A, he would find that, notwithstanding the

acceptance which his endeavour to solve the climatal problems of past epochs by astronomical computation has very deservedly met with on the part of Geologists, his denial of the possibility of a thermal circulation in the ocean is utterly repudiated alike on mathematical and on experiential grounds, by those whose authority as physicists ought to make him feel less confident in his own conception of the question. W. B. CARPENTER

Source of Volcanic Energy

A FEW words of explanation are necessary concerning my letter which appeared in NATURE, vol. xii. p. 396. Mr. Mallet's *prime* source of energy for producing tangential pressures is the force of cohesion developed in a cooling globe, gravitation giving only partial assistance; and when I spoke of "gravitation of the whole mass to itself," I wished to convey that, setting aside altogether the force of cohesion and its accompanying motions, there still remains the force of gravitation, which, acting in a globe of such size as the earth, and composed of heterogeneous materials, must of itself produce enormous local pressures.

Mr. Fisher objects to my supposing the possibility of the development of heat without room being left for motion, but so far as I understand the doctrine of energy, it is only necessary to have *force* for the production of heat when motion is impossible.

In Mr. Fisher's interesting paper his objection appears to be to the localisation of *fusing*, and not to the localisation of heat, fusing in some cases being prevented by the accompanying pressure. But in my little diagram I attempted to explain that the forces producing the high temperature might act in one set of strata, the neighbouring strata above and below at the same time being under much lower pressure, the pressure upon them being equal to the pressure of the rocks doing the work, minus the cohesion of said rocks; this difference of pressure being sufficient to allow one set of rocks to melt while others are crushed.

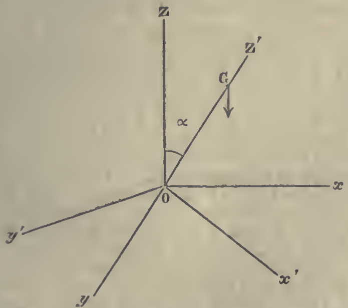
Gyrostat Problem: Spinning-top Problem

IN vol. xi. p. 424 is given the solution, by Sir W. Thomson, of his gyrostat problem at p. 385. I venture to send a slightly different method * of obtaining the result (far inferior to Sir W. Thomson's in elegance and simplicity), in which Euler's equations for the motion of a rigid body about a fixed point are employed.

1. Take point of suspension for origin; the string for axis of z. The axis of the wheel Ox' revolves in horizontal plane xOy with uniform angular velocity Ω, and the wheel revolves round its axis Ox' with angular velocity w_1. The weight of wheel and axis will have moments round an axis Oy' in horizontal plane



perpendicular to Ox'. Let w' = weight of wheel and axis; A, B, B, moments of inertia round Oz, Ox', Oy'; w_2 angular velocity round Oy' at time t; a = the distance of C. G. from Oz, $xOx' = \phi$ = angle described by Ox' in time t. Taking moments about Oy', we have

$$B\frac{dw_2}{dt} + \overline{A-B}\,w_1\Omega = w'ag \quad . \quad . \quad . \quad (1)$$

(Pratt, "Mech. Phil." 446). Also since there is no velocity about an axis in horizontal plane perpendicular to resultant axis of $w_1 w_2$,

$$w_1 \sin.\phi - w_2 \cos.\phi = 0 \quad . \quad . \quad . \quad . \quad (2)$$

where $\phi = \Omega t$.

$\therefore \frac{dw_2}{dt} = w_1\Omega \sec.^2\phi = w_1\Omega$ for $t = 0$ in (1), since w_1, Ω are independent of the time; whence (1) becomes

$$A w_1 \Omega = w' a g,$$

where $A = wk^2, \Omega = \frac{1}{4}$ . . . . Q.E.D.

2. A similar question (concerning a spinning top) was proposed in the Senate House, Cambridge, in 1859, of which indeed the preceding is a particular case.

A uniform top spins upon a perfectly rough horizontal plane, its axis being inclined to the vertical at a constant angle α, and revolving about it with constant angular velocity Ω. Prove that the velocity of rotation of the top about its axis must be $\frac{(a^2+k^2)\Omega^2\cos.\alpha + ga}{k_1^2\Omega}$, where a is the distance of the centre of gravity from the extremity of the peg, $k'\,k$ the radii of gyration about the axis of figure, and about an axis through C. G. perpendicular to it respectively. Take O, the extremity of the peg, which remains fixed, as origin, and let Oz' be position of axis at any time t; $OG = a$; $zOz' = \alpha$. Let M = mass of the top; A, C, C, moments of inertia about Ox', Oy', Oz' (rectangular axes moving with the top); $w_1 w_2 w_3$, angular velocities about Ox', Oy', Oz' at time t.

The intersection of planes xOy, $x'Oy'$ will move round Oz with angular velocity Ω. Let ϕ = angle which Ox' makes with this line.

If we take moments about Ox', we have by Euler's equations (Pratt, art. 446)—

$$A\frac{dw_1}{dt} + \overline{C-A}\,w_2 w_3 = Mga\cos.zy^1 \quad . \quad . \quad (1)$$

Also $w_1 = \Omega\sin.\phi\sin.\alpha$, $w_2 = \Omega\cos.\phi\sin.\alpha$, $w_3 = \frac{d\phi}{dt} + \Omega\cos.\alpha$

$$\cos.zy^1 = \cos.\phi\sin.\alpha \text{ (ibid. 447)};$$

$$\therefore \frac{dw_1}{dt} = \Omega\cos.\phi\sin.\alpha\frac{d\phi}{dt} = \Omega\cos.\phi\sin.\alpha\,(w_3 - \Omega\cos.\alpha).$$

Substituting in (1) and reducing, we get—

$$C\Omega w_3 = Mga + A\Omega^2\cos.\alpha. \quad . \quad . \quad . \quad (2)$$

But $A = M(k^2 + a^2)$, $C = Mk_1^2$;

$$\therefore w_3 = \frac{ga + (a^2+k^2)\,\Omega^2\cos.\alpha}{k_1^2\,\Omega}.$$

If $\alpha = 90°$ in equation (2), we get the solution of the preceding question as a particular case. F. M. S.

Arnesby

* A comparison of this method with Sir W. Thomson's (which is virtually the same as that adopted by Airy in his tract on Precession and Nutation) is instructive as illustrating the dynamical meaning of Euler's equations.—ED. NATURE.

OUR ASTRONOMICAL COLUMN

THE MASS OF JUPITER.—M. Leverrier has made a special communication to the Paris Academy of Sciences with reference to the bearing of his researches on the motion of Saturn, in a period of 120 years, on the value of Jupiter's mass. Laplace, in the *Mécanique Céleste*, had fixed $\frac{1}{1067{\cdot}09}$ making use of the elongation of the fourth satellite as determined by the observations of Pound, the contemporary of Newton, observations of which it appears we have no knowledge, except from the reference to them in the "Principia;" subsequently Bouvard, comparing Laplace's formulæ with a great number of observations, discussed with particular care, constructed new Tables of Jupiter, Saturn, and Uranus, in which important work he formed equations of condition, wherein the masses of the planets entered as indeterminates, and by the solution of which their values adopted in the Tables were obtained. The denominator for Jupiter's mass, expressed as a fraction of the sun's taken as unity, is 1070·0, and Laplace stated that on applying his theory of probabilities to Bouvard's equations it appeared to be nearly a million to one against the error of the mass thus deduced, amounting to one-hundredth part of the whole. M. Leverrier then

refers generally to the discussion of the observations of several of the minor planets with the view to correcting the mass of Jupiter, and to the observations of elongations of the fourth satellite by the present Astronomer Royal at Cambridge, which last assigned for the denominator of the fraction 1046·77. He then remarks upon the circumstance of Bouvard having deduced from his comparison of the theory of Saturn with seventy-four years' observations a mass so nearly identical with that of the *Mécanique Céleste;* Bouvard left no details of his work behind him; it is only known that he adopted at the outset the value of Jupiter's mass admitted at the time, that of Laplace, and M. Leverrier explains that on the method of procedure adopted, Bouvard could not do otherwise than reproduce at the termination of his calculations the value he had assumed at starting. This is illustrated by the result of Leverrier's solution of his own equations of condition, founded upon the much longer period of 120 years, which proved wholly insufficient for the correction of Jupiter's mass. He remarks, with respect to Bouvard's work, that any value of the mass taken arbitrarily within certain limits will allow of a tolerable representation of the observations of Saturn, on the condition that this same arbitrary value is introduced throughout in the functions representing the mean longitude, mean motion, excentricity and longitude of perihelion; the elements obtained by Bouvard are therefore found represented by these functions of his arbitrary quantity, and he reverts to the mass assumed at the commencement of his work.

In conclusion, M. Leverrier insists that the use of the elongations of the fourth satellite for the determination of the mass of the Jovian system, has at present an incontestable superiority over the employment of the theory of Saturn, on account of the too short period over which the observations as yet extend, but in the lapse of time this superiority of the former method will diminish and the use of the perturbations will become the more advantageous. It is really, he adds, the same question as that which presents itself with regard to the solar parallax, which is determinable on two methods: the one, geometrical, the method by transits of Venus; the other, mechanical, depending for instance on the large inequalities in the motion of Mars. The method by transits, so important in 1760, but limited in its means of application, must eventually give way to the method of perturbations, the accuracy of which will increase unlimitedly with the course of time.

The first evaluation of the mass of Jupiter is that of Newton in the Cambridge edition of the "Principia" (1713), inferred from Halley's observation of an emersion of Jupiter and his satellite from the moon's limb, giving for the denominator of the fraction (whereby it is usual to express the mass) 1033. In the later editions of the "Principia" the mean distance of the fourth satellite resulting from Pound's observations, to which allusion is made above, was substituted in the calculation of the mass, which was found to be 1067. (It may here be mentioned that from later observations by Pound with a micrometer on a telescope of 123 feet focus, on the mean distance of the third satellite, Bessel found for the mass 1066). The next attempt in this direction appears to have been made by Triesnecker, Director of the Observatory at Vienna. In 1794 and 1795, making use of a Dollond object-glass micrometer, he obtained a series of measures of distances of all four satellites, the notice of which appears in the Vienna Ephemeris for 1797. Bessel deduced from them, by a mean of the four values, 1055·68. Then follow Bouvard's investigations already mentioned. It is understood that Gauss was the first to bring the perturbations of the minor planets to bear upon the determination of the mass of Jupiter, and that from the perturbations of Pallas he perceived the necessity of an increase to the mass adopted by Laplace. The circumstance, so far as we know, rests upon the authority of Nicolai, who, following in the same steps, discussed observations of Juno at fifteen oppositions, between the year 1804 and 1823, and (in the *Berliner Astronomisches Jahrbuch* for 1826) deduced for Jupiter's mass 1053·92. Encke, from fourteen oppositions of Vesta, between 1807 and 1825, made its value 1050·36, in a paper published by the Berlin Academy of Sciences in 1826.

Sir George Airy's observations at the Cambridge Observatory, alluded to by M. Leverrier in his recent notice, are next in order of time. They were commenced in 1832 and continued till 1836. The final result appears in vol. x. of the Memoirs of the Royal Astronomical Society; it is 1046·77, and depends upon observations on thirty-three nights. Details of the earlier Cambridge observations will be found in vols. vi. and viii. of the same memoirs. Sir George Airy considered it very improbable that there could be an error of a single unit in the denominator of the fraction expressing the mass, being led to this opinion by the close agreement of the separate results.

In the year 1835 Prof. Santini, the present venerable director of the Observatory of Padua, by sixteen nights' measures of the distance of the fourth satellite from both limbs of Jupiter, obtained for the mass 1049·2 (*Ricerche intorno alla Massa di Giove*, Modena, 1836).

Bessel's elaborate series of measures of distances of the four satellites commenced in October 1832 and were completed in the middle of 1839. They are fully discussed in his very valuable memoir, *Bestimmung der Masse des Jupiter*, in vol. ii. of his *Astronomische Untersuchungen:* the definitive value of the mass (p. 64) is 1047·879. Bessel's mass, which has been generally adopted in the calculation of the perturbations of minor planets and comets, and which is so close a confirmation of that deduced by the Astronomer Royal, has received much additional support from recent and, as regards method, essentially different investigations. Thus Krueger, of Helsingfors, from the perturbations of Themis, one of the minor planets which approaches nearest to Jupiter, assigns 1047·16; Axel Möller, by his masterly researches on the motion of Faye's Comet, 1047·79; while Von Asten, from his last investigations relating to Encke's Comet, finds 1047·61.

THE HOPKINS UNIVERSITY, U.S.

THE munificent bequests made by wealthy Americans for the promotion of education in the United States frequently excite our astonishment, for they are unparalleled in Europe at the present time. One of the most unique and well-devised of these bequests has lately occurred. Last year there died a Mr. Jonas Hopkins, a rich citizen of Baltimore, who, after providing for his relatives and leaving various minor benefactions, bestowed the chief part of his estate to found a university with an affiliated medical school and hospital. Both the university and the hospital receive separate landed and other property of such a substantial character that the value of the total amount is over three millions of dollars. Each institution is to be controlled by a board of nine trustees, and the same persons are to be on both boards. The university will have no ecclesiastical or political character or supervision, and will be modelled as far as possible after all that is best in similar American and European institutions. It is intended to give the highest instruction that can be obtained, and the trustees are to act in accordance with the most enlightened experience of the day. The scientific and literary departments will first be organised, and then will follow the departments of Medicine and Law.

No permanent buildings will be erected till all the Faculties are in working order and the wishes of each professor can be carried out; meanwhile a building has

temporarily been secured in Baltimore, on the outskirts of which city are the grounds Mr. Hopkins has left for the hospital and university which in future will bear his name. The trustees have already selected the President of the University, and an admirable head they have found in Mr. Henry Gillman, formerly the Principal of the San Francisco University. Mr. Gillman is now in England, maturing his plans and gaining information from various universities in Europe. The dominant wish of the new president is to gather round him a body of professors and lecturers devoted to original research in their different spheres. Only one chair has yet been filled, namely, that of Mathematical Physics, and to this Mr. H. A. Rowland has been appointed. Though still quite a young man, the good work Mr. Rowland has already done in magnetism has made his name well known among English physicists, and in his new position a brilliant career lies before him. It is hoped that students will be received in 1876, and we heartily wish Mr. Gillman every success in his noble work.

SCIENCE IN GERMANY

(From a German Correspondent.)

MUCH as may have been written about bone-formation, yet this theme seems still to be inexhaustible, as in the current series of the "Archiv für mikroskopische Anatomie" (of which we gave the contents in a former report) no less than three papers are published on this subject. Two of these, those by Strelzow and by Stieda, speak of the ossification of cartilage and of bone-growth, and arrive at quite contradictory results. The older view on bone-growth starts from the supposition that the bones once formed undergo no further plastic change, that their single parts cannot displace each other, that therefore an insterstitial growth cannot be imagined. If the growing bone, as usual, does not merely show a uniform increase in size, but little by little changes its shape too (the bent bones for instance, the bends of which change during growth), this naturally leads to the supposition that besides the deposit of fresh material, a solution or absorption of those older materials took place, which did not fit the new shape. In opposition to this view, which Stieda also defends, Strelzow tries to prove that the bone grows interstitially, that therefore it can change its shape in an outward direction without reabsorption of any of its parts, that it is useless therefore to suppose the latter to take place, and that there is no reason for such a supposition. Now, with regard to the change from cartilage to bone, it has certainly been proved, for most cases, that the cartilage is first destroyed before in its place a bone grows from fresh materials. But while Stieda thinks this the case everywhere, Strelzow observes that the lower jaw and the shoulder-blade form exceptions to the general rule, the cartilage there passing immediately from its softer state to bone. Hertwig's observations, which he makes with regard to his investigations of the teeth of Reptilia, have a much more extensive range. In Hemibatrachia the teeth form earlier than any other bones of the head, and starting from this basis those bones in the oral cavity are destroyed, which only cover the exterior of the original cartilage skeleton, and are therefore called covering bones. In frogs these bones certainly form without the help of the teeth, which only appear at a later stage; but as frogs (Batrachia) and salamanders (Hemibatrachia) are of the same order, and particularly as the former are the more recent family, Hertwig thinks that in their ancestors the formation of teeth took place in the same way as in the salamanders now, but that in course of time they lost the primitive bone-forming teeth and retained only the bones resulting from them. The formation of teeth now observed in frogs is therefore a secondary phenomenon. Just as the bones of the oral cavity have their origin in the teeth, Hertwig supposes the covering bones on the exterior of the head to result from scales, and states that this is still very evident with certain fishes. What is a rule for lower vertebrata may also be applied to the higher orders, so that *all* covering bones may be derived from scales or teeth, which in sharks and rays are still equivalent and homologous formations. Therefore sharks and rays must be looked upon as the oldest forms of Vertebrata provided with bones; they are succeeded first by salamanders, then by frogs, and finally by the remaining reptiles, birds, and Mammalia.

It is a well-known fact that the gland-cells only absorb certain materials from the blood in order to convey them, more or less changed, into the hollow interior of the gland organ, and thus to furnish useful substances to the organism (secretions), or to remove useless ones from the same (excretions). Wittich demonstrates these relations in a particularly clear manner ("Archiv für mikroskopische Anatomie," 1875). After the injection of differently coloured solutions (carmine ammonia, indigo-sulphate of soda) into the blood of living rabbits, these colours are again excreted by the kidneys. If the animals are killed during this excretion, and the glands are examined, the carmine is only found in the gland vessels, not in their cells; the indigo, however, in the cells also. Such experiments evidently show that the gland-cells have a sort of selective affinity for the two colouring materials, letting the one pass entirely, and partly retaining the other in their interior.

In the same journal Neumann acquaints us with an interesting property of the cells which coat the abdominal cavity of a frog. It is known that some of these cells in female frogs are furnished with cilia, by the motion of which the ova ejected from the ovary into the abdominal cavity are introduced into the openings of the oviduct. Waldeyer, in his book, "Ovary and Ovum," had maintained that as the essential parts of the female genital organs result from the coating of the embryonal abdominal cavity, those ciliated cells physiologically connected with them result from the same basis, viz., the germ-epithelium; while the whole remaining coating of the *later* developed abdominal cavity, with its entirely different physiological signification, must be a formation genetically different from the former. Goette had already proved ("Entwickelungsgeschichte der Unke") that all those formations, together with several others, result from the uniform cell-coating of the abdominal cavity of the embryo. Neumann now specially proves their genetic identity by the observation that these ciliated cells only occur at the time of sexual maturity in the uniform epithelium of the abdominal cavity, and that therefore they represent local transformations of the same. This again confirms the theory, which Goette (*l.c.*) defends for the whole organism, that each embryonal part is not unconditionally intended for certain formations (which has been an accepted belief since Remak), but that from one single and uniform part in the embryo quite different tissues and organs can and may result, solely depending on the locally changing conditions of development. For instance, the coating of the embryonal abdominal cavity, besides the parts already mentioned, also furnishes the fibrous tissue of the intestines, the kidneys, and the heart.

THE LAWS OF STORMS *

Recent Criticism and Contrary Theories.—The rules referred to in last article are only empirical and are derived from no theory. Mechanics ought to take them in hand and explain them; but it has not been able to do so, for the circulatory movements of both liquids and gases are as yet a closed letter to that science. They are to-day in the same position as were Kepler's laws before

* Continued from p. 403.

the theory of attraction. Why ellipses? said theorists at the beginning of the seventeenth century. And why put the sun in the common focus of all these ellipses? Are there not also other curves followed by these planets in their course around the sun? But once connected with the principle of universal gravitation, these laws, so neglected by contemporaries, became "the immortal laws of Kepler."

Such at present is the position of the Laws of Storms. Despite the adhesion of practical men, meteorologists do not recognise the essential features which *ought*, according to them, to characterise storms. On this account, the practical rules themselves which sailors have followed for thirty years must be rejected; for they are entirely founded, as we have seen, on the circular movement of the air in storms.

These criticisms, more or less direct, based on the theory of centripetal hurricanes or of aspiration, have at the present time all the greater force that mariners themselves have an innate belief in the mere idea of this theory. We even find this belief in the writings of authors who have shown themselves best acquainted with the laws of storms and with the corresponding practical rules. Two examples may be referred to.

The well-known hydrographic engineer, Keller, in his "Treatise on Hurricanes," says that in intertropical regions where cyclones originate, the atmospheric strata underneath the sun dilate and draw up the inferior air of the dilated zone; that if ordinary aspiration, due to the calorific action of the sun, is further promoted by an *electric attraction*, the affluent air will rush with more force into the interior vacuum, &c. Within this space or vacuum he conceives that the water of the sea raised by the central aspiration of a typhoon or a waterspout ascends. When the gyratory column passes from the sea on to the land, it hurls against the shore the water raised by aspiration, and the sea suddenly inundates the low coast to a considerable distance inland. Finally, on land, the force of aspiration of these phenomena exercises its ravages not only by throwing down, but by tearing up trees, and overturning even solid buildings.

M. Bridet, again, asserts that there is formed under the action of the sun, a sort of vacuum resulting from the rapid ascension of masses of heated air. This vacuum is rapidly filled up by the lower currents of air which flow towards it from all directions. These currents, flowing along the surface of the earth, acquire a gyratory motion from the daily rotation. On reaching the base of the ascending column, near the centre of rarefaction, the air carried by these currents gets heated, and expands in its turn; it follows the ascensional movement of the molecules that it replaces, and rises, preserving its rotatory motion.

Persuaded of the reality of this immense draught which the aspiration of ascending columns of heated air must exercise on the lower stratum, in the manner of a chimney, sailors themselves must say that the circular diagram which Reid and Piddington have used for cyclones is scarcely admissible from the theoretic point of view; that already the centripetal movement has been recognised in waterspouts and tornadoes, which, after all, are only cyclones in miniature; that the convergent diagrams proposed recently by Mr. Meldrum, of Mauritius, have perhaps a better foundation, more especially if, as Mr. Meldrum affirms in the cases of two storms which he has recently discussed, these convergent diagrams better represent the true features of the hurricane than concentric circles. Mr. Meldrum's "Note on the form of Cyclones in the Indian Ocean" has been published by the Meteorological Committee of the Royal Society, and is thus well known. We reproduce one of the figures (Fig. 4), and ask the reader to compare it with the circular diagrams of the hurricane in Cuba (Fig. 1); the difference of the two systems will be seen at once.

According to the first the centre is situated perpendicularly to the direction of the wind; according to the second, it will be situated (neglecting for the moment the curvature of the spirals) in that very direction. There is here a difference of nearly 90°.

What will hereafter be the position of sailors in the face of an imminent danger? This is in substance what they are told:—You feel, you see, that a danger menaces you; the aspect of the sky, the state of the sea and of the winds, the steady fall of the barometer, already tell you that there is not a moment to lose if you wish to take the step which may save all. Hitherto you have believed, in the faith of certain empirical rules, that the danger is on your left; not at all—by my theory it is before you.

The captain has no time to search the works of Reid, of Redfield, of Piddington, or to examine the theory of centripetal hurricanes. This is a question which must be quickly answered. Is it necessary, in order to this, to make one's self familiar with all that has been done during the last thirty years in order to *try*, in this repetition of the first investigation, if the centripetal diagrams represent the direction of the wind better than the circular diagrams? This is a labour which would require at least many years.

Happily there is another method of solving the question, which is to examine that theory of hurricanes of centri-

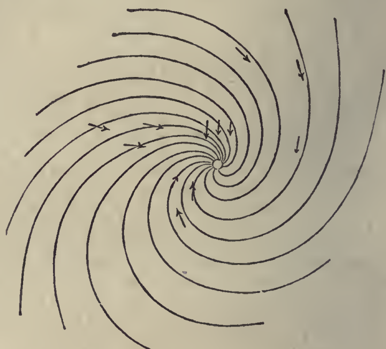


Fig. 4.

petal aspiration which has given rise to all these doubts with regard to the laws of storms. If this theory is found to be true, the authors of the "Laws of Storms" will certainly have been wrong in neglecting its indications. Let us therefore put aside their pretended circulatory movements. The air moves towards a centre of aspiration instead of turning round a point; all will thus be changed, and especially will it be necessary to promulgate practical rules altogether different. But if the theory of aspiration is proved to be false—and, to know what to believe on the subject, long years are not necessary—a rapid examination will be sufficient; if it is false, we say, sailors may continue to place confidence in the rules which have been so serviceable to them for thirty years.

By investigating the whirling movements of which the sun is the theatre, M. Faye was led some time ago to examine this theory without any reference to nautical matters. He has found it completely illusory. On the contrary, that theory which fits into the solar phenomena is found to agree thoroughly with the Laws of Storms; and we need not be astonished at this agreement, for the laws of mechanics are the same everywhere, and the gyratory movements of fluid masses will not vary more in the case of one heavenly body as compared with another than the laws of gravitation. Putting aside solar questions, which interest only astronomers, we shall treat

of the purely meteorological question, and in the meantime place before the reader the conclusions of this essay:—

1. The idea of centripetal hurricanes of aspiration originates in an illusion of the sense of sight; it is an old prejudice whose history it is easy to follow from the most remote times to the present day.

2. The theory of centripetal hurricanes, suggested by this prejudice and the hypotheses which it implies, cannot be accepted. The adoption of similar ideas by enlightened minds is only to be explained by the venerable authority of this prejudice.

3. Bases of the mechanical theory of gyratory movements; agreement of that theory with the Laws of Storms. These ought to be considered as a first but excellent approximation; a means of making further advances.

1. *History of a Nautical Prejudice.*—In the midst of the profound calm which often precedes thunderstorms, the lower strata of the atmosphere are not agitated by the least breath; heavy clouds approach at a great speed and cover the sky—a clear proof that powerful currents prevail above, the influence of which does not extend to the ground. From one of these clouds a sort of bag or end of a tube or funnel is seen to issue, and which gradually descends, lengthening at the same time. It seems to be formed of the same material as the cloud; and in fact is a true fog which envelops the cloud, thus rendering it visible to our eyes.

FIG. 5.

Meantime the centre of this funnel is agitated by a violent whirling movement of which the small whirlwinds of dust that are sometimes seen on our roads give a very accurate idea. When the waterspout reaches the ground and encounters obstacles in its way, it sets to work upon these after the manner of a turning machine of great speed at the end of a vertical axis. It raises around its lower extremity a cloud of dust, overturns trees, batters down walls, and unroofs houses. If, instead of land, the waterspout meets with a water surface, it acts upon it like a square-bladed scoop at the end of a vertical axis, and the churned water is thrown to a distance in foam; if it advances on a pool, is empties it in an instant; if on a lake or a sea, the water spurts out all round the foot of the waterspout in clouds of spray.

Look particularly at this long vaporous tube (Fig. 5), which extends from the surface of the earth to the clouds, to a height of from 1,600 to 2,000 feet and upwards; it appears flexible, and has an undulatory movement through its entire length: the least breath of air alters and distorts its form; and its whirling movements are felt down even to its base, which sweeps over the earth, carrying devastation in its train. If it assumes greater dimensions, it is no longer a waterspout, but a tornado. We have here in two words the history of the tornado of Jan. 20, 1854, which occurred in the county of Knox, Ohio, and which in half an hour levelled 50,000 trees with the ground, hewing for itself a pathway through the forest a quarter of a mile broad, which could not have been made in some weeks by a whole army of backwoodsmen.

The tube, which takes the form of a pillar, a funnel, the trunk of an elephant, &c., usually disappears after being as it were broken across, by the violence of its own gyratory movements. Further, the misty vapours which compose it slowly ascend, and the combination of the ascending and whirling motions gives the appearance, when seen at some distance, of a spirally ascending movement, which, however, bears no relation to the internal gyrations of the waterspout. Movements, not real but illusory, are all that are perceived. The spectator supposes he sees objects ascending in the interior of the waterspout. Thus a bit of cloudy vapour looks like a bird caught by the waterspout and rapidly whirled aloft. If the vermicular motion is continuous and along the whole length of the waterspout, the question is asked, what can in this manner ascend in a long tube whose base is plunged into the sea and which violently agitates its surface. At once and without any inquiry the logic of the imagination comes into play, and the conclusion is come to that it is the water of the sea which the waterspout is in quest of; this it pumps up and distributes among the clouds, and its ascent up the tube is plainly seen. No question is put as to how a tube composed of aqueous vapour can hold and sustain deluges of solid water. Moreover, are the clouds not seen rapidly to grow portentously heavier and bigger by the water so abundantly supplied by the waterspout?

It were idle to listen even to observations made under such impressions. For thousands of years sailors have transmitted from age to age tales of waterspouts which have lifted ships into the air, sucked up the water of the sea, and poured it down again on some hapless ship which was unfortunate enough to pass under and break the tube of the spout. Tales like these, unceasingly reproduced with ever-fresh details, powerfully aid the illusion in determining the event before it is seen.

(*To be continued.*)

NOTES

AN interesting service to astronomy has been rendered by Mr. Davidson, the head of the American Transit Expedition to Nagasaki, Japan; he has determined the exact site of Abbé Chappe d'Auteroche's Observatory in 1769, when he observed the transit by order of the French Academy of Science, at St. Joseph, California. As Abbé Chappe died soon afterwards from a fever caught while fulfilling his mission, his narration was completed by people who had never been on the spot; a blank has been left in the records of his observations, which has now been filled up 108 years after the event. The Abbé Chappe was an uncle of the celebrated Chappe who invented telegraphs during the wars of the Revolution.

M. LECOCQ DE BOISBAUDRAN, who is well known in connection with spectroscopic analysis, has just announced the discovery, by means of the spectroscope, of a new chemical element which he calls *gallium* and affirms to be closely allied to zinc. The spectroscopic character of gallium is two violet lines, one corresponding to wave-length 417, and the other to 404, but fainter. The communication was made by M. Wurtz, at Monday's sitting of the French Academy. A commission has been appointed to report on the discovery. Gallium is said to be found in a special blende from Pierrefite mining works, in the Argeles Valley.

IT appears that M. Janssen's observatory is to be built at Fontenay at the expense of 80,000 francs. A sum of 50,000 francs is to be spent on instruments, exclusive of the apparatus used in the transit of Venus. He is to have two assistants, each of

them receiving 4,000 francs yearly. The instruments are to be under the direct supervision of the Minister of Public Instruction.

METEORS of unusual brilliancy have been seen from several points of late. We recently noticed one seen from the Radcliffe Observatory, Oxford, on Sept. 3, and from the same place we learn that a large meteor was observed on Sept. 7, 11h. 21m. Greenwich mean time, about twice the apparent magnitude of Jupiter, increasing to about four times that of Jupiter, with an accompanying tail of about 5° in length, from near 4 Arietis to a point near *f* Tauri, where it burst into five or six pieces. Colour, blue to green, with red at bursting. Time visible, about seven seconds. It was seen by Mr. Lucas and Mr. Bellamy. Another very peculiar one was seen from Edinburgh and neighbourhood on the 11th inst. A Burntisland correspondent, Mr. G. J. P. Grieve, writes that about 11 P.M. that evening, while pacing a gravel walk in moonlight and partly gaslight, a sudden vivid gleam from behind threw his shadow clear cut on a bright ground. Turning sharp to see the origin of the blaze, after a second or so he noticed a serpentine meteor: the glow or trace left in the path of a shooting star, whose maximum intensity, if not explosion, lay at the west end of the trace. The trace appeared in Auriga, and so close to the three leading stars next south of Capella, that he had not the least difficulty in sketching the position. The particulars are these:—Station in lat. N. 56° 3′ 57″; long. W. 3° 13′ 10″. Position of meteor, in constellation Auriga. Duration from first blaze to disappearance of trace, three to four minutes. Timed at disappearance of trace, 11.2¼ P.M. by Edinburgh gun time. Several letters on this serpentine meteor—"the sky snake" they call it in the north—appear in the *Scotsman*, all agreeing as to its peculiar form and great brilliancy. One observer near Mid Calder "was attracted by the appearance of a magnificent meteor, which was visible for about two seconds, and which, being apparently interrupted in its flight, assumed a zigzag course; and, flashing brightly at each angle thus formed, it disappeared, leaving the snake-shaped track behind it, which was visible for several minutes afterwards, finally disappearing in the form of a ring." On the night of the 14th inst. another magnificent one was visible, apparently over all England. It is noticed in the *Bradford Observer* of the 15th, and Mr. T. W. Shore writes us that he saw it while in the Southampton Water. The time of its appearance, both in the north and south of England, was 8.30 P.M. Mr. Shore, while looking towards the land on the north, observed the meteor commence its luminous course at an apparent altitude of about 30°, and travel to the horizon in a direction from S.E. to N.W. The meteor appeared to him to be about three or four times the brightness of Jupiter, and the time of its course rather more than two seconds. The *Bradford Observer* states that "all accounts agree in saying that it presented the appearance of a flying body of light of considerable size, and that during the period of its passage it lighted the whole sky. It would seem that it first made its appearance from the south-west, its course being over Bowling Park and in a north-westerly direction over Bowling, Horton, and Manningham, and a spectator describes it as an oblong body of light, several feet in length, and bearing the appearance of some solid body in a state of combustion, the sparks flying out on all sides, and a track of flame being left after its passage. Its passage was accompanied by a noise as of a loud explosion, which was plainly heard, not only by those who were outside, but by persons inside the houses who did not see the aërolite itself. All parties concur in saying that so strong a light was cast around that a newspaper could easily be read for the space of half a minute." The same meteor was seen from Manchester and London, and no doubt from various other places. In the report of the meteor of Sept. 3, δ should be λ Piscis Australis.

IN order to stimulate research, experiment, and invention, and to promote the advancement of mining enterprise in Cornwall and Devon, Mr. G. L. Basset, of Tehidy, offers prizes under the following conditions:—1. For the discovery of a new mineral, in Cornwall or Devon, which is deemed likely to become commercially valuable, a prize of 50*l*. An accurate analysis and a description of the leading physical properties and distinguishing characteristics of the mineral to be given, specimens to be handed to the Committee, and the locality and mode of occurrence to be distinctly described. 2. For the invention of a method—mechanical or chemical—of making marketable with commercial advantage, ores or minerals produced in Cornwall or Devon, and hitherto regarded as worthless or of little value. The method to be clearly described, and specimens of the product in its several stages to be handed to the Committee; or, for the discovery of some new application of a mineral substance already known to occur in Cornwall or Devon, either by itself or in combination, to some useful purpose, so as to render it of marketable value, or materially to enhance its value if already marketable to some extent—a prize of 100*l*. The prizes to be awarded at the discretion and according to the judgment of a Committee, consisting of the President and Hon. Sec. of the Miners' Association, and some other gentlemen to be nominated by Mr. Basset. All communications on this subject must be addressed, in the first instance, to Mr. J. H. Collins, F.G.S., hon. sec. of the Miners' Association of Cornwall and Devon, 57, Lemon Street, Truro.

ACCORDING to information communicated to *Aftonbladet* from Christiania, the Norwegian vessel, which in the end of August met Nordenskjöld west of Novaya Zemlya, was the yacht *Elvire Dorothea*, belonging to J. Berger, in Hammerfest. The yacht has returned from the Arctic Sea to Hammerfest. Its master, Johan Alexandersen, states that the Sea of Kara was nearly free of ice, and that it cannot be doubted that Nordenskjöld will reach the goal of his journey, the River Obi.

M. LEVERRIER has announced to the French Academy that Mr. Hind, the superintendent of the *Nautical Almanack*, intends to employ his new Tables of Saturn as soon as they are printed. He reminded the Academy that this will be the sixth table constructed by him that the British Admiralty has introduced into the almanack, and he expressed his sense of the honour thus done him by the Admiralty.

AN interesting and very useful publication comes to us from Germany, under the title of "Die Fortschritte des Darwinismus," by J. W. Spengel (Cologne and Leipzig, E. W. Mayer). This is the second number of the publication, and originally appeared as a paper in Klein's *Revue der Naturwissenschaften*. The purpose of the brochure of eighty pages is to give a brief review of all the works and articles of importance bearing on Darwinism, either *pro* or *con*, published during 1873-4. A very large number of such works, in various languages, is noticed, and their bearing on the Darwinian hypothesis pointed out. The work will be found of great use to those who have not access or have not time to consult all the various publications bearing on the important theory, and will also serve as an excellent bibliography to those who wish to make a thorough study of the subject.

THE German Scientific and Medical Association was opened at Graz on the 17th inst. Lieut. Weyprecht, of the recent Austrian Arctic Expedition, made a speech deprecating all past Arctic expeditions as adventurous and valueless because they constituted an international rivalry that resulted only in giving names to some ice-bound islands. The speaker, amid general applause, expounded a new programme for making Arctic expeditions more fruitful for natural science, and to enable poorer countries to undertake such expeditions.

IN the American *Boston Medical and Surgical Journal* for July there is a paper by Dr. H. P. Bowditch, on the course of

the nerve-fibres in the spinal cord. From his experiments the author demonstrates, in opposition to the results of many other investigators, that the channels of motor and sensitive impressions lie in the lateral, and not in the anterior and posterior columns of the cord.

THE International Congress of Physicians was opened at Brussels on Sunday by the King of the Belgians with great ceremony.

IN connection with the Science and Art Department, South Kensington, the following candidates have been successful in obtaining Royal Exhibitions of 50*l.* per annum each for three years, and free admission to the course of instruction at the following institutions:—1. The Royal School of Mines, Jermyn Street, London: John Gray, engineer; Frederick G. Mills, student; Thomas E. Holgate, farmer. 2. The Royal College of Science, Dublin: C. C. Hutchinson, engineer; Henry Hatfield, student; Thomas Whittaker, clerk.

PROF. FLOWER'S important monograph on the structure and affinities of the Musk-deer (*Moschus moschiferus*) has just appeared in the new 3rd part of the Proceedings of the Zoological Society for this year.

WE commend to our readers a paper in Tuesday's *Daily News* on the scientific work of the *Valorous*, by a member of the expedition. Under somewhat trying circumstances much good work was done. Many new and valuable facts bearing upon the very important question of the geographical distribution of particular forms have been added to those already obtained by the *Porcupine* and *Challenger*.

IN a letter in the *Morning Post*, signed "W. S. M.," attention is drawn to the provision in the New Code of the Privy Council Committee of Education for instruction in cooking, house management, &c., in elementary schools, and a very happy suggestion is made. The writer can see no reason why some portions at least of the subject should not at once be introduced into all schools which are in connection with the Science and Art Department. He then shows how very large a number of students attend the classes for Animal Physiology, Organic and Inorganic Chemistry, and Heat, and says: "There is thus already given, though scattered over four subjects, much of the instruction which would belong properly to the special subject of 'Food and its Preparation.' To make the subject an efficient one, all that is needed is to select certain portions from the subjects already taught, 'Physiology,' 'Acoustics, Light, Heat,' 'Inorganic Chemistry,' 'Organic Chemistry;' to group these portions as one subject, and to add to it some additional instruction that is not at all more difficult than much that is already given." We commend "W. S. M.'s" suggestion, indeed the whole of his letter, to the notice of the South Kensington authorities.

THE Cryptogamic Society of Scotland will hold its first Annual Conference at Perth on September 29 and 30, and October 1, the president being Sir T. Moncreiffe, of Moncreiffe, Bart., President of the Perthshire Society of Natural Science, and the secretary, F. Buchanan White, M.D., F.L.S., editor of the *Scottish Naturalist*. The following is the programme of the meeting:—Wednesday, September 29, field-excursions to Moncreiffe, Dupplin, and Scone. Thursday, September 30, (1) Arrangement and examination of specimens; (2) Business meeting (reading of papers and communications, &c.); (3) Fungus dinner. Friday, October 1, show of fungi and other cryptogamic plants in the City Hall, Perth. All fungi, &c., intended for exhibition must be delivered (addressed to the care of the "Keeper of the City Hall, Perth") not later than 10 A.M. on Thursday, September 30. Ferns in pots must be delivered between 8 and 10 A.M. on Friday, October 1. Botanists (especially in distant localities) who purpose attending the conference are requested to give early intimation of their intention, in order to facilitate arrangements. Further information may be obtained on application to the general secretary, Dr. Buchanan White, Rannoch, Perthshire; or the local secretary, Mr. J. Young, C.E., Tay Street, Perth.

A FRENCH blacksmith has devised a perforated plate, put in rotation by clockwork, and intended to place behind the lock of a safe. The consequence is that the safe cannot be opened except at certain times during business hours, when there is no danger of any robber intruding into the offices.

THE patrons of the Lille Catholic University are trying to get an hospital placed at their disposal in order to start a school of medicine, and they have offered a sum of 150,000 francs to the administration of public hospitals in order to have a *clinique* of their own. The answer has not yet been given, but it is doubtful whether the requisition will be complied with.

THE death of M. Duchesne de Boulogne, one of the most celebrated practitioners who engaged themselves in studying medical electricity, took place on Saturday, Sept. 18. M. Duchesne de Boulogne was the author of several cleverly written books on the subject. His death will be felt as a loss by those who are organising the International Exhibition of Electricity, which is to take place only in 1877, having been postponed owing to the amount of work required to collect all the objects relating to that immense science.

THE admirable "Report on the Progress of the Iron and Steel Industries in Foreign Countries," by Mr. David Forbes, F.R.S., has been reprinted in a separate form in the *Journal* of the Iron and Steel Institute.

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus*) from India, presented by Mrs. Kent; a Common Raccoon (*Procyon lotor*) from North America, presented by Mr. W. Binder; a Goffin's Cockatoo (*Cacatua goffini*) from Queensland, presented by Mrs. Barton; an Egyptian Gazelle (*Gazella dorcas*) from Egypt, a Green Monkey (*Cercopithecus callitrichus*) from West Africa, a Brazilian Hangnest (*Icterus jamaicai*) from Brazil, a Sulphury Tyrant Bird (*Pitangus sulphuratus*), two Red-rumped Hangnests (*Cassicus hæmorrhous*), three Blue-bearded Jay. (*Cyanocorax cyanopogon*) from South America, deposited; a Getulian Ground Squirrel (*Xerus getulus*) from Morocco, six Houbara Bustards (*Houbara undulata*) from North Africa, purchased; a Wapiti Deer (*Cervus canadensis*), and a Reeves's Muntjac (*Cervulus reevesi*) born in the Gardens.

THE BRITISH ASSOCIATION

REPORTS.

Third Report on the Sub-Wealden Exploration.—Mr. W. Topley made a statement on this subject, embodying the chief points of the report drawn up by Mr. H. Willett and himself. Up to the year 1872 nothing was known as to the beds which lie below the Wealden strata in the south-east of England. The lowest beds exposed were those on the north and north-west of Battle, long worked for limestone. The age of these beds was doubtful, some geologists correlating them with the Purbecks of Dorsetshire, others regarding them as Wealden but of somewhat exceptional character. In 1872, when the Association met at Brighton, Mr. H. Willett proposed to commence a bore hole in these doubtful strata, with a twofold object: (1) to determine the order, thickness, and character of the Secondary rocks below the Weald; (2) to prove the Palæozoic rocks which were supposed to lie beneath at a depth which could be reached. Judg-

ing from what is known of the Secondary strata near Boulogne, and comparing them with those exposed in the middle of England, it was hoped that the Palæozoic rocks would be reached at a depth not greater than 1,700 feet from the surface. In August 1874 the boring had reached a depth of 1,030 feet, and was then delayed in consequence of an accident to the rods. This hole was ultimately abandoned, and a new boring was commenced in February 1875, which has been carried to a depth of 1,812 feet. At this point the work has been stopped, in consequence of great difficulties in keeping the hole clear, and it is not proposed to continue the boring further. From the surface down to 175 feet the strata are shales and impure limestones, with gypsum in the lower part. These beds are referred to Purbecks, and with them are now classed the lowest rocks exposed at the surface, formerly called the "Ashburnham Beds." From 175 to 257 feet the strata are chiefly sand and sandstones; these are held to represent the Portland Beds. Below 257 feet there is a great series of bituminous shales and clays, with occasional bands of cement stone and sandstone. Kimmeridge Clay fossils extend down to 1,656 feet at least, possibly lower; so that this formation is here at least 1,400 feet thick. The bottom beds of the boring, just reached, are oolitic in structure, and contain bands of hard limestone. To this extent, then, the Secondary rocks have been traversed, and their order and structure ascertained. A discovery of some commercial value has been made, for two companies are in existence to work the gypsum. One of these has been for some time in operation; a shaft has been sunk and the mineral is now being raised. Scarcely less important is the knowledge now attained that no supply of water can be got by deep wells or borings into the Sub-Wealden strata. As regards the Palæozoic rocks, the boring has not had the success that was anticipated. The Secondary strata have proved too thick, and there is little or no hope of reaching the older rocks here. A boring is now in progress at Cross Ness by the Metropolitan Board of Works; this will be carried through the gault, and may possibly throw some light on this question.

Report of the Committee on Erratic Blocks, by the Rev. H. W. Crosskey.—The Committee continue their record, without attempting the more ambitious task of connecting the facts they report with theories of the history of the Glacial epoch. It will be observed, however, (1) that the facts reported increase our knowledge of the area over which erratic blocks are distributed; (2) that the boulders are connected together in more definite groups, distinctly pointing to special centres of distribution; (3) that the possibilities are increasing of obtaining a more exact history of the periods into which the great Glacial epoch must be divided from the grouping and distribution of erratic blocks. Boulders and scratched stones are reported in South Devonshire. New Red Sandstone boulders occur on the left bank of the River Dart, at Waddeton, the largest measuring 6 × 3 feet, at elevations extending from 15 to 200 feet. Are they travelled masses? If so, whence did they come? When were they lodged where they now lie? What was the agent of transportation? The boulders may have been remnants of New Red beds which once covered the older formations now exclusively overlying the district; but the different levels at which they are found, the present configuration of the surface of the country, and the great weight of some of them, indicate the possibility of their having been transported by ice from some part of the district lying between Berry Head and Galmpton Common. At Englebourne scratched blocks occur of fine grained trap over an area having slate as its subsoil. Although the size of these boulders renders their mobility under the action of waves possible, yet the grooves upon them appear to indicate ice action with considerable distinctness. A group of small boulders of mountain limestone have been found in the north-east of Hertfordshire, 100 miles from their source in Derbyshire. In Nottinghamshire remarkable boulders have been exposed by a new railway cutting, many of them finely striated, which have been described for the Committee by the Rev. A. Irving. The boulders are of lias, millstone grit, and carboniferous limestone. The boulders of lias limestone are derived from the liassic strata of the immediate neighbourhood upon which they chiefly lie. The nearest millstone grit is formed at Castle Donnington and Stanton-by-Dale in Derbyshire, on opposite sides of the Trent Valley; the former place twelve miles south of west, the latter twelve miles north of west from the deposits in which they occur. The nearest carboniferous limestone corresponding to that of the boulders is found at Ticknall in Derbyshire, about eighteen miles distant south of west. The height of the group above the sea is about 200 feet. The extent of the boulder clay and deposit is at least several square miles. In the cutting between Plumtree and Stanton the boulders are largest and most numerous, and are mingled with an immense number of quartzite pebbles, the whole being compactly bound together. In Leicestershire, there is no doubt, Charnwood Forest was a centre of distribution by ice, of blocks of all sizes. The position of various boulders is reported seven miles from their source, together with a block of peculiar millstone grit, at Hoby, near Melton, which must have come from Durham or Northumberland. In Worcestershire (Bromsgrove district) ninety-three boulders have been examined, many of them of considerable size, consisting chiefly of varieties of felspathic rock. It is impossible as yet to generalise on their distribution, but it is noticeable that no specimens of granite have been observed in this district, although they occur so abundantly around Wolverhampton. A list is given of the size and position of the principal erratic blocks, which are rapidly being destroyed. The group of felspathic boulders extends through Northfield and King's Norton to Birmingham. Isolated, and in many cases striated, boulders are reported in the neighbourhood of Liverpool, including blocks of greenstone, syenite, felspathic ash, &c. On the north-west of Bradford a few boulders are reported, similar to the rocks at Scaw Fell, Cumberland, and containing small garnets. The destruction of erratic rocks is going on so rapidly through the country that the Committee earnestly request that reports may be forwarded to them of their occurrence. Some are being buried to get them out of the way of the farmers; others are built into walls, made the foundations of houses, or blasted into fragments. In some cases they constitute the foundations of church towers. A timely record will preserve many facts of large import and assistance in the discussion of problems connected with the centres of ice action, the range of the land ice, the courses of icebergs, and the existence of interglacial epochs.

SECTIONAL PROCEEDINGS.

SECTION A—MATHEMATICS AND PHYSICS

On the Measurement of Wave Motion, by Prof. Frederick Guthrie.—The rate of progression of a wave in a liquid of infinite depth and extent depends upon the wave length; scarcely at all upon its height, and not at all upon either its breadth or the density of the liquid. The measurement of rate of wave-progression in open water is difficult and at best inaccurate. Natural waves generated and supported or restrained by wind have abnormal rates of travelling. Artificial waves in ponds degenerate rapidly in height and increase in wave length, and so in wave progress-rate. The time required by a wave generated in the middle of a pond in reaching the edge, is dependent on its mean wave length. Perhaps after reflexion from the edge the conditions are sequentially reversed, and the time occupied in returning is equal to that of departure. Perhaps not. I think not, because the increase of wave length (and therefore of wave progress) is a function of the height. Be this as it may, many sources of error are got rid of by using troughs of limited surface and indefinitely great depth, by causing the original and reflected wave so to interfere as to produce one or more nodes; and instead of measuring the time required for the crest of a wave to travel in a straight line over a given distance, by measuring the number of times the crest of the wave system reappears in the same place in a given time; in other words, by transferring to liquid waves the method used to measure the rate of sound in solid bodies. As far as the method is trustworthy we get by means of a trough whose diameter is one or two feet, a more accurate method of measuring the rate of wave progress than by an experiment in an ideal pond a mile across.

Experiment shows that if a concentric binodal wave system be generated in a cylindrical trough of water of more than a certain depth (say half its diameter), the following conditions hold good. A nodal ring is formed at one-sixth of the diameter from the circumference. The amplitude at the centre is double that at the circumference unless the disturbance is very great. The rate of undulation—that is, the number of times in a given time that the crest appears in the centre—does not depend sensibly upon the amplitude, nor upon the temperature, nor upon the density of the liquid. It depends almost wholly upon the wave length of the waves formed—that is, upon the diameter of the trough—and is identical with the number of beats of a pendulum whose length is equal to the radius of the trough. Hence the rate of undulation varies inversely as the square root of the trough radius or

diameter. This confirms the assertion that the rate of wave-progress varies directly as the square root of the wave length; because the rate of recurrence must vary as the rate of progression divided by the path.

Experiment shows that a wave of 1 meter wave length would travel 83·07 meters in one minute if it did not alter its wave length, and moved automatically. A cylindrical trough of water more than, say, 500 millimeters deep and 1·988 meters in diameter, will, in the latitude of London, undulate in seconds, and will remain isochronous with the London seconds' pendulum wherever they travel together.

In rectangular troughs, the wave progress is hindered. The rates of recurrence of phase in rectangular troughs are slower than in circular troughs when the wave lengths are the same; and this difference is greater when the wave length is greater. Both circular and rectangular troughs accept mononodal undulation. The rate of progress between parallel walls of a wave 1 meter long is found to be 74·7, and this is independent of the distance of the walls apart. The mononodal undulations in circular and rectangular troughs have also been examined.

The comparative empirical mean constants in minute-millimeters are—

Circular.		Rectangular.	
Mononodal. (*a*)	Binodal. (*b*)	Mononodal. (*c*)	Binodal. (*d*)
$n\sqrt{d} = 1762{\cdot}56$	$2613{\cdot}24$;	$n\sqrt{e} = 1594{\cdot}16$	$2360{\cdot}04$.

where d is the diameter of the circular trough and e the length of the rectangular one.

The water in a circular trough can also undulate with two perpendicular rectilinear nodes.

Taking the same trough, it is found that the number of undulations per minute, when (*a*) the circular binodal, (*b*) the mononodal, and (*c*) the binodal rectangular systems were established, were—

$$a = 106{\cdot}9 \qquad b = 71{\cdot}6 \qquad c = 94.$$

These numbers a and c agree well in ratio with those of a circular elastic plate in similar vibration. The details of this communication were laid before the Physical Society in June last. They will, I hope, appear in part in the *Philosophical Magazine* for October.

SECTION B—CHEMICAL SCIENCE

Prof. Cayley read a paper *On the Analytical Forms called Trees, with application to the theory of chemical combinations*, before a good audience composed to a considerable extent of mathematicians.

The author in commencing stated that the subject he was about to consider was more mathematical than chemical, but as the results bore considerably upon the latter subject he had introduced it in this Section. The problem to be solved was to find the theoretic number of the hydrocarbons C_nH_{2n+2}.

The only assumptions are that an atom of hydrogen can link itself to one other atom, and an atom of carbon to four other atoms. A combination of n carbon atoms can then link itself on to 2_{n+2} hydrogen atoms at most, but this number is only attained when the carbon atoms are linked together without cycles, or so as to form a "tree": given the tree, the hydrogen atoms can be linked on in one way only, and the question thus is to find the number of trees which can be formed with n carbon atoms. The atoms, or dots representing them, are termed "knots," the lines joining two knots are termed "branches"—the trees in question are such that from each knot there proceed at most four branches; but this limitation is in the first instance disregarded. A tree may be considered as springing from any one of its knots as its root, and trees which are chemically the same thus present themselves under different forms. For the treatment of the chemically distinct forms it is necessary to introduce the notions of a "centre" and a "bicentre" (due to Prof. Sylvester); and the question is reduced to that of finding the number of the *central* trees with n knots: this is solved by the method of generating functions, viz., the number of the central trees of altitude N is given by a series of the form—

$$t\,x^{N+1} + \{t, t^2\}x^{N+2} + \{t, t^2, t^3\}x^{N+3} +, \text{\&c.}$$

where the numerical coefficient of any term $t^\alpha x^{N+\beta}$ shows the number of trees of α main branches and $N+\beta$ knots. The final result as regards the carbon-trees, or say the hydrocarbons C_nH_{2n+2} is given by the following table:—

n =	1,	2,	3,	4,	5,	6,	7,	8,	9,	10,	11,	12,	13
Central	1,	0,	1,	1,	2,	2,	6,	9,	20,	37,	86,	183,	419
Bi-central	0,	1,	0,	1,	1,	3,	3,	9,	15,	38,	73,	174,	380
Total	1,	1,	1,	2,	3,	5,	9,	18,	35,	75,	159,	357,	799

so that theoretically for the body whose formula is $C_{13}H_{28}$ there exist 799 isomeric bodies.

It is worthy of remark that the mathematical theory agrees with experiments for the first five bodies, thus affording strong confirmation of the truth of the remainder.

The Professor also drew attention to the fact that any number is sometimes rather more and sometimes rather less than double the preceding number.

Prof. Armstrong suggested that probably a large number of these isomers would be unstable, illustrating his meaning by the two isomeric di-nitro-phenols, one whose melting-point was 76° C. readily passing into the other whose melting-point was 116° C., which was objected to on the ground that it was not fair to compare the action of bodies as complicated as the phenols with the simple hydrocarbons.

Prof. Clifford also made some remarks on the bodies represented by $C_nH_{2n+2-2x}$, and stated that it would be found that x represented the number of cycles that would occur in the trees.

Mr. P. Braham made some remarks on some further experiments on *Crystallisation of Metals by Electricity*, in which he stated that he had placed the positive and negative electrodes of a battery in a vessel containing a mixed solution of copper and zinc, and that with terminals of copper he obtained a dull crystallisation proceeding from the negative pole of mixed crystals of copper and zinc, and beyond this, crystals of copper alone. With terminals of zinc he got a mixture of crystals as before, and in front of these, crystals of zinc alone. But if terminals of brass (a compound of zinc and copper) are used, there is a dull crystallisation of zinc across the field. He also observed that with zinc terminals, by increasing the battery power, the crystallisation is broken up; but not so when the terminals are copper or brass, but then the crystallisation extends above and beyond the positive pole.

Mr. Gatehouse read a paper *On Silver Nitrite*, giving the results of some investigations into the causes of what is termed by photographers "woolliness" in their negative baths.

The five methods given of preparing the nitrite were as follows:—

1. By mixing solutions of potassium nitrite and silver nitrate.
2. By sensitising a collodion film and evaporating to dryness a mixture of nitrite and nitrate is obtained.
3. By fusing silver nitrate with organic matter.
4. By electrolysis of silver nitrate with platinum electrode.
5. By means of metals placed in neutral solution of silver nitrate.

By this last method he found that metals which produced reduction, viz., K, Na, Bi, Hg, As, Th, did not produce nitrite, but those which did not produce reduction, viz., Fe, Ni, Co, Mg, Zn, Cu, Pb, Sn, Sb, did produce nitrite. The former, it was observed, have an uneven equivalency, and the latter an even equivalency, with the exception of Hg and Sb, the latter of which may, like Fe, be tetratomic. The physical forms of the crystals were observed to vary from modular masses to filiform crystals.

Mr. A. H. Allen, in making some remarks *On a Method of effecting the Solution of difficultly-soluble Substances*, stated that he had found that many so-called insoluble substances could, when heated with fuming hydrochloric acid in sealed combustion tubes, be either completely dissolved or decomposed with separation of silica. In some cases where hydrochloric acid failed, sulphuric acid succeeded. The heating of the tubes was generally done by means of a water bath, but for some substances a chloride of calcium bath must be used.

Mr. J. C. Melliss read an account of the method of purification of a river by precipitation, at present adopted at Coventry. He stated that 2,000,000 gallons of sewage liquor, contaminated by dye, refuse, &c., were daily passed through these works and completely purified. The process employed is briefly the follow-

ing:—The water of the river, after being mechanically strained from solid impurities, is passed into tanks, where it is mixed with sulphate of alumina; it is then passed to a second set of tanks where it is mixed with milk of lime, and thence on to a field or filter bed 4½ acres in extent, which ejects 80,000 gallons of water per hour, pure enough for fish to live in. The greatest difficulty to be contended with was the freeing of the precipitated matter from the water, of which it contained 80 per cent.; this quantity, however, was considerably reduced by means of mechanical appliances, which reduced the water to such a percentage that it could either be dried (and so rendered portable) by heat, or by mixing it with some substance which increased its manurial value. In conclusion, the author stated that the primary object was to secure sanitary rather than commercial success, and that this certainly had been achieved at a cost of about sixpence per head per annum for a population of 40,000.—Some discussion ensued as to the relative merits of the method of irrigation and the method just described.—In reply, Mr. Melliss said that he was not prepared to say that the Coventry method was the best in all localities; the physical characteristics of the land in neighbourhood must always be taken into account, as of course it would make a great difference whether the soil consisted of clay or of sand.

Prof. Debus read a paper *On the chemical theory of Gunpowder*, in which he stated that nothing illustrated in so striking a manner the molecular changes produced by chemical action as the explosion of gunpowder. He said that some years ago the eminent French chemist Berthelot showed that if CO_2 be passed into a mixture of BaO and CaO in insufficient quantity to precipitate the whole of the barium and calcium as carbonate, then neither is the whole of the barium precipitated nor the whole of the calcium, but they are precipitated in a certain definite proportion, which is a multiple of their molecular weights. Hence, in general, if a mixture of the salts A and B be decomposed by some other substance, C, in insufficient quantity to decompose the whole of both, then the bodies formed will be $AC_1 + BC_2$ where $C_1 + C_2 = C$; and moreover, if the quantity of B is doubled or trebled, &c., the quantity C_2 will be increased in a definite proportion. After making some further remarks of a like nature on the decomposition of a mixture of $BaCl_2$ and $CaCl_2$ by CO_2, and also of the explosion of mixture of H and CO with an insufficient supply of oxygen (as investigated by Bunsen), the Professor went on to show that the same arguments might be applied to the explosion of gunpowder which was a mixture of carbon, sulphur, and nitrate of potash.

He then placed upon the black board the result of one of a large number of analyses of one grain of powder.

Compound.	Grain.	
(1) K_2CO_3	·3098	·00224
(2) $K_2S_2O_3$	·0338	·000177
(3) K_2SO_4	·0658	·000378
(4) K_2S	·1055	·00096
(5) CO	·0473	·00170
(6) CO_2	·2770	·0629 *

In addition to these were also formed in *small* quantities the following: potassium sulphocyanide, potassium nitrate, ammonium carbonate, sulphur, sulphuretted hydrogen, marsh gas, hydrogen, and nitrogen, most of which appear to have been the result of gaseous impurities in the carbon.

Referring to the table it will be seen that by adding up the total molecular value of the sulphur salts we get ·00151, which bears to the molecular weight of potassium carbonate (·00224) the ratio 2 : 3 nearly. Hence it is inferred that at the first moment of combustion the potassium in the saltpetre divides itself into five parts, two of which go to unite with the sulphur, and three to form the carbonate. Again, it will be seen that the carbonic oxide bears to the potassium very nearly the simple ratio 3 : 4. The CO_2 must have been formed in more than one reaction, because it does not give any simple molecular ratio. The conclusions thus arrived at are, that in the first moment of explosion the sulphur existed either as sulphite or as sulphate, and that the carbonic oxide must have been formed simultaneously with the potassium carbonate. The equations of the decomposition of gunpowder would then be the following:—

(1) $24KNO_3 + C_{35} + O = 12K_2CO_3 + 9CO_3 + 14CO_2 + 12N_2$
(2) $16KNO_3 + C_8 + S_8 = 8K_2SO_4 + 8CO_2 + 8N_2$
(3) $6K_2SO_4 + C_{11} + S + O = 5K_2S + K_2S_2O_3 + 11CO_2$.

The first two reactions taking place simultaneously.

* The third column is the number found by dividing each quantity by the corresponding molecular weight.

Prof. Thorpe, in giving some account of a *New Compound of Fluorine and Phosphorus*, said that having had some occasion recently to make a considerable quantity of the terfluoride of arsenic, by heating calcium fluoride with arsenious acid in the presence of Nordhausen sulphuric acid, he was induced to study the behaviour of this body with various other substances. When this terfluoride of arsenic is dropped into a solution of the pentachloride of phosphorus, such an immense amount of heat is evolved that it is necessary to keep the vessel surrounded with a freezing mixture, and dense white fumes are given off, while only chloride of arsenic remains in the solution. This gas is decomposed by water, but may easily be collected over dry mercury, in which condition it may be kept, but after some time the glass is observed to become dim. The specific gravity of the gas answers to the formula PF_5, and its molecular weight is 63. It acts readily upon alcohol, but the substance formed quickly corrodes glass. It is believed that it will be found to be a condensable gas under a pressure of six or seven atmospheres. It is not impossible that when decomposed by the electric spark it may give *fluorine*. It is remarkable as the only known pentatomic compound of phosphorus.

Mr. B. J. Fairley, F.R.S.E., read a paper *On New Solvents for Gold, Silver, Platinum, &c., with explanation of so-called Catalytic Action of these Metals and their Salts on Hydrogen Dioxide*, in which he stated that it was perfectly easy to dissolve silver in dilute acids, as acetic, sulphuric, or hydrochloric, provided hydrogen dioxide were present in the solution, and that if under the same circumstances the silver were dissolved in nitric acid no lower oxides were evolved. Repeating the experiments with gold, it was found that acetic and nitric acids scarcely dissolved it at all, but hydrochloric acid readily, and without the evolution of free chlorine. Some remarks were also made on the great liberation of heat observed when two unstable compounds of oxygen react upon one another so as to produce more stable compounds, especially with reference to the heat evolved during the decomposition of ozone and hydrogen dioxide, the author stating that this great *heat* must correspond to a great *force* of union.

The same gentleman also made some remarks *On the Use of Potassium Dichromate in Grove's and Bunsen's Batteries to ensure constancy*, in which he stated that he had used a small quantity of that substance dissolved in the nitric acid, and had found that the battery remained constant so long as any chromic acid remained to be reduced, and that no red fumes appeared.

Two other papers were also communicated by the same author: (1) *On a New Process for the separation of Lead, Silver, and Mercury (Mercurous) Salts*; (2) *On a Process for the Preparation of Periodates, with their application as a Test for Iodine and Sodium.*

Dr. J. H. Gladstone read a paper *On the relation of the Acids and Bases in a mixture of Salts to the original manner of combination.* In a former set of experiments the author had shown that if a molecule of copper nitrate and a molecule of potassium sulphate be dissolved in any quantity of water, and two molecules of potassium nitrate with one molecule of copper sulphate be dissolved in an equal quantity of water, then the colour produced is the same: and similarly for other sets of salts. The author, however, thought that the colours of these mixtures being comparatively faint, it would be better to try mixtures of colourless salts, and add to these mixtures some substance such as ferric sulpho-cyanide, ferric mæconate, or bromide of gold, whose colour is easily reduced. Accordingly, he mixed together potassium sulphate and magnesium nitrate, and the corresponding salts potassium nitrate and magnesium sulphate; also acetate of potassium and nitrate of lead, and the corresponding salts, &c.; in every case these were found to reduce the colour of ferric sulpho-cyanide equally. All the experiments united to confirm the supposition that the effect of a mixture does not depend upon the position of the acids and bases in it, so long as the proportions of each remain the same.

Dr. Russell asked if the amount of colour would indicate a small change in the nitrate, and also if the element *time* had been taken into the experiments.

Dr. Tilden preferred the old method, on the ground that by adding a reagent new conditions are introduced.

In reply, Dr. Gladstone said that the ferric sulpho-cyanide was much more delicate than the solutions of copper salts.

Dr. J. H. Gladstone read two notes, *On the Copper-Zinc Couple*, by himself and Mr. Alfred Tribe. In the first he showed that whereas a piece of zinc in dilute sulphuric acid (3½ in 1,000 parts of water) gave off seven volumes of hydrogen in one hour,

the same piece of zinc, when covered with spongy copper, gave off eighty volumes in one hour, which showed an elevenfold increase for an addition of the negative element of only 0·11 per cent. In the second note he showed that if a quantity of arsenical zinc foil was "coupled," washed and heated with water, and two litres of hydrogen evolved therefrom were passed through a tube heated to redness, not a trace of arsenic was observed; but when a portion of the same arsenical zinc was treated with dilute sulphuric acid, and two litres of hydrogen evolved by the action were passed through a heated tube as before, ·0019 gramme of arsenic was deposited in the cool part of the tube. Arsenical zinc, when covered with spongy copper and acted upon with dilute sulphuric acid, also gave arseniuretted hydrogen. This appears to show that it is not the copper, but the inability of the arsenic to get into solution when hydrogen is made from water and the "couple," which is confirmed by adding an aqueous solution of arsenic to the same couple, when the mirror immediately appears.

The same gentleman also read a paper by the same authors, in which it was shown that if aluminium be "coupled" with more negative metals, such as copper or platinum, then at the ordinary temperature of the air in the latter case, 4 c. c. of hydrogen are evolved in twenty-two hours, and if the temperature be raised to 100° C., in the first six hours 484 c. c. are evolved. Aluminium alone, according to Deville, only decomposes water at a white heat.

The President read a paper *On an apparatus for estimating Carbon Bisulphide in Coal Gas.* The principle upon which the success of the method depends is the following:—When carbon bisulphide is heated in the presence of hydrogen, sulphuretted hydrogen is formed.

The apparatus consists of a flask filled with pebbles and asbestos (to expose a large surface to the action of heat), and surrounded by fire-clay cylinders, in which gas is kept burning. This flask is connected through a solution of lead with an aspirator. There are other connections also by means of which gas from the source requiring to be tested circulates through the flask and is burnt. When the flask has been heated for about twenty-four hours continuously (to expel all moisture), a measured quantity of water is drawn off from the aspirator, which causes the same volume of gas to bubble through the lead solution, and on account of the presence of sulphuretted hydrogen to produce a decolorisation of the lead solution. A similar vessel containing the same quantity of lead solution and a *known* quantity of sulphuretted hydrogen is placed beside it, the gas being allowed to bubble through the first until the colour is judged to be equally intense; the amount of sulphuretted hydrogen in a known volume of the gas is thus found, and hence the amount of carbon bisulphide. Having once got the apparatus started, gases from several different sources may be tested.

Prof. A. Oppenheim made some remarks on *oxyuvitic acid*, which he stated belonged to the aromatic series, and said he was able to show that it could be prepared from its elements, thus making the fifth of that series which could be prepared by synthesis. The formula of the acid he showed to be $C_6H_2\left\{\begin{matrix}CH_3\\OH\\COOH\\COOH\end{matrix}\right.$ thus making it a derivative of benzole. It gives a reddish brown colour with ferric chloride in the presence of alcohol. If it is slightly heated it changes its composition to $C_6H_3\left\{\begin{matrix}CH_3\\OH\\COOH\end{matrix}\right.$ which gives a violet colour under the same circumstance: if it is still further heated it is converted into $C_6H_4\left\{\begin{matrix}CH_3\\OH\end{matrix}\right.$ or cresole.

The Professor also made some remarks on the derivatives of mercaptan, which were founded on some researches of Dr. Williamson on the action of chloroform.

Mr. Chas. T. Kingzett read a paper *On the Oxidation of Essential Oils*, which he observed was a continuation of papers which had previously been communicated to the Chemical Society. The object of the paper was to give some results on the limited oxidation (by air) of terpenes of the general formula $C_{10}H_{16}$, certain terpenes of the formula $C_{15}H_{24}$, and cymene, $C_{10}H_{14}$. The terpenes experimented upon were hesperidine, myristicene (obtained in three different ways from oil of nutmeg), wormwood, all of which gave on atmospheric oxidation, peroxide of hydrogen and acetic acid. Citronella and Ylang Ylang, clove-terpene ($C_{15}H_{24}$), were found to develop no peroxide of hydrogen. Cymene obtained from three sources and exposed to atmospheric oxidation was also found to develop peroxide of hydrogen. These researches prove that in terpenes of the formula $C_{15}H_{24}$ the carbon exists in an allotropic form.

SECTION D—Biology

Department of Anthropology.

One day was chiefly occupied by a valuable series of papers on the population of the Indian region. A combined discussion on the three papers now to be noticed followed their reading. The first paper was by Sir Walter Elliot, *On the original localities of races forming the present population of India.* After some preliminary remarks, he said that the circumstance of colour was one of the most observable signs of difference of race, and the very word for the Aryan institution of caste was *varanum*, or colour, they having doubtless introduced it to distinguish themselves from the Dasyns or alien peoples with whom they came in contact on crossing the Indus. The author detailed the different colours or races now inhabiting India, and went on to remark that it is now generally admitted that the centre of dispersion from which all the peoples of the earth had migrated was Central Asia. The first great wave that surmounted the Himalayan barrier, at a time when the earth's surface was in a different condition from what it is now, could no longer be traced as a separate and distinct people. Remnants of the primeval movement were now only to be found amongst the most degraded denizens of the hills and forests, and probably in the despised slave population. The great Dravidian migration must have been made much later in time. It was probably not a simultaneous movement, but consisted of successive swarms, which would account for the existence of well-defined groups among them, which had preserved their characteristics unchanged to the present day.

But the normal representatives of the race were to be found in the mountaineers of Central India, where, protected by regions of deadly malaria encircling their highland territory, they have for ages bid defiance to hostile aggression, and preserved their habits and independence unchanged. The ground on which so many at first sight heterogeneous races were united under the title of Dravidian was mainly community of language, but that test was not infallible. A better link was furnished by similarity of form, features, colour, and structural coincidence. He maintained that the characters of Prof. Huxley's Australioid type could be traced among the classes of Dravidians, modified as was to be expected, among those most exposed to external influences, but still always apparent to a practised eye. There was nothing to show by what routes the first settlers arrived. Their advance was probably a slow and gradual percolation from different parts of the north through the mountain barrier that cuts off India from the rest of Asia. The migratory instincts or necessities of the people of Central Asia exerted themselves in all directions. Of the exact seat of the brown-skinned, wavy-haired Australioids, they had no definite knowledge. But the Mongols and Mandchurians sent off successive hordes to the south-east, whence in time the teeming population of China sought an eastern direction. Those people were thus brought into contact with tribes already settled there from a more westerly quarter. Thus the inhabitants of Siam, Burmah, and the Malayan Peninsula, spoke a monosyllabic language, but wrote it in a Dravidian character, and Mr. Hodgson found the scattered tribes around Nepaul partaking of the same mixed characters, both with regard to race and language.

Mr. Hyde Clarke's paper *On the Himalayan Origin of the Magyar and Fin Languages*, attempted to prove his theory by facts of analogy in the languages themselves, and by inferences from facts of history. He found that the affinities of Magyar and Fin were strongest for the languages of East Nepaul.

Mr. Bertram Hartshorne, of the Ceylon Civil Service, read a paper on the interesting *Weddas of Ceylon*, who still depend for their means of subsistence upon their bows and arrows, and pass their lives in the vast forests of Ceylon without any dwelling-houses or system of cultivation. There is an entire absence of any flint or stone implements among them, and their state of barbarism is indicated by the practice of producing fire by means of rubbing two sticks together, as well as by their habitual disregard of any sort of ablution. Their intellectual capacity is very slight; they are quite unable to count, or to discriminate between the colours; but while their moral notions lead them to regard theft or lying as an inconceivable wrong, they are devoid of any sentiment of religion except in so far as that may be inferred from their practice of offering a sacrifice to the spirit of one of

their fellows immediately after his decease, their idea of a future state being that they become devils after death. They never laugh, and they are very noteworthy as being the only savage race in existence speaking an Aryan language. Their vocabulary consists largely of words derived directly from the Singhalese; others indicated an affinity with Pali or Sanskrit, whilst there remained a considerable residue of doubtful origin. There was an absence of any distinctly Dravidian element.

In the discussion on these papers, Prof. Rolleston said that the ethnology and languages of Hindostan were now in pretty much the same state of fusion as those of Great Britain. Since the writings of Sir George Campbell and others, and the excellent publications of the Indian Government, he had arrived at the conclusion that the Australioid and not the Mongolian type was that which formed the substratum all through the outcast tribes of India: this accorded also with the probabilities of evolution. He believed that the earliest races of mankind were eminently Australioid, with long and narrow heads. With regard to the Weddas, it was a most interesting question whether they were really a degraded outcast Sanskrit population. Max Müller was of that opinion; and their possession of the bow and arrow, which no Australioid ever had, tended in that direction. Their skulls were not Australioid.—Sir George Campbell did not know that there was any authentic case of degradation of a race. In this instance the *primâ facie* inference seemed to him to be that the Weddas were an aboriginal race. Very small tribes which had been reduced in numbers easily changed their language under the influence of a more powerful surrounding people. From the photographs of the Weddas he pronounced their absolute identity in feature with many of the barbarous aboriginal tribes of India which he had seen, and which were distinctly non-Aryan. The use of the bow was universally known among the aboriginal races of India, which had the same notions about witchcraft, &c. as the Weddas. He asked for information as to their strength in the left arm, which Mr. Hartshorne had mentioned, for he had always supposed that the use of the bow called forth strength in the right arm.—Mr. Hartshorne said that in his experience of shooting with the bow, he had found that the great tension in pulling the bow was on the muscles of the left fore-arm. He was therefore prepared to find that the Weddas were stronger in the left arm, and it was so.—Sir Walter Elliot agreed with Sir G. Campbell as to the aboriginal character of the Weddas, but believed in the possibility of great degradation.—Mr. Hyde Clarke said they had all the appearance of being an aboriginal people. Their speaking an Aryan language was no decisive reason for calling them Aryans.

Dr. Leitner gave a graphic summary of the results of his travels and researches in the Central Asian region to which he has given the name Dardistan. He gave the following as the chief results of his investigations:—"First, we have ascertained the existence of a number of languages—one of which, Chilasi, the object of my mission, is a mere rude dialect—which were spoken at or before the time that Sanskrit became the 'perfect' language, for no one who can speak any of the derivative languages of India can class the bulk of the Dard languages among them. Secondly, the legends and traditions of the Dards show a more European tone and form than anything we find in India. Thirdly, by the adoption of the term Dardistan for the countries between Kabul, Kashmir, and Badakshan, we are driven to compare a number of races which offer certain analogies, and which may have a certain history in common since the time of Alexander the Great's invasion of India. Fourthly, our Government now know accurately what they certainly did not know before 1866, the modern history of the countries bordering on Kashmir." He found that the dialects in this district, which were in a highly inflexional state, had been preserved from deterioration by isolation and other causes. He had very little doubt that Dardistan was the first halting-place of the Aryan migration to India; the second being Kashmir. There was as great a difference among some of their dialects as between French and Italian. They had songs, legends, and fables of superior character, which he had carefully taken down and would publish. Among the evidences of their high state of civilisation were the respect shown to the female sex, and the liberty and responsibility accorded to them; their love and charity to animals; and the charm and beauty of their legends. They called themselves the brethren of the Europeans. Associated with them was a race of predatory kidnappers, very similar to them, but speaking a somewhat different language. He had found a great quantity of art products, especially sculptures, which clearly indicated a great influence of Greece upon them in very early times, probably through the existence of the Bactrian kingdom. There was no trace of the later and more extravagant influences of Buddhism, but scenes essentially Buddhistic and Asian were treated after the Greek manner, and very much with the Greek success. Expression attained a high level in these works.

Prof. Rolleston read a paper *On the Applicability of Historical Evidence to Ethnological Inquiries*, in which he showed the danger of drawing conclusions from isolated expressions of historians unless they were of the first class, such as Cæsar and Tacitus. He quoted modern examples of carelessness and inaccuracy in this respect. He referred especially to the Cimbri, who were dealt with in the next paper, and expressed his inability, from any historical investigation, to come to a satisfactory conclusion as to who they were.

Prof. Rawlinson's paper *On the Ethnography of the Cimbri* was in favour of the Celtic theory of their ethnological character. He said that in favour of the theory that they were Germans the following considerations were urged:—The supposed etymology of their names; their geographic position before they began their wanderings in Jutland and between the Rhine and the Elbe; their close alliance with the Teutons, whom all allowed to be Germans; their physical characteristics, blue eyes and flaxen hair; some points of their manners and customs, especially the fact that their armies were accompanied to battle and directed by priestesses rather than priests; and, lastly, the statements of Julius Cæsar, Strabo, Pliny the elder, and Tacitus, who include the Cimbri in their lists of German nations. The advocates of the Celtic theory relied chiefly on five arguments: (1) the name Cimbri, which they identified with the term Cymry or Cymraeg, which was still the native name of the Welsh; (2) the almost unanimous authority of the Greek and Roman writers, excepting Julius Cæsar; (3) the individual names of Cimbri, which were Celtic; (4) the fact that the Romans employed Celts as spies to bring them intelligence of the designs of the enemy during the Cimbric war; (5) the manners and customs of the people, which were held to be far more Celtic than German. They also joined issue on the argument from the physical characteristics of the race, which they held to be, according to the description given, at least as near the Celtic as the German type. Prof. Rawlinson then proceeded to examine the various arguments, holding that the balance was in favour of the Celtic origin, though it was a point open to dispute, and unless fresh data should be obtained, which seemed very unlikely, would always remain among the vexed questions which would divide ethnologists.—Dr. E. A. Freeman dissented from Prof. Rawlinson's conclusions, holding strongly to the opposite theory. He especially censured his rejection of the evidence of Julius Cæsar and Tacitus.

The ethnology of New Zealand and Polynesia received much attention owing to the presence of two distinguished authorities, the Rev. Wyatt Gill, from the Hervey Islands, and Dr. Hector, of the New Zealand Geological Survey. The connection between the origin of the Maories and the Polynesians was brought out in a series of papers followed by a valuable discussion. Mr. W. S. Vaux, in a paper *On the probable origin of the Maori race*, concluded that the Maories were the descendants of the great colonising race of yellow men who originally migrated from Central Asia. The Rev. W. Gill then read a paper *On the origin of the South Sea Islanders.* Mr. Gill said that Mr. A. R. Wallace, in his "Malay Archipelago," has advanced the theory that the Polynesians are descended from a race which once overspread a vast submerged southern continent. As the land gradually sank, a few of the aborigines may have escaped to the tops of the loftiest mountains, around which subsequently coral reefs were found. Admitting that Polynesia is pre-eminently an area of subsidence, and its great widespread groups of coral reefs may mark out the positions of former continents, Mr. Gill believed that Mr. Wallace's reference was unwarranted. (1) Supposing that human beings inhabited this great southern continent at the period of the subsidence, and that a remnant escaped, it is not probable human life could have been sustained on the tops of these mountains for any considerable time, owing to the want of food and water. (2) The theory is utterly opposed to the native accounts of their own origin, which all point to the north-west. (3) The spread of the race can easily be accounted for on the basis of historical facts. In 1862 he saw on Manuâ, the easternmost island of the Samoan group, a small boat which had accidentally drifted from Moorea, a distance of 1,250 miles, and no life was lost. A few months later on in the same year Elikana and his friends drifted in a canoe from Manihiki to Nukurairae, in the Ellice group, lying N.W. of

Samoa, a distance of 1,360 miles. Half of the party on board perished from want of food and water. In both these instances the drifting was from east to west, before the trade winds. A far more remarkable event occurred in Jan. 1858, during the prevalence of the violent easterly winds, when a numerous family of adult natives drifted from Fakaofo, in the Union group, north of Samoa, to an uninhabited spot known as Nassau Island; thence to Palmerston's Island; and finally to Maugaia, where Mr. Gill lived; altogether a distance of more than 1,200 miles in a south-easterly direction. (4) The colour, hair, general physiognomy, habits, character, and especially the language, of the Polynesians clearly indicate a Malay origin. This could not be accidental. Mr. Gill's impression was that long ages ago the progenitors of the present race entered the Pacific from the S.E. fork of New Guinea, but were driven eastward by the fierce Negrito race. The greatest distance from land to land, as they pressed eastward, would be from Samoa to the Hervey group, about 700 miles, which had been successfully performed by natives in their fragile barks under Mr. Gill's own observation.

In the subsequent discussion Prof. Rolleston expressed his opinion that there was little difference between Papuans and Australoids; the superficial differences were outweighed by great radical points of resemblance. He referred to the Rev. S. J. Whitmee's paper in the *Contemporary Review* for February 1873 as of the highest value on this question of the origin of the races of the Polynesian islands. This opinion was diametrically opposed to Mr. Wallace's.—Dr. Hector described the three chief race-types among the Maories. The first was rarely met with except in the extreme south; it was of the same type as the aborigines of the Chatham Islands, with a distinct dialect, only comprehensible by old Maories. They had a sloping forehead and strong muscular ridges on their skulls, which were very distinct from the great majority of Maori skulls. The other two types were now pretty well intermixed. One was more common in the northern extremity of the Northern Island, having yellow shock hair and high cheek-bones. The third was the ordinary Maori. He mentioned the fact that the Maories had a much better knowledge of the natural history of their country than any people he had ever heard of. The older Maories had noticed and had distinct names for nearly all their plants, not merely those that were of use; and the same names, with slight modifications, were universally in use throughout a country a thousand miles in length. They had generic names by which they grouped plants according to their affinities in a way impossible to most people who were not educated botanists. The Veronicas of New Zealand appeared under a very great variety of external forms, yet they were all identified by one name.—The Rev. W. Gill, in closing the discussion, said that difference in shade of colour was not to be relied upon as a test of difference of race; for he had seen the most intense blackness produced in Polynesia in those of the poorer classes who habitually spent much time in salt water, while the wealthier classes remained of a much lighter hue.

General H. B. Carrington, of the United States army, read a very interesting paper *On the Indians of the North-Western States*.

The Anthropological Department has been one of the best sustained this year, a result attained by its inclusiveness of a wide range of subjects relating to the history of mankind, and by reason of the high authority of many who addressed the department on their respective studies. The President showed himself a worthy leader, illuminating most of the subjects discussed and fostering discussions which were interesting alike to students and to the general public.

SCIENTIFIC SERIALS

American Journal of Science and Art, September.—The original articles are: On the formation of hail in the spray of the Yosemite Fall, by W. H. Brewer. The paper describes a visit paid to the fall in April last. The amount of water passing over the fall was estimated at 250 or 350 cubic feet a second, and the height is 1550 feet. In the spray, which stung the hands and faces of the visitors, hail or ice-pellets were found. "It will be noticed that at the time when this hail was observed, the sheet was in the full blaze of the sun from top to bottom. . . . The air near was of a temperature of 70°. Prof. Le Conte has suggested that perhaps the cooled air within the sheet is somewhat compressed and condensed in the base of the fall, and when liberated just outside by its expansion, freezes a part of the spray."—On Southern New England during the melting of the great glacier, by J. D. Dana: Part I. (we reserve our notice till the completion of the article).—On the mechanical work done by a muscle before exhaustion, and on the "law of fatigue," by the Rev. S. Haughton, M.D. Dr. Haughton announces his aim is be to show (1) That both series of experiments made by Prof. Nipher (given in the February number) are a valuable contribution to the facts of animal mechanics; (2) That they are not only consistent with "the law of fatigue" proposed by Dr. Haughton, but illustrate both that law and his "Coefficient of Refreshment;" (3) That Prof. Nipher's discussion of his own valuable experiments is worthless, as it is based on an empirical formula, which has no meaning and leads to no further consequences: (4) That the law of fatigue, which explains not only Prof. Nipher's experiments, but so many other experiments also, is entitled to be received provisionally as a law of animal mechanics, and followed up by deduction to its legitimate conclusions.—Earthquake of December 1874, by Prof. D. S. Martin. "The general phenomena presented nothing peculiar."—On some interesting equine calculi, by R. H. Chittenden.—Results of dredging experiments off New England coast, by A. E. Verrill. Four pages of tables are given, and a note is added on methods of preserving specimens. Picric acid was found to be valuable.—On the passage of two bolides in 1872 and 1874 over Middle Kentucky, by J. Lawrence Smith.—Notes on the gases accompanying meteorites, by Prof. J. W. Mallett. The purpose is to question whether Prof. Wright has sufficient evidence for his conclusion, "the stony meteorites are distinguished from the iron ones by having the oxides of carbon, chiefly the dioxide, as their characteristic gases instead of hydrogen."—On a new vertical lantern galvanometer, by Prof. G. F. Barker. The arrangement is for demonstration to a large audience, deflections obtained by induction currents, thermo-currents, voltaic currents, &c.—On another gigantic Cephalopod (*Architeuthis*) on the coast of Newfoundland, December 1874, by A. E. Verrill. The total length is estimated at forty feet.

THE *Journal of the Chemical Society* (June 1875) contains in detail Prof. Clerk-Maxwell's paper On the dynamical evidence of the molecular constitution of matter, which was duly published in NATURE. The other papers in this part are:—Researches on the action of the copper-zinc couple on organic bodies, by Dr. J. H. Gladstone and A. Tribe. The authors in this (eighth) paper treat of chloroform, bromoform, and iodoform.—On the action of nitrosyl chloride on organic bodies (second paper), by W. A. Tilden; the action on turpentine oil is considered.—A note by Prof. Story Maskelyne on the crystallographic characters of nitrosoterpene is given as appendix to the last paper.—Dr. H. Armstrong contributes a note on isomeric change in the phenol series, which gives new proof of the energy and unceasing attention this gentleman bestows upon his interesting researches.—The last paper is a note on the effect of passing the mixed vapours of carbon disulphide and alcohol over red-hot copper, by Th. Carnelley. It was found that the following bodies were formed: $CH_3.COH$, COS (carbon oxysulphide!) C_2H_4, C_2H_2, CH_4, and H, and neither H_2S nor SO_2. The copper is superficially converted into sulphide, and amorphous carbon is deposited.

Zeitschrift der Oesterreichischen Gesellschaft für Meteorologie, Aug. 1.—This number contains the concluding part of Herr Wilczek's paper on the calculation of the arithmetical mean of constant quantities. Also an account, by Herr von Jedina, of a cyclone encountered by the corvette *Helgoland* in the North Atlantic, remarkable for the steadiness with which the wind blew from east at its commencement, the great expansion of the front in comparison with the rear, and the slow rise of the barometer after passing the centre.—Among the Kleinere Mittheilungen is a notice of the late Dr. Theorell, and a paper by Herr C. Braun, on the theory of storms.

Rendiconto delle Sessioni dell' accademia delle scienze dell' istituto di Bologna.—The longer papers read at the Academy during the academical year 1874–5 were twenty-nine in number, besides numerous notes and memoirs of smaller interest. We note the following, as of special interest to our readers:—On some phenomena consequent upon contusions of the abdomen and of the spine, by Dr. P. Loreta.—On some argillaceous slate of Miocene origin, by G. A. Bianconi.—Several papers by Prof. F. Selmi, on researches made on poisonous alkaloids, their differences in properties, their determination when mixed with others in organic matter, and with innocuous alkaloids,

&c.—Helminthological observations by Dr. Ercolani, on dimorphisms, on *Filaria immitis*, and on a new species of dog Distoma.—Anatomical description of the eye of the European mole, by Dr. Ciaccio.—On the organisation of the brain of Eolidida, by Dr. Trinchese.—On the changes of form of *Amœba limax*, by the same.—On a non-microscopic new and rare parasitic fungus, which is developed on the larva of a living cricket, by G. Bertoloni.—Analytical remarks on some theorems of Feuerbach and Steiner, by Prof. E. Beltrami.—On the continuity of feeling, by Dr. D. C. Biagi.—On the reasons of the low statures which were generally observed amongst the conscripts of the last decennium in some communities in the neighbourhood of Bologna and other districts of Italy, by Dr. P. C. Predieri.—New observations on the minute structure of muscular fibre, by Dr. Ercolani.—Proofs for the contemporariness of the glacial epoch with the Pliocene period at Balerna and at Monte Mario, on the Rhine, by G. A. Bianconi.—On the effects of electric sparks on phosphorus in hydrogen, in nitrogen, in ammonia, and in muriatic acid; and on the effects of electric currents on water, on sulphuric acid, on alcohol, and on bisulphide of carbon, by Dr. Santagata.—Researches on capillary tubes, by Prof. Villari.

Sitzungsberichte der naturwissenschaftlichen Gesellschaft Isis in Dresden, October to December, 1874.—The meetings of this society are divided into five classes, besides general meetings, viz., one for mineralogy and geology, one for prehistoric archæology, one for chemistry, physics, and mathematics, and one each for botany and zoology.—The more important papers read in the different sections during the last three months of 1874 were:—In the mineralogy and geology class: On a peat-like formation occurring at Lindenau, near Leipzig, containing a great number of beetles, one or two species of which are now extinct, by Von Kiesenwetter. On a number of minerals collected during a tour in Saxony, by E. Zschau. On the occurrence of calc-sinter near Quedlinburg, by Herr Ackermann.—In the botany class: On hedge plantation in Australia, by W. Ferguson. On the culture of plants in rooms, particularly of Palmæ, by Adolph Petzold. Report of the results of botanical excursions made during 1874, by A. Voigt.—In the zoology class: Remarks by Th. Kirsch, on "Darwinism and the Researches of Cuvier and Newton," a work lately published by Herr Wiegand.—On Haeckel's calcareous sponges and his Gastræa theory, by Herr Ebert.—In the archæology class: Report on the Archæological Congress at Stockholm, by Dr. Mehwald. On some flint implements from the cave near Rochefort, by Dr. Geinitz. On a piece of reindeer horn upon which rough drawings of horses are visible, and which was found near Thayingen, in Switzerland, by the same.—In the physico-chemical class:—On ozone, by Dr. Schürmann, a highly interesting and elaborate paper; the author gives a detailed account of the history of ozone, and then speaks of its properties, preparation, reactions, presence in the atmosphere, action on the animal organism, and thoroughly exhausts the subject. On tables for barometrical measurements of heights, by Prof. Neubert. Meteorological phenomena observed at Dresden during 1874, by Herr Fischer.—At the general meetings, a paper on the earthquakes of the sixteenth and seventeenth centuries was read; the others being all of minor interest.

SOCIETIES AND ACADEMIES

Paris

Academy of Sciences, Sept. 13.—M. Frémy in the chair.—The following papers were read:—A note by M. Faye relating to the approaching eclipse of the sun.—M. Bertrand then made some remarks on the paper read at the last meeting by M. Bienaymé.—Report on a memoir by M. Lefort, entitled "Critical examination of the basis of calculation usually adopted to appreciate the stability of metal bridges with straight prismatic beams, and propositions for the adoption of a new basis."—Report on M. Boussinesq's paper on the theory of flowing waters.—Memoir on the observations made at Peking of the Transit of Venus, by Mr. J. C. Watson, chief of the American expedition.—A note on the greasy matter in the grain of the oil-tree of China, by M. S. Cloez.—On the development of Heteropoda, by M. H. Fol.—On the migrations and metamorphoses of marine endoparasitic Trematoda, by M. A. Villot.—On some reactions of hæmoglobine and its derivatives, by M. C. Husson.—On the probable origin of the two hailstorms observed on July 7 and 8, in some parts of Switzerland and the South of France, by M. D. Colladon.—On the non-regeneration of the crystalline lens in man and in rabbits, by M. J. Gayat.

Vienna

K.K. Geologische Reichsanstalt, April 6.—On Miocene chestnut trees, by O. Heer.—Diallogite after manganese blende and barytes; pseudomorphs after fahl-ores of Przibram, by Ed. Döll.—On the occurrence of native gold in the mineral shells of Verespatak, by F. Posepny.—On the Culm flora of the Moravian-Silesian roofing slates, by D. Stur.

April 20.—On remains of *Ursus spelæus* from the cave of Igritz, by F. von Hochstetter.—On the meteorite of Lancé, by R. von Drasche.—On a geological detailed map of the surroundings of the Seisser Alp and of St. Cassian, by E. von Mojsisovics.—On a map of the upper Vilnöss and the lower Enneberg valleys, by R. Hörnes.—Geological report from the investigation district of the Oetz-valley group, by G. A. Koch.

May 4.—Presentation of a new special map of the Austro-Hungarian Monarchy, F. v. Hauer.—Characteristics of some minerals occurring on the Przibram ore deposits, by F. Babánek.—Report by Dr. E. Tietze from his travels in Persia.—On a new fossil resin from the Bukowina, by J. von Schröckinger.—On *Cervus megaceros* from Nussdorf, by Dr. F. von Hochstetter.—On a human cranium found in the diluvial Loess of Manners-Porf, by Dr. J. Woldrich.—On Noric formations in Transylvania, by E. von Mojsisovics.—On the phosphorites of the Lavant valley, by H. Wolf.

Göttingen

Royal Society of Sciences, July 10.—At this meeting of the Society the following papers were read:—On the electric elementary laws, by Herr Riecke.—A note on the toxicological action of phenols, in particular of thymol, by Th. Husemann.—On Rötteken's eye of Actinia, by Dr. Hub. Ludwig.—A note by Herr Fromme on the maximum of temporary magnetism in soft iron.—On the potential function in space extended in several directions, by M. Jouelli.

BOOKS AND PAMPHLETS RECEIVED

British.—The Royal Tiger of Bengal: Dr. J. Fayrer, M.D., F.Z.S. (Churchill).—Jummoo and Kashmir Territories. A Geographical Account, by Frederic Drew, F.R.G.S., F.G.S. (E. Stanford).—Proceedings of the Berwickshire Naturalists' Club.—Brande and Cox's Dictionary of Science, Literature, and Art. 3 vols., new edit. (Longmans).—Further Researches in the Mathematical Science, by the author of "The Two Discoveries" (Bridgewater, Pine).—Bristol and its Environs (Bristol: Wright and Co.)—The Geology of British Guiana: C. S. Brown, F.G.S., and J. G. Sawkins, F.G.S. (Longmans).—A Manual of Mollusca: S. P. Woodward, A.L.S., F.G.S. (Lockwood).—The Native Races. Vol. iii.: Hubert Howe Bancroft (Longmans).—Tapeworms: T. Spencer Cobbold, M.D., F.R.S, F.L.S. (Longmans).—An Introduction to Animal Physiology: E. Tully Newton, F.G.S. (Murby).—The Abode of Snow: Andrew Wilson (Blackwood).—Quarterly Journal of the Geographical Society (Longmans).—Journal of the Scottish Meteorological Society (Blackwood).

Colonial.—Centrifugal Force and Gravitation. Six parts: John Harris (Montreal).—The Immortality of the Universe: J. A. Wilson (Melbourne, G. Robertson).—Report of the Meteorological Reporter of Bengal.—Report of the Nidnapore and Burdwan Cyclone.—Magnetical and Meteorological Observations at the Magnetic Observatory, Toronto, Canada, 1841 to 1871 (Toronto: Copp, Clark, and Co.)

THURSDAY, SEPTEMBER 30, 1875

THE SCIENCE COMMISSION REPORT ON THE ADVANCEMENT OF SCIENCE*

IN our last article under the above head we commenced our analysis of that part of the Commissioners' Report which deals with the Administration of Science. In our present article we shall conclude our notice of the Report by stating the chief arguments and opinions of the witnesses regarding the formation of a Council of Science. Thus, following the evidence of Sir Wm. Thomson and Dr. Frankland, to which we have before referred, we find Dr. Hooker, Admiral Richards, General Strachey, Dr. Roscoe, Dr. Balfour Stewart, Dr. Sclater, Mr. De la Rue, Sir H. Rawlinson, and others in favour of a Council, while the Astronomer Royal, Prof. Owen, Lord Salisbury, and Lord Derby are opposed to its formation.

Admiral Richards, late Hydrographer to the Navy, is of opinion that the appointment of a Minister of Science and of a Council stand and fall together; and thinks "that the one would not be of very much value without the other."

Dr. Sclater's idea of the Council is as follows:—

"The heads of the different scientific institutions that are put under the control of the department of science and the minister of education might form a consultative body and be called a council of science, and that there might be certain other members added to assist them in deliberation, if it were thought necessary, such as representatives of the College of Physicians, the College of Surgeons, and of the scientific branches of the army and navy.

"Most men of science, I think, see that something of the sort is imperatively required. All lament the piecemeal way in which scientific subjects are dealt with by Government, in consequence of their being subdivided amongst all these different offices, and of there being nobody to appeal to upon a question of science, and therefore I think the proposal to establish such a Council would meet with universal acceptation amongst scientific men."

Dr. Hooker, the President of the Royal Society, gives it as his opinion "that the general proposition, that the Government should be aided by scientific persons, is an excellent one, both with respect to the administration of the existing Government scientific institutions and with respect to the occasional grants which the Government may be called upon to make for scientific objects." Like Dr. Roscoe, he thinks that the Council should not consist exclusively of scientific men.

Mr. De la Rue considers that the usual permanent staff of a secretary and assistant secretaries, as suggested by Prof. Owen, even if they were men of science, would not be sufficient; urging as a reason that science is really now so extensive that one could hardly imagine any secretary to be so intimately acquainted with every branch of science as to be able, even with the aid of his assistant secretaries, to advise, or to point out where to obtain specific information on every question which might be brought under consideration. Nor does he think the Government Grant Committee, a body regarded with favour by many witnesses, could be so modified as to render a special Council unnecessary.

Sir Henry Rawlinson regards the nomination of a Permanent Council of Science as the natural remedy for the "spasmodic" action on the part of the Government; and another Indian officer, General Strachey, gives the following important evidence:—

"The persons who are employed in the public administration are certainly as a class not amongst those who have anything deserving the name of scientific education; therefore, for a long time to come, it is not to be expected that the members of the Government, or their chief subordinates, will have any such general knowledge of science as would enable them at all satisfactorily to deal with the scientific questions which come before them. Therefore I conclude that it is absolutely essential for the Government, under any circumstances, to get advice from outside; and then comes the question as to how this advice is to be got. If there is no recognised and regularly organised body whose business it is to give advice to the Government on such subjects, then the only thing that a minister can do is to get his information from unrecognised and irresponsible authorities, persons whose opinions, perhaps, may be very valuable, but still persons of whom the public never can have any cognisance; and private advice given in that way seems to me given in the worst possible form. If, then, that form of advice is bad, how can you obtain advice of proper intrinsic value on the multifarious subjects on which it is certain to be needed by an administration really striving to advance science to the utmost, and how can you secure its being given under a sufficient sense of responsibility, and in such a way as to carry the greatest weight possible to the mind of the minister who is expected to act upon it? And here I would repeat that any specific proposal to give effect to such an idea must be made to fit into the general form of the administration; and I therefore consider that the best course would be to adopt the proposal that has been made by many persons, that there shall be some sort of council constituted to advise the responsible Government department as to its proceedings in connection with science."

He then proceeds:—

"I would take the opportunity of saying that it is a question that is open, and which I believe has been discussed, whether the Council, for instance, of the Royal Society, with or without any addition, might not be made to perform satisfactorily some or all of the functions which it has been suggested should devolve upon this Commission. But I think not. And the principal reason that I have for thinking that such a body as the Council of the Royal Society is not suitable for the purpose is, that it cannot have that specific responsibility put upon it which should be put upon a body such as I have spoken of, and that it is got together for totally different purposes and objects. The Council of the Royal Society has to manage the business of the Royal Society, and is not at all selected to advise the Government on matters connected with the advancement of science, or the application of science in the operations of the public departments."

He further points out that the Minister would have a perfect right to repudiate any scheme which the Royal Society might put forward, or any advice they gave—that he would be justified in doing so on the ground that he was not responsible for their selection.

Capt. Galton points out that "the institutions which are maintained by the State for scientific purposes are maintained upon no principle whatever with regard to their administration. You have got the British Museum under trustees, you have got South Kensington under the President of the Council, you have Kew under the Office of Works, you have the Botanic Gardens at Edinburgh, I think, under the Queen's Re-

* Concluded from p. 432.

membrancer. You have the Observatory at Edinburgh as part of the University of Edinburgh, and you have the Observatory at Greenwich under the Admiralty, besides several others. You have every possible variety of jurisdiction, and, consequently, it seems to me that you have a great waste of power; there is the School of Chemistry, and the School of Mines, and the Museum at Edinburgh, all under South Kensington Museum, and the Meteorological Department, which is partly under the Royal Society and partly under the Board of Trade. There is no possibility of getting any correlation between those different scientific bodies, and if you are to get proper unity of administration you must bring them all under one head, or to one focus. I should recommend placing them all under a scientific commission or council, and I should place that council probably under the Privy Council; but I should make it a body for administering all questions connected with all the scientific institutions, or all grants made by the Government for scientific purposes in the country, and I should give to this council the same status, with regard to its administration, or very much the same, that the Indian Council have. . . . . The parliamentary head of the department, if he differed from them in opinion as to their recommendations upon the scientific questions connected with those institutions, or any other that might be founded, should record his differences of opinion in a minute."

Dr. Siemens would "assemble the heads of departments at frequent intervals for the discussion of general questions, and would propose to add to their number such men as the president of the Royal Society, the president of the Institution of Civil Engineers, and at least one representative of the two great Universities. This Board would decide general questions appertaining to the advancement of science."

We could fill many more columns with evidence analogous to the above samples. Making due allowance for the different ways in which a new and complex question like this, compounded of scientific, political, and administrative elements, must present itself to a variety of minds trained to dissimilar pursuits and habits of thought, the almost general consensus as to the necessity of some such advising body as that proposed is most striking.

Still those who object to the creation of a Council on various grounds are not wanting, and we now glance briefly at the evidence of these witnesses.

Sir G. Airy thinks a paid Consultative Council could not do very much to assist the Government, and that the Council of the Royal Society would be the best body to which the Government could have recourse in any matters of that kind.

Prof. Owen prefers a Minister of Science, with a permanent Under-secretary and administrative staff, as in his opinion the representative of any particular branch of science on the Board would have too great an influence.

The Earl of Derby is very sceptical either as to the necessity, or as to the utility, or as to the successful working of such a Council. One objection he urges is that if matters for which the head of a department is responsible are to be referred to the Council, and if upon those matters the Council is to pronounce an authoritative opinion, the responsibility of Ministers to Parliament will be considerably lessened.

In reply to the suggestion that one function of the Council would probably be to advise the State as to the application of money for the higher teaching of science and for scientific research, and also to advise the Government with respect to any applications that may come before it for grants of money connected with science, whilst objecting to a Council, Lord Derby thinks that it is a matter which falls strictly within the province of the Minister of Education.

Lord Salisbury is opposed to a Council because he has never seen anything to lead him to believe that such a Council of Science would have anything to do; and he considers that the Government would always get better opinions on any scientific point that arises, by applying to the most distinguished scientific man in that particular branch at the time, than it would by having a set of permanent officers to give advice on such subjects.

There appears to have been before the Commission practically three solutions of the question. First, that no change should be made in the present condition of things. The Astronomer Royal is apparently the sole witness of eminence in science who seems to desire no reform in the scientific administration of the country. Secondly, that the Council of the Royal Society should be constituted the official advisers of the State—a view held generally by those who are adverse to the creation of a new Council; and third, that a Council be provided to assist the Minister charged with science and the Departments concerned with science.

The Commission arrive at the conclusion that the balance of argument and authority is in favour of the last-named arrangement, which accordingly they recommend in terms which, though general, leave no doubt that they contemplate the creation of a new official body so constituted as fairly to represent the various branches of science. We think that no unprejudiced and competent person can read the whole evidence without accepting this conclusion as undeniably sound, if not indeed absolutely unavoidable.

THE GOVERNMENT RESEARCHES IN PATHOLOGY AND MEDICINE

THE third volume of the "New Series of Reports of the Medical Officer of the Privy Council and Local Government Board," brings before us another instalment of the work paid for by the annual grant of 2,000*l.* "in aid of scientific investigations related to pathology and medicine." This grant has been actively opposed by a small minority in the House of Commons mainly upon the narrow and invidious ground that the medical profession was thereby obtaining knowledge and instruction which the medical profession ought to obtain at its own expense. "The medical profession lives upon the public; the medical profession makes use of its knowledge to extract money from the public; the grant will add to the knowledge which the medical profession uses with such object—therefore the grant is money drawn from the pockets of the public to aid in the further depletion of the pockets of the public."

Such appears to be the main inspiration of the

opposition. Whoever will be careful to read the last public report, and the short but most weighty statement with which Mr. Simon introduces it to his chiefs, will see plainly that this kind of opposition is founded in misapprehension or ignorance. The information sought is such as may help to inform the State how to offer most effectual resistance to the introduction of disease from without, and to the extension of disease within. It concerns resistance to typhoid fever, small pox, and many other diseases of well recognised contagious nature, and the possibility of controlling the extension of diseases less recognised as having like nature, as for instance what Mr. Simon calls "the tubercular infection." "It aims to be a systematic study of the intimate pathology of the morbid infections, acute and chronic."

Mr. Simon in his remarks points out that much of the study involved is most elaborate and purely scientific, never immediately convertible to pecuniary profit, but perhaps, on the contrary, involving heavy cost; not pretending to immediate popular application, but addressing itself primarily to the deeper scientific requirements of the medical profession, and therefore in an extreme degree technical. Studies of this sort cannot be cultivated to any adequate extent by private medical investigators, and the scientific investigations set going by the 2,000*l.* grant have a distinctive intention to supplement the ordinary resources of private medical observation in the direction already indicated. The work connects itself with the objects of preventive rather than with the objects of curative medicine, and in addition to investigations into the ætiology of infective diseases, it includes some very elaborate research concerning normal standards, histological and chemical, of the tissues involved in the morbid infective processes.

The latest published volume, entitled "Report made to the Lords of the Council on Scientific Investigations, made under their direction, in aid of Pathology and Medicine," contains the result of five researches:—(1 Dr. Sanderson's Further Report on the Intimate Pathology of Contagion; (2) Dr. Klein's Research into the Contagium of Variola Ovina; (3) Dr. Klein's Research into the Lymphatic System and its relation to Tubercle; (4) Dr. Creighton's Anatomical Research towards the Ætiology of Cancer; (5) Dr. Thudichum's Research into the Chemical Constitution of the Brain.

Dr. Sanderson's paper is a sequel to a former Report on the nature of infecting agents or contagia, in which Chauveau's opinion, expressed in the sentence "All contagia are probably particulate," was supported. The present paper treats of the infecting agents and morbid processes in diphtheria, erysipelas, splenic fever, and relapsing fever. In relation to all of these a mass of evidence collected from many observers is adduced to show that vegetable forms are connected with the contagions or with the morbid process. In splenic fever and relapsing fever organisms of a distinctive and specific form are declared to be present in the blood; bacterium-like rods accompanying splenic fever, minute organisms to which the name of *spirilla* has been given accompanying relapsing fever. In an "addendum" some observations of Dr. Letzerich, of Bramfels, Nassau, and of Dr. Oertel, of Munich, on the inoculation of animals with diphtheric poison are reported. From these it appears that in animals receiving the poison (derived from the throat of a child) by subcutaneous injection, the characteristic affection of the throat was developed after a few hours, and that the infiltration of tissues with the same sort of micrococci as are found infiltrating them in diphtheria always occurred.

Dr. Klein's first communication relates to the contagium of Variola Ovina, and describes certain small organised forms—bacteria, micrococci, and microsphæra gathered into colonies by long filaments—as found in the lymph from vesicles. The same forms are found in cavities formed in the rête Malpighii and subjacent corium, where the pock is developed after inoculation, extending afterwards into and occupying in vast numbers the lymphatics of the corium.

Dr. Klein's second communication treats of the Lymphatic System in relation to Tubercle. It commences with a minute and original description of the microscopical anatomy of the serous membranes, and their relation to the lymphatics, and compares with this the conditions in acute and chronic inflammation, noting in particular the processes leading to the formation of new blood-vessels and lymphatics both in healthy and diseased membranes. The second part of this communication relates to the lymphatics of the lungs in health, in certain chronic inflammations, and in tubercular infection. The appearances in the lungs of guinea-pigs after the production of artificial tuberculosis and in human lungs in tuberculosis are compared. Dr. Klein comes to the conclusion that the two processes are only to a limited extent similar (a conclusion opposed to the opinions of Sanderson and Wilson Fox). According to Dr. Klein, "in artificial tuberculosis of the lung of the guinea-pig the parts first attacked are the small branches of the pulmonary artery or pulmonary vein, whereas in acute miliary tuberculosis of man the capillary blood-vessels of the alveoli seem to be the tissue from which the action of the morbid agent starts.

Dr. Creighton's paper is a very thoughtful contribution to the present knowledge of cancer. It relates some unsuccessful attempts to propagate cancer by inoculation, and a number of careful observations as to the process of formation of secondary cancerous tumours. The attention is chiefly fixed upon the epithelium in relation to hyperplastic and heteroplastic (endoplastic) growth. Dr. Creighton infers from his observations that the efficient cause of secondary tumours in the liver is the substitution of the endoplastic for the normal (or excessive but still homo- though hyper-) plastic activity of the liver cells. The operation of deeper or extraneous causes is discussed, but left undecided. Hope is expressed that aids to a decision may be obtained from the results of a systematic examination of mammary tumour now proceeding.

Dr. Thudichum's research is a study of the normal chemical constitution of the brain, undertaken to prepare the way for a study of the brain in fevers, and other morbid states and processes. The paper is very long, occupying more than half of the 247 pages of the Report, and most elaborate. Dr. Thudichum believes that he has both added to and corrected former knowledge of the chemistry of the brain. In particular he describes with careful detail a number of newly observed

principles, both phosphorised and nitrogenised. Among the phosphorised, kephalin and myelin (both of which contain nitrogen, as well as phosphorus) are new, and are associated with lecithin. They are described as typical colloids, of no true solubility, of almost indefinite power of soaking up water so as to form an imperfect solution, of feeble chemical activity, of a remarkable readiness to combine with acids salts and alkalies, and to part with them on the addition of excess of water. Kephalin and myelin are stable, lecithin so unstable as to elude proper analysis. Similarly the nitrogenised bodies, cerebrine (Müller's), kerasine, and phrenosine, are colloids, but of less perfectly marked type, and less interesting natural history.

In his summary Dr. Thudichum, speaking of the phosphorised bodies, remarks that "we have therefore here a diversity of affinities such as is not possessed by any other class of chemical compounds in nature at present known; and the exercise of these affinities being greatly influenced by the mass of reagent and the mass of water which may be present, the interchange of affinities may produce a perfectly incalculable number of states of the phosphorised and consequently of brain matter. This power of answering to any qualitative and quantitative influence by reciprocal quality or quantity we may term the state of *labile equilibrium*; it foreshadows on the chemical side the remarkable properties which nerve matter exhibits in regard of its vital functions."

The volume now under consideration has been preceded by two volumes, containing a first and second report by Dr. Klein, on the Lymphatic System and its relation to Tubercle, a report by Dr. Sanderson on the Infective Products of Inflammation, and by Dr. Thudichum on Chemical Changes in cases of Typhus. Reports are now in course of preparation by Dr. Baxter on Disinfectants, by Dr. Sanderson on the Febrile Process and on Infective Inflammations, by Dr. Thudichum on the Chemical Constitution of the Brain, by Dr. Creighton on Anatomical Studies with reference to Cancer, by Dr. Klein on the Contagium of Enteric Fever. The whole represents four years' work, for which 8,000*l*. has been voted. The value and importance of all this work in relation to the welfare of the community, as a contribution in aid of preventive medicine, cannot be doubted by any careful reader of the record. Nor, after even a superficial reading of the record can there be doubt but that the work is of a kind which can only be set going by such means as public grants, since it involves a special training and a special devotion inconsistent with the earning of livelihood by other direct or incidental means. The grant is on the evidence justified.

But there are other aspects of the work which claim a serious regard. The department of the Government concerned in protecting the country from the invasions of contagious disease, whether represented by Minister of Health or principal medical officer, needs in all things to be fully informed of the latest discoveries in pathology, hygiene, and therapeutics. Of such minister or officer the body of scientific men whose work is here recorded, together with others who are engaged in sanitary investigations and inspections under the central authority—men like Drs. Seaton and Buchanan and Mr. J. N. Radcliffe—constitute a body of advisers or council representing the most advanced knowledge bearing upon the public health. They constitute a council to which the minister or officer may refer for latest knowledge when legislation is concerned, or for practical advice when action has to be taken. They are, in fact, at this moment practically such a council. In the Science Commission Report on the Advancement of Science, the formation of a similar council as adviser of a Minister of Science is advocated. We would suggest that we have in what we have stated an excellent illustration of the principle proposed, with a wider application, in the Science Commission Report.

THE INFLUENCE OF THE PRESSURE OF THE ATMOSPHERE ON HUMAN LIFE

Influence de la pression de l'air sur la vie de l'homme. Par D. Jourdanet. 2 vols. (Paris: Masson, 1874.)

AFTER having practised medicine for six years on the borders of the Gulf of Mexico, and rendered himself familiar with the diseases and conditions of life of the inhabitants of low levels, M. Jourdanet removed to the elevated plateau of Anahuac—more than 2,000 metres above the sea level. Here, as might have been anticipated, he found the pathological conditions different, but to his surprise he discovered that the differences were not simply such as result from temperature, or are paralleled in places of lower level and higher latitude, but presented peculiarities which he conceived to be dependent on the elevation of the situation alone. A residence of twenty years in the locality enabled him to confirm this idea and to prove that, while the blood of the inhabitants presented no poverty of corpuscles, the corpuscles themselves were deficient in oxygen, on account, as he believed, of the too feeble pressure of the atmosphere in these high regions. This led him to undertake the study of the whole question of the influence of the atmospheric pressure on health, and to call to his aid M. Paul Bert, Professor of Physiology at the Sorbonne, by means of whose experiments he believes himself to have arrived at some definite results. These, with every other possible point of interest connected with the subject, he now presents us with, in two large and beautifully illustrated volumes; leaving, however, the details of the physiological experiments to be published in a forthcoming work by M. Bert himself.

The question so fully discussed by M. Jourdanet is certainly of very great interest, and, in spite of previous observations and opinions on the therapeutic action of compressed air and on the possible limits of life in regard to height and other similar points, it is also of some novelty as treated by him.

According to M. Jourdanet the pressure of the atmosphere has not always been as small as it is now; and assuming, what is probably true, that a greater pressure would involve greater heat, he would account in this way for the warm periods known to have existed in Tertiary times. This leads him to make an hypothesis as regards the cause of the glacial epoch, the occurrence of which would be contrary to the above theory; but it is not an hypothesis that could recommend itself to geologists. The glacial epoch arose, he imagines, in this way: by some sudden convulsions the crust of the earth was torn open, and prodigious quantities of gas and vapour driven

up, which forced up the atmosphere to a prodigious height, where it was chilled and its vapour condensed, which fell in diluvial torrents, leaving the air so free from vapour that radiation took place at an enormous rate, chilling the earth and causing the glacial epoch! He also concludes that on account of the too great density of air in the plain, man must have made his first appearance on elevated plateaux, and he accounts in this way for the veneration of high places among the early races. These and similar speculations, though they may sometimes amuse, do not detract from the real merit of the work in more determinable matters.

We reach the substantial part when we come to the experiments of M. Bert, of which the results are here given. Small animals were placed in chambers of various capacities, which were then filled by the same absolute quantity of air, necessarily at various pressures; when the animals were dead, the remaining air was analysed, and it was found that in the larger vessels the proportion of oxygen was greater, and this proportion was such that the total amount of oxygen left was proportional to the capacity of the chamber. The animals died as soon as the oxygen by itself was reduced to a density of 4 per cent. of what it would be if the whole chamber were filled with it at the normal pressure—the amount being thus independent of the quantities of the other gases present. This being true for any sized chamber, it follows we may suppose the chamber indefinitely large; and an animal would die in the open air if the oxygen should have less pressure by itself than 4 per cent. of 76 millimetres. Taking the air to have its ordinary 21 per cent. of oxygen, these experiments would appear to prove that life is impossible in air of less pressure than 14·5 mm. The proportion of oxygen, however, seems to be much less than that which is ordinarily supposed to be small enough to produce asphyxia. Further experiments were performed, pointing to the same result. Dogs were so fastened that they could breathe only from a bag of limited size, and from time to time the air in the bag and the blood of the dog were analysed, and it was found that the oxygen in both decreased *simultaneously*, though not at the same rate. These and similar experiments, together with the fact ascertained by M. Jourdanet, that the blood of Mexican dogs contains a less proportion than usual of oxygen, are the proofs offered that the blood cannot be sufficiently oxygenised for health without a certain amount of atmospheric pressure.

In all these experiments, however, no allowance is made for the possibility of the human lungs accommodating themselves in time to the smaller pressure, so as to enable the blood to take up a sufficiency of oxygen; and this objection is seen by M. Jourdanet, who, after giving an interesting account of the various evils that have befallen noted climbers, discusses the question whether an increased number of respirations, or an enlargement of the thorax, could counteract the effect of the rarity of the air. As to the first, numerous experiments on himself during his residence in Mexico have enabled him to verify the law given by Lehmann, that the carbonic acid expired is in part constant and in part only variable with the number and magnitude of the respirations; and he calculates from hence that, in order to counteract the loss of pressure and diminution of oxygen by increased respiration, it would require twenty-four ordinary respirations per minute, which of course the Mexicans do not make. As to the size of the thorax, which has been stated by Forbes to be larger in the inhabitants of these high regions, he objects that this statement was made on too restricted data, and that Coindet has found that it does not generally hold true. Whatever may be the truth on this point, the explanation which M. Jourdanet offers of the result of the low pressure on the temperature of the body cannot be considered satisfactory. He considers that, as a general rule, the temperature of Mexicans is not below the average, although their surface temperature often is, and that the loss of heat which would arise from the more easy radiation and the lower oxygenisation of their blood is prevented by "the repose of their functions," while their respiratory organs are specially modified so as to be capable of "exceptional exercise." The latter would require proof, and as to the former, although the body must lose temperature by the exact amount of work done on external objects, "a care to avoid every effort" would prevent the body doing work upon *itself*, and less heat would therefore be produced. The "apathy" of the Mexicans and other inhabitants of high levels must have another cause than this.

M. Jourdanet's work ranges over a wide field, discussing, without much plan, various points in connection with the climate of plateaux. Thus, in one chapter he attempts to prove, by statistics of population, that the low pestilential area round the Gulf of Mexico is more healthy than the elevated table-land, the former having increased six per thousand and the latter three per thousand in forty-seven years; that the decadence of the Peruvian race is due to the influence of the atmosphere, without apparently seeing the obvious objection that they must have *risen* under the same influence, since they are a very ancient race; that the mental and physical work of the Mexicans is below that of the inhabitants of the plains; and then he discusses the extreme height at which it is possible to live permanently, which he places between 4,000 and 5,000 metres. This variety makes the book very readable, but, in spite of its large size, the arguments on many points are too brief to be convincing.

The second volume is engaged in discussing the influence of atmospheric pressure on disease, M. Jourdanet being "convinced that the true nature of exterior influences is far better seen in the maladies caused by them than in the health which they favour." This portion of the work has a principally medical interest, although some of the results of his experience may be usefully mentioned. He finds that consumption is rare in Mexico, and is principally confined to the poorer classes who have insufficient nourishment, which he explains by their feebly oxygenised blood being unfavourable to the development of the disease;—typhus fever, on the contrary, finds there its most suitable subjects, as do other inflammatory disorders, while yellow and intermittent fevers are almost unknown.

The elevation of the country where these observations were made, and concerning which M. Jourdanet's conclusions have been arrived at, is 2,000 metres and over; and the climate of these places he speaks of as "climats d'altitude;" while intermediate heights he characterises as "climats de montagne;" to which latter he also devotes

a few chapters. These, however, are of less interest as not embodying the results of his personal observations, but being a discussion of the various well-known moral, mental, and physical characteristics of mountaineers. To these follow chapters on the influence of mountain travelling on health, and detailed experiences of the application of artificial rarefaction of the air in disease.

With the desire of making the work as complete on the subject as possible, the author has compiled a large part of it from well-known writers, and recapitulates much that is of everyday observation; and these parts have naturally less interest than those which deal directly with his Mexican experiences. The whole of the facts, however, which bear upon the question discussed are conveniently collected together and put in an interesting form for the perusal of the general reader, for whom, however, much of it has too medical an aspect.

OUR BOOK SHELF

The Royal Tiger of Bengal: his Life and Death. By J. Fayrer, M.D. (London: J. and A. Churchill.)

In this small work Dr. Fayrer gives a popular description of the zoological relationships, anatomical structure, geographical distribution and habits of the tiger. Accounts are also introduced of tiger-hunts, which well exemplify the dangers to be feared and the precautions to be taken in the pursuit of that large game, which even under the most favourable circumstances cannot be followed without a great amount of risk. The author's considerable Indian experience gives great weight to his opinions on many of these points, especially with reference to the nature of the wounds inflicted by the enraged creature.

Anatomically Dr. Fayrer brings to our notice a point in the disposition of the claw-bearing or ungual phalanges of the digits in the cat-tribe, which is not without interest. In the fore-limbs, as is well known, these bones, when the claws are fully retracted, bend extremely backwards in order to allow of the claws themselves being protected during progression. To so great an extent is this retraction carried, according to Prof. Owen, that the bone passes back to the side of the second phalanx in the same way that the blade of a clasp-knife may be said to do the same with reference to each lateral portion of the handle. In the hind limb of the tiger, Prof. Owen remarks that they are retracted in a different direction, "viz., directly upon, not by the sides of the second phalanges, and the elastic ligaments are differently disposed." Dr. Fayrer finds that in the smaller Felidæ, as the Ocelot, the hind claws are constructed and retracted on exactly the same principle as the fore. Such being the case, either the tiger differs from its smaller congeners, or Prof. Owen is wrong. Till Dr. Fayrer proves the latter, we prefer to assume that the former is the case.

"Contrary to custom, I propose to give him (the tiger) precedence of the lion. He is generally described as inferior, though nearly equal, to the so-called king of beasts; but in size, strength, activity, and beauty he really surpasses him; and therefore, though he may neither be so courageous nor so dignified, he is entitled to the first place—at all events in India." Thus says our author, and many of his descriptions fully exemplify all the animal's best points. Nevertheless, though he may be slightly greater in length, and is perhaps more active, we considerably doubt his greater strength, and as the work before us fully proves, we cannot say of him as a recent writer tells us of the lion, that "it should always be recollected, before meddling with lions, that if you do come to close quarters with them death is the probable result," the tiger having a much less dignified habit, an example or two of which we quote with reference to a case in the Madras Presidency, where a sportsman wounded the creature more than once. "It charged and seized him by the loins on one side, gave him a fierce shake or two, dropped him, and then seized him on the other side, repeated the shaking and again dropping, left him and disappeared." In a second instance a military man, "a most distinguished soldier and sportsman, when following a wounded tiger on foot in the long grass, was suddenly seized and carried off by the animal he was seeking. He managed, however, to effect his escape without having received any serious injury, and rejoined his companions, who had deemed him lost."

When so acute an observer as the late Mr. Edward Blyth, with his great experience, expresses uncertainty as to whether the lion or the tiger is the larger animal, we may be certain that there is no great difference either way. Dr. Fayrer tells us, "I have been informed by Indian sportsmen of reliability, that they have seen and killed tigers over twelve feet in length." In none of the special instances he mentions, in which careful measurements were made, did the length exceed ten feet by more than an inch. We quite coincide with the author in looking with doubt on Buffon's statement that one has attained the length of fifteen feet.

For further information on the above and kindred points with reference to the Royal Tiger of Bengal, we cannot do better than recommend the reader to glance through the small work under review.

An Introduction to Animal Physiology. By E. Tulley Newton, F.G.S. (Mumby's "Science and Art Department" series of Text Books.)

In more than one of the Science Primers which we have lately had occasion to look through and notice, it has been painfully apparent that the author is not nearly so well grounded in the subject he is endeavouring to teach as even some of his probable pupils. Some write on human physiology without having studied human anatomy; others even do not know their physiology. The author of the work before us is not one of these. It is accurate, and therefore reliable. The descriptions are precise and clear. The limits of space within which the author is confined have, in some of his descriptions, made it necessary for him to sacrifice clearness to a certain extent, but this cannot be avoided. A novel feature of the work is the addition to each chapter of a practical section, in which directions are fully given for study, by the student himself, of the more simple physiological and anatomical points referred to. These directions are particularly clear, and if carefully worked out by everyone who reads the book, will be found to lead to a sound knowledge of the first principles of physiological science. The illustrations, which are numerous, though mostly to be found elsewhere, are well selected, and sufficiently large to be distinct.

Abstracts and Results of Magnetical and Meteorological Observations at the Magnetic Observatory, Toronto, Canada, from 1841 *to* 1871. (Toronto, 1875).

In this thick pamphlet of 249 pages, Professor Kingston gives the results of an elaborate, able, and discriminative discussion of the magnetical and meteorological observations made at Toronto during the thirty-one years ending with 1871, in a series of fifty-one tables. To these are appended the daily observations from January 1863 to December 1871. While all the results of the observations, devised and carried out with so much care, and extending over so long a period, are of very great value, we would point to the wind observations as regards the diurnal changes, but particularly in their relations to differences of temperature, pressure, humidity, and cloud, and to light, moderate, and heavy falls of rain and snow respectively, as affording, from the fulness and

originality with which they are discussed, much valuable information on many intricate points which it would be difficult if not impossible to find elsewhere. The influence of Lake Ontario is seen in the diurnal changes of the wind, which in July is nearly S. from 10 A.M. to 3 P.M., W. at 5 P.M., nearly N. at midnight, about which it remains till 9 A.M., when it rapidly shifts to S.W., and ultimately to S. at 10 A.M. From October to March, when storms are most frequent, the greatest depression of the barometer and increase of vapour occur with winds from N.E. to S.S.E., and the greatest rise of the barometer and diminution of vapour with winds from W. to N.N.W. On the other hand, in summer the greatest depression of the barometer occurs with winds from E.N.E. to E.S.E., but the greatest increase of vapour with winds from E.S.E. to S.S.W. Most of the light falls of rain occur with winds from N.E. by S. to W., and of snow with winds from S.W. by N. to N.E.; most of the moderate falls of rain with winds from N.E. to S.S.W., and of snow with winds from N.N.W. to S.E.; and most of the heavy falls of rain with winds from N.E. to S.S.E., and of snow from N. to E.S.E. The important bearing of these facts on the question of North American storms as well as on the climate of no inconsiderable portion of that continent is evident. Tables II. and XX. giving by interpolation-formulæ the mean temperatures and mean pressures of different days of the year, while of very slight scientific value, may be found to be useful in a meteorological office, but a simpler and in everyway more preferable table of normal daily values for pressure and temperature could be constructed from the arithmetic means of the thirty-one years' observations treated by Bloxam's method of averages.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*]

"Tone" and "Overtone"

In the very favourable estimate of the work I have done in my translation of Helmholtz, in your number for Sept. 23, I am taken rather severely to task for my use of "Sensations of *Tone*" on my title-page, and my refusal to use the expression *overtones* in the body of the work. The title was long a matter of anxious consideration to me, and I have not yet seen my way to improving it. True, practical musicians, physiologists, and artists have each their own, very different, technical meanings for *tone.* The two last generally use it without an article, and in the singular; but musicians are accustomed to speak of "*a* tone," or of *several* tones, when they allude to musical intervals. In common speech, however, all three agree with the outside world in speaking of a "loud and soft, gentle and angry *tone* of voice," of a "fine-*toned* instrument," of the "splendid or miserable *tone* produced by a violinist," of the "magnificent *tones* of the organ." That is, we are all accustomed to use *tone,* as I have done on my title, for "a musical quality of sound." I know no other single word in English which expresses the same conception. In the original German, Prof. Helmholtz (and after him Prof. Tyndall) endeavours to use *tone* for a "simple tone" only. Neither have contrived to be consistent in so doing. I have had to correct the text several times in my translation on this very point, and instead of using *tone* for "simple tone" only, which is a new conception, and *clang* (in English, a *din*) for "compound musical tone," which is also a new and not an easy conception, I have invariably used the word *tone* (except when distinguished by a capital letter—thus, *Tone,* for the interval) in the usual general sense of the word, and distinguished the particular cases by the prefix "simple" or "compound." It seems to me that this is not so much "a little waywardness" on my part, as a desire for scientific accuracy.

As to "overtones," it is well known to those who, like my reviewer, are acquainted with the work in the original, that Helmholtz's expression "Obertöne" is a mere contraction for "Obertheiltöne" or "Oberparzialtöne," both of which terms he not unfrequently uses, and these are literally rendered by my "upper partial tones." Waiving my strong linguistic objection to the term "overtones" as an English word, my scientific justification for not using it in my translation must be sought for in the fact that even the German "Obertöne" has led Prof. Helmholtz himself not unfrequently to its inaccurate use for "partial tones" simply, including the lowest partial tone, which the word was especially invented to exclude. Singularly enough, even my reviewer has many times fallen into the same error (NATURE, p. 451, col. 2) in speaking of the "overtones" of a pianoforte string. Thus he says, "the first six overtones are all audible," which is not correct; but he means "the *lowest* partial tone and first *five* of the *upper* partial tones," or briefly "the first six partial tones," which *is* correct. Again, he says, "the seventh and ninth (overtone) which are *inharmonious,* &c., which is not correct, for the *seventh* and *ninth over*tones are the *eighth* and *tenth* partial tones, and are perfectly harmonious; but he meant the seventh and ninth partial tones. Again, he cites from p. 126 of my translation, the relative force of the first six "partial tones," as they are there called, but refers the table to the first six "*over*tones," which is altogether incorrect. Now if such men as Helmholtz, who invented the term, and as my reviewer, who uses it familiarly, can be led by it into what with them are mere inaccuracies of *expression,* must we not look to the utmost confusion of *thought* among persons to whom the whole subject is new, and who employ the term with a very vague or loose conception of its meaning? In point of fact, many such cases have come to my notice. Hence, again, I cannot agree to think that my deliberate rejection of the word "overtones" is "the chief fault" or "a blot on the translation," but rather submit that it is a consistent endeavour to attain scientific accuracy of expression, and avoid confusion of thought.

I thank the reviewer for his generally favourable estimate, gladly accepting his rectification of the accidental Germanism "the musically beautiful" for "the beautiful in music," and I apologise for the length of this communication on the ground that it is not a merely personal vindication,

Sept. 25 ALEXANDER J. ELLIS

Colours of Heated Metals

I HAVE just watched the casting in gun-metal, in an engineering establishment in this town, of what is intended to be the rudder-post of a large vessel, which when completed will weigh about three tons. As the casting was a simple one, it was accomplished very quickly, and as the contents of the huge four-ton ladle were emptied into the mould, the dazzling stream of the metal flowed in a large volume over its lip. Brilliantly glossy it appeared as it broke through the folds of thin dross with which its surface was encrusted; and this it did at the lip of the vessel, while fold after fold of the encrusting pellicle was swept down the stream, and left behind it a straight or ragged edge of the thin film, from underneath which the metal welled out for a moment with an appearance on the surface of perfectly transparent purity. The appearance was a deception arising from the strong bluish-green colour of the light emitted by the pure surface of the metal, which I have never seen exhibited under similar circumstances by melted iron or steel. It extended also for only a short distance from the encrusting edge, the green colour soon passing into white, or paler green, where exposure to the air enveloped the metal again in a rapidly increasing film of oxides that tarnish its surface and render the stream white, or nearly so, in every part, excepting in a bluish-green ring, or border where the fresh metal made its appearance, and flowed over in a beautifully coloured stream from the mouth of the ladle. The strongest patches of the colour there were transient, the film of oxide apparently soon thickening enough to eclipse it, and by connecting itself to the broken edge of the thin film in the pot to tear away another fold, when the characteristic greenish glow of the metal immediately presented itself along the freshly-broken edge. I had watched and thus interpreted this beautifully varied play of natural colours in the molten stream for some time before it occurred to me that the peculiar hue of the freshly-exposed surface of the metal, glowing as it does with the brightness of what in the black film of oxide appears as white heat, is no other than the very colour of the heated metal which the theory of exchanges would lead us to expect. For as the colour of gun-metal in a cold state is yellow, the selective absorption of its surface in that condition must be exercised chiefly upon rays occupying the blue portion of the spectrum, and consequently in the heated state these rays

are emitted in excess; or if the heat is sufficiently intense to produce them largely, as in the melted metal, where the thin films of oxide on its surface glow with perfect whiteness, the metal itself must shine with bluish, or it may be with geeenish-blue light, if the heat is only high enough to make the excess of green rays very strongly visible. If this should be, as I suppose, the real explanation of the very curious appearance of depth of a certain tint of colour, contrasting strongly in some parts of the melted stream by its greenish hue with the surrounding redder lights, according as the natural tinted appearance of the vivid metal is effaced or diluted by the floating films of white-hot oxides in lines and parts of the stream depending on the surface-flow, and suggesting in some degree the idea of a transparent cascade, and even from its colour of a waterfall, the process often repeated in large foundries of running gun-metal into large castings presents an instance of well-defined action of the law of exchanges which must be constantly witnessed and noted inquiringly by daily observers, and which certainly presents, if a different and more natural explanation can be given of its origin, to eyes unaccustomed and unprepared to receive it, a somewhat surprising and otherwise unaccountable appearance. In gun-metal, when the proportion of zinc introduced is very small, the coating of the melted surface by copper oxide is comparatively slow, and in melted brass it might not be possible, from the rapid oxidation of zinc upon the surface, successfully to observe the same phenomenon. In order to render melted copper fluid enough for casting, a small proportion of alloy sufficient to give it almost the colour of brass is required to be mixed with it, and large pourings of the pure metal cannot commonly be made; but perhaps in small castings of this metal, and probably also in those of gold, opportunities would present themselves similar to that which I have here attempted to describe, of verifying the same general law of radiation connecting together the qualities of luminosity and absorption in the surfaces of highly coloured metals.

Newcastle-on-Tyne, Sept. 20 A. S. HERSCHEL

Changes of Level in the Island of Savaii

WHILE feeling some diffidence about setting myself in opposition to so careful an observer as the Rev. S. J. Whitmee (NATURE vol. xii., p. 291), I cannot allow his statements in regard to changes of level in the island of Savaii, Samoan group, to pass altogether unchallenged. In the month of June 1874 I spent some weeks on the island, during which time I travelled around nearly the whole of it on foot. Though not a scientific observer, I was on the look-out for indications of change of level along the coast, and it is my decided opinion that such indications are quite as little apparent in Savaii as in Upolu. Mr. Whitmee, whom I had the pleasure of meeting on the island, directed my attention to what he believed to be a line of upheaved cliffs a couple of hundred yards back from the sea, near Tufu, on the south side of the island. On examining the place, after parting from Mr. Whitmee, I particularly observed that the floor of volcanic rock at the base of the cliffs bore exactly the appearance of lava that had cooled in the open air. The creases and ripples left on the surface of the lava in cooling were distinctly visible, which could not have been the case if the rock had ever been exposed to the action of the waves. No doubt was left on my mind that the floor of volcanic rock between the base of the cliffs and the sea was at one time on a level with the top of the cliffs, and that it had broken away and sunk several feet, from some cause which I do not attempt to explain.

I brought away the impression that Savaii was at one time much more fully supplied with barrier reefs than at present, and that recent lava-flows had extended the island out beyond the reef. So far as my observations extended, where reefs do exist they are terminated by points or capes of volcanic rock, looking as if the lava had overflowed and cut off the reef.

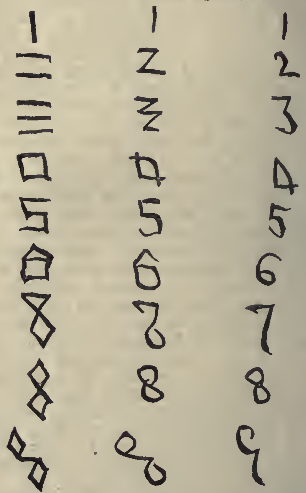
One circumstance almost, if not quite, fatal to the theory that Savaii has been upheaved in whole or in part in recent times, is that nowhere are there any signs of coral *in situ* above the sea-level. In this respect it is very different from the island of Rarotonga, in the Hervey group, which has most unquestionably been upheaved several feet, at least on the south side. There the barrier reef is altogether out of water, and what was once the enclosed lagoon is in some places dry land.

In regard to the absence of barrier reefs in front of lava-flows, I venture to suggest that it is more likely to be caused by the depth of the water or by the recency of the lava-flow than by any effect of existing submarine volcanic action on the coral insect.

San Francisco, Sept. 7 RICHARD WEBB

Origin of the Numerals

HAVING never met with any explanation of the origin of the numerals, or rather of the figures symbolising them, perhaps I am right in supposing that nothing satisfactory is known of it. In that case the following may be interesting to your readers. The first column contains the original figures, each containing as



many lines as the number which it is intended to represent. The other columns show the transitions likely to result from quick writing.

W. DONISTHORPE

17, Porchester Terrace, W.

Pugnacity of Rabbits and Hares

I HAVE occasion just now to keep over thirty Himalayan rabbits in an outhouse. A short time ago it was observed that some of these rabbits had been attacked and slightly bitten by rats. Next day the person who feeds the rabbits observed, upon entering the outhouse, that nearly all the inmates were congregated in one corner, and upon going to ascertain the cause, found one rat dead and another so much injured that it could scarcely run. Both rats were of an unusually large size, and their bodies were much mangled by the rabbits' teeth.

I never before knew that domestic rabbits would fight with any carnivorous antagonist. That wild rabbits never do so I infer from having several times seen ferrets turn out, from the most crowded burrow in a warren, young stoats and weasels not more than four inches long.

It is evident that the show-fight instinct cannot have been developed in Himalayan rabbits by means of natural selection, but it is no less evident that if it ever arose in wild rabbits it would be preserved and intensified by such means. And in this connection I should like to ask any of your readers who may be able to supply information upon the point, whether there is any difference between the hares of Great Britain and those of the Continent with regard to pugnacity. I have been assured by Germans that in their country a hare will fight a good-sized dog rather than run, and that it is dangerous to handle a wounded individual. I do not know, however, whether or not to trust these statements, and as there appear to be very few examples of local varieties of instincts, it is desirable that anyone who can should either confirm or deny this curious instance.

Dunskaith, Ross-shire GEORGE J. ROMANES

OUR ASTRONOMICAL COLUMN

"35 CAMELOPARDI," B.A.C. 1924.—The principal component of this double star is not included either amongst the certain or suspected variables in Professor Schönfeld's last catalogue, but there would appear to be sufficient evidence of change to justify its being placed in the former class. Variability was suspected by the Baron Dembowski from his own estimates of magnitude 1865-

68 (A.N. 1810), and the following are almost decisive of fluctuation through about two magnitudes, so that at times the star will be visible to the naked eye, and at others fairly beyond unassisted vision.

As lower estimates we have Argelander 1842 January 25—8 mag., and Radcliffe Obs. 1870 February 22—7·5 mag.

As higher estimates we find, Flamsteed, 1696 January—$5\frac{1}{2}$, Lalande (in Fedorenko's Catalogue), 1790 February—5·6, Dembowski, 1868 February 2—5·5, and Radcliffe Obs., 1872 March 9—6·0.

It does not occur in the *Uranometria*, but is B.A.C. 1924, and there very properly removed from Camelopardus, to which it could only have been originally assigned by a mistake. It belongs to Auriga, though it is hardly, as the Bedford *Cycle* tells us, "in the Waggoner's eye."

THE DOUBLE STAR Σ 2120.—M. Camille Flammarion sends us some remarks on this object, to which allusion was made in NATURE, vol. xi. p. 147. Identifying it with No. 89 of Sir W. Herschel's Class III., M. Flammarion thinks the early observation tends to establish the binary character of the star, notwithstanding the measures from 1829 to 1873 may be represented by rectilinear motion. We shall revert to this subject next week.

THE MINOR PLANETS.—The elements of No. 148 have been calculated by M. Bossert and Herr V. Knorre; the orbit is one of the most inclined to the ecliptic (26°).—No. 136, Austria, was recovered at the Observatory of Berlin on the 6th of the present month. Dike and Camilla, with one or two others, are still adrift.

THE AUGUST METEORS.—As previously stated, the systematic course of observation of the meteors of the August period, organised by the French Scientific Association, has this year been attended with considerable success, the atmospheric conditions on the nights of the 9th, 10th, and 11th having been as favourable as possible at many of the stations. The greatest number was observed during the night between the 10th and 11th, but this number varies much in the different accounts so far published by M. Leverrier. The Lisbon observers would appear to have recorded the greatest number, 1,227 meteors having been noted between 10h. and 15h. 25m., when the sky clouded. A table of more than forty tracks, exactly noted, appears in the Paris "Bulletin International" of Sept. 23, the co-ordinates of the points of commencement and extinction being expressed in right ascension and declination, with the corresponding mean times. At Avignon, on the same night, 858 meteors were recorded between 8h. 35m. and 15h. 40m. At Bordeaux M. Lespiault remarked that four-fifths of the meteors seen were Perseids, generally very small, though in a few cases they had considerable brightness and left trains. At Dijon, on a mean of the three nights' observations, the radiant was fixed approximately in R.A. 37°, and polar distance 45°, and in addition to this point, two secondary radiants were detected, one in R.A. 320°·4, N.P.D. 91°·8, and the other in R.A. 331°·0, and N.P.D. 90°·0. With respect to these it is remarked that although, by the means, these coordinates appeared to be confused together, yet for each night the points of radiation were very distinct, the meteors of the first group appearing to be directed towards the second radiant, and those of the second group towards the first. At Rouen, 500 meteor-tracks were entered upon the charts, the invariable direction being from Perseus. At the Observatory of Palermo, Prof. Tacchini and M. Delisa made numerous determinations of the position of the radiant from August 9-12 inclusive, the mean of the whole being in R.A. 2h. 50m.9, N.P.D. 36° 51′, but when the points are laid down on a chart it is seen that they are comprised in a very narrow ellipse, a circumstance to which Prof. Tacchini has already drawn attention.

M. Wolf, in reporting the results of this year's observations, considers that the phenomenon advances rapidly towards a very brilliant maximum; the next year will enable us to judge if this maximum has been attained, and it may then be possible, he thinks, to determine the period of revolution of a swarm of meteors, which, though now extended far along the orbit, still presents a very marked region of condensation. On the contrary, M. Wolf observes, the November shower has so nearly ceased, passing now almost unperceived, that it may be unnecessary to call upon observers, who have previously co-operated in this class of observations, to expose themselves again to the possible severity of the nights at that season.

THE CLINICAL LABORATORIES ANNEXED TO THE PARIS HOSPITALS

THE first and typical clinical laboratory was created at the Hôtel-Dieu, by private exertions, a very few months after the time when blood had been running so freely on the pavement of the great city. It was organised at the expense of two doctors, who had shared the disappointments and dangers of those troubled times.

Dr. Liouville, a nephew of the celebrated academician who edited for so many years the *Annals of Mathematics*, having learned by his travels, before the Franco-German war, that Prussia and other German powers had established special laboratories at Berlin and other large cities for promoting physiological researches in the Universities, resolved to introduce establishments of that description in his native land, but under a different system. He laid his ideas before Dr. Behier, one of the most popular professors of the Faculty who adhered to the scheme, and lent all his influence and patronage to bring physical and chemical instruments to the very bedside of the patients at the hospitals.

The intention of these two distinguished physicians was not only to open an institution where physiological science might be promoted as it is at Berlin and Vienna, but to place under the hands of practitioners ready means for enlarging the degree of accuracy of their diagnoses. At a moment's notice an able microscopist armed with a powerful instrument is to answer any question put for ascertaining the composition of humours, the nature of abnormal secretions, &c. A competent chemist, well acquainted with the properties of reagents, is ready to make an analysis of blood, of virus, of medicaments, of urine, of *excreta*, suspected poisonous matters, &c. The use of the spectroscope was not so general at the time as to call for the service of a spectroscopist, but the utility of the speciality even then was made apparent to MM. Behier and Liouville.

These operations can be done daily for the instruction of the students following the daily practice of the hospital.

When the patient dies, his autopsy being carefully made, it can be shown whether the diagnosis was true, or whether the fatal result was due to some uncontrollable circumstance. The unhappy inmate whom science and humanity were powerless to save, is turned into an object of instruction, so that human knowledge may be enlarged and other sufferers cured under similar circumstances. The laboratory was also open from the time of its infancy to foreign men of science or to practitioners wishing to investigate any points connected with their patient.

To the Hôtel-Dieu Laboratory was annexed a "chenil," where a number of rabbits and the like are constantly bred and kept in an excellent state of health. These animals are destined to be employed in testing the efficacy of new medicines to be tried, if proved innocuous, on the patients. In cases of poisoning, the localisation of toxic substances is ascertained, as well as the symptoms of death, and in some cases antidotes are administered for testing their restorative power. They may be considered as living instruments for exploring and extending scientifically the scope of *Pharmacology*.

The results obtained by the two learned associates were so rapid and so unquestionable, that in 1872 their laboratory at the Hôtel-Dieu was declared to be an establishment of public utility.

A few weeks afterwards the Commissioner of the Budget of the National Assembly having paid a visit to the Hôtel-Dieu, inserted in his report a clause asking support for the then existing establishment, at the expense of the Government, and the extension of the system to other Paris hospitals. A sum of 32,000 francs was voted without opposition, and three laboratories were opened, one at La Pitié, the second at the Charité, and the third at the Clinical Hospital. The reports of the *Commission de Budget* were succesively presented by M. Beulé, the ex-Minister of the Interior, and, after he had met his untimely death, by the present sub-Minister of Justice, M. Bardoux, who both of them asked for *frais de premier établissement.* A sum of 90,000 francs was voted, partly by the Versailles National Assembly and partly by the Municipal Council of Paris.

Dr. Liouville was appointed the chief of the Hôtel-Dieu Laboratory; Dr. Carnhill, an anatomist universally known by his researches on the diseases of the liver, was appointed the chief of the *La Charité* Laboratory.

In one of the first sittings of the last session the Municipal Council decided that a large pavilion on the northern part of the New Hôtel-Dieu, now building, should be reserved for the clinical laboratory. No money is to be spared in order to procure the most important instruments which can be designed for chemical or medico-physical observations, either in the way of galvanic batteries, microscopes, spectroscopes, &c. A clinical laboratory will also be established in the new hospital to be inaugurated at the end of next November, which will be one of the most extensive in Paris.

NOTE ON HÆMATITE INDIAN AXES FROM WEST VIRGINIA, U.S.A.

THROUGH the kindness of Horace Fisk, of Trenton, and Major Jed. Hotchkiss, of Staunton, Va., I have been able to procure two specimens of hæmatite iron ore hatchets, of aboriginal manufacture. They possess great interest from the fact of being very similar to native copper axes, characteristic of the "finds" of relics of "mound builders." The specimens, one of which is here figured, have unquestionably been hammered out cold, and shaped from a fragment of the ore, without the aid of fire in previously refining the mass. The specimen figured measures five inches and a quarter in length, by three inches in breadth at the cutting end. The opposite end is square, nearly two inches in width, and somewhat thinner than the broader portion of the implement, which is nowhere of greater thickness than one-fourth of an inch.

The entire surface still shows the hammer marks made in shaping the hatchet, even to the edge, which now shows no trace of grinding or polish; but this may have been obliterated by the rust; but I am inclined to believe from close inspection of both specimens, that the edge originally was a hammered one, and not a ground one; making the specimen more nearly allied to the "clipped" jasper hatchets than polished (ground) porphyry axes.

The accompanying specimen is four-and-a-half inches in length, by two in breadth, is nearly uniform in thickness about three-sixteenths of an inch, and has a well-defined edge, which from its slightly wavy outline, and slight variation in width, I believe to be a hammered, and not a ground or polished edge.

Two other specimens, similar to these, were found with them, and are now in the calimat of Major Hotchkiss, who informs me that the series of four were found under an uprooted tree, on an Indian trail, at the Forks of Kelley's and Rich Creek, Gauley Mt., Tayette Co., West Va.

It has been suggested that the use of hæmatite for paint among our Indians may have led to its employment for other purposes ("Flint Chips," by E. T. Stevens, p. 553), and this is no doubt true, inasmuch as small irregular fragments of this mineral were often utilised, if the shape would at all permit, as arrow heads. Among the thousands of arrow-heads gathered in New Jersey, I have not met with one of iron ore that has been worked into any of the various patterns of flint points; but from graves, associated with others, I have found fragments of the ore, and once, of native copper, of such shape and size, and so placed, that they were evidently arrow-heads.

A curious form of "relic," known here as a "plummet," occasionally occurs, made of iron-ore. One such is figured in the "American Naturalist," vol. vi., p. 643, Fig. 132. This specimen "is made of iron ore, ground down and polished until it is almost as smooth as glass." As such plummets are found in the western mounds, as well as on the surface of the ground throughout the Atlantic coast States, and are always polished, it seems fair to presume that a cutting instrument of such hard material would undoubtedly be polished and ground, if, at the time of its manufacture, grinding was known or practised among the aborigines in fashioning their various weapons and instruments.

When we consider that these iron hatchets were found in a locality once thickly populated by Indians, and probably frequently visited, if not occupied, by the mound-builders, and now yield, on search, an abundance of ordinary stone implements of every grade of workmanship and variety of pattern, it seems at least probable that the specimens in question were not fashioned at a time when the polishing and grinding of weapons was customary, but earlier, as the labour of beating so hard a material into its present shape would doubtless be supplemented by polishing, if the additional value given to an implement by the operation had been recognised.

As the writer has already endeavoured to show, through an extensive series of New Jersey specimens (NATURE, vol. xi., p. 215), that the ruder chipped implements of "our native rocks" are older than the more elaborate jasper and porphyry specimens, so I consider these hammered iron hatchets to be of an earlier age than either the polished iron plummets of the mound-builders, or ground axes of the Indians.

CHARLES C. ABBOTT

Trenton, New Jersey, U.S.A.

DOHRN ON THE ORIGIN OF THE VERTEBRATA AND ON THE PRINCIPLE OF SUCCESSION OF FUNCTIONS

THE introduction of the doctrine of Descent into the study of organic phenomena has opened the floodgates of speculation, of hypothesis, and theory. Probably, with very few exceptions, this is regarded with regret and impatience by zoologists and botanists, even though staunch Darwinian converts, who had made any name in biology in the period anterior to the publication of Mr. Darwin's work on the "Origin of Species." Those were the days of a reaction brought about by the fantastic imaginings of Oken and his school; and the naturalists brought up in those days cannot rid themselves of a dread of speculation which has become as much an organic part of their nervous systems as has the fear of precipices, bricklayers' ladders, and of the mythological personages of their childhood, to most men. It remains for the present and later generations who will be brought up, not to fear, but to use speculation, to turn fully to account the immense engine of research which Mr. Darwin has placed in their hands. We see, in fact, no reason for refusing to welcome any number of hypotheses and theories on biological topics: let every one make his suggestion—the more ingenious and original the better—and let it be taken for what it is worth. If in its author's or another naturalist's hands it should lead to the discovery of new facts—if it should in a more or less modified form be established as true—it will bring thanks and honour to its promoter. If, on the other hand, it should lead to nothing, should be tested and found neither true nor suggestive of truth, it will fall to the ground quietly enough, and do no harm to anybody. This, be it said, applies only to the publication of such hypotheses within the scientific area—a totally different and a very grave responsibility is incurred when an author represents a hypothesis as an established doctrine, and appeals to the support of an uninstructed public. The fact is that we have acquired this freedom of speculation as compared with the proscription of it in the pre-Darwinian period, through the circumstance that biological theory has passed from the theological to the scientific form. To-day—no matter who its author—a speculation as to the mode of development of this or that group of animals and the significance of this or that organ, may be verified or rejected; no one will attach undue value to it until this process has been gone through. Formerly it was not possible to test such speculations; we had in fact no link by which organic phenomena were made part of the whole series of phenomena of which science takes cognisance, and biology had no foundation in the so-called experimental sciences. Hence speculations were liable (as in theological discussion) to be launched by authorities, and to be received not as speculation, but as something like *inspiration*, by disciples; and on the other hand to be rigorously and almost puritanically tabooed by a constantly increasing number who, refusing to occupy themselves with these vain imaginings, endeavoured to keep the facts pure and undefiled, waiting for the coming of an interpreter—who was realised in Mr. Darwin. The doctrine of organic evolution as elaborated by Mr. Darwin and his immediate successors has provided us with a proper scientific framework, and we can now proceed to build on that by the legitimate methods of modern inductive science. It will be some time before biology fully emerges from its theological form; at least another generation must pass; and in the mean time we must expect the continuation of special claims on the part of authorities to advance speculative doctrines *ex cathedrâ*; and on the other hand a lingering antagonism to all speculation, even to that which makes no pretension to authority, on the part of those who have imbibed the horror of fantastic "Natur-philosophie" and of dogmatic pretensions.

To those who belong to neither of these sections, it is worth while pointing out that even the most careful observation and recording of phenomena in the absence from the observer's mind of some theory or speculation which shall, so to say, sharpen his wits and keep his eyes open, is likely to be of the very smallest value. It cannot be too strongly asserted that in observing a complicated phenomenon—such as an organic structure or series of structures—the investigator is only likely to see what he has already imagined *may be* there; the chances are greatly against his detecting an arrangement or a mode of development of which he had previously no suspicion. Though cases of unforeseen discovery do occur, yet it may be safely stated that, as far as all but the most patent and macroscopic appearances are concerned, the observations of no predecessor should be trusted by an investigator beyond the limit which is given by the hypotheses which are known to have been present to that predecessor's mind. In fact, a man can only expect to get answers from Nature to specific questions; she will not give him unsolicited information, nor make a voluntary statement, however attentive the listener. Hence the value and legitimacy of speculations, even *ad nauseam*, on such matters as the pedigree of animals and plants. When advanced, with due knowledge of ascertained facts, they suggest to the embryologist, to the palæontologist, and the anatomist, a number of possibilities which he holds before him as so many questions to be answered by the material of his studies. It is true that it is desirable in a high degree that the person who frames a hypothesis should also himself be active in using it in a practical way, and indeed if he is not, he may find no one who will take the trouble to bear it in mind. Therefore, one must admit the generosity of those who now-a-days make a present of their speculations to scientific *confrères*, and undertake the part of the profound thinker, whilst assigning to others the more practical task of verification and elaboration. For, since the days of scientific inspiration are past, but little credit will attach to the launchers of hypotheses, and more and more to those who destroy them, either by showing their error or by transubstantiating them, in demonstrating that which was supposed, actually to be. It is Darwin whose name we associate with the doctrine of evolution—not Lamarck's, nor Goethe's, nor Wells', nor Freke's.

These remarks are a necessary prelude to the consideration of the bold speculations with which Dr. Anton Dohrn, the founder of the zoological station of Naples, known also for some interesting observations on the development of Crustacea, has recently astonished the zoological world in his "Ursprung der Wirbelthiere und Princip des Functionswechsels." The necessary sequence of the general acceptance of Darwin's theory of the origin of species by descent and natural selection has been an attempt to establish the pedigree of the animal kingdom, and to indicate the degrees of consanguinity among the different members of it known to us. In the first attempts in this direction no one can doubt that errors and vagaries of all kinds must occur. It is only when naturalists have fairly set themselves to the task and made some few false starts that we can expect to see anything like a just appreciation of the methods to be pursued, of the difficulties to be encountered, and of the fallacies to be avoided. We are obliged to admit that the first attempts in the way of constructing the pedigree have been influenced, as they were likely to be, by the remnants of old notions and by the lack of a perfectly unprejudiced appreciation of the question in hand. The pamphlet of Dr. Dohrn comes opportunely enough to insist upon one or two important considerations which have been neglected; and even though, by an excess of antagonism to prevailing prejudice, Dr. Dohrn may be

led to oppose exaggeration to exaggeration, we cannot the less feel that there is sound sense and truth in the general purport of his views.

In the pre-Darwinian period naturalists looked upon the series of classes and orders of the animal kingdom as a more or less branched ascending series. The effort in nearly all classifications was to distinguish the lower from the higher and to place the groups in their supposed order of merit, as competitors for the highest rank of organisation. This has led—now that Darwinism is accepted—to a tacit assumption that the order of "degree of organisation" which was worked out in the pre-Darwinian era, is necessarily the order of historical development; that consequently the lower forms of any group which are existing to day, are nearer to the ancestral forms of that group than are the more highly organised forms.

Whilst an exception has been made to this unreasoned and unchallenged assumption in favour of the parasitic forms for which the term "retrogressive development" has been coined, it does not appear to have occurred to any prominent naturalist, at any rate it has not been prominently maintained, that the "retrogressive development" which all so readily admit for parasites, may be a very general phenomenon, as widely or more widely diffused as that of "progressive development." To have insisted on this possibility even to an excess (of which more below) is the merit of Dr. Anton Dohrn. Dr. Dohrn has arrived at an appreciation of the possibilities of degradation or retrogressive development, by divesting himself of all preconceived notions and of all respect for authorities. In his pamphlet he grapples courteously, but fearlessly enough, with Von Baer, Darwin, Haeckel, Gegenbaur, and for the matter of that by implication with almost every zoologist of note.

We claim for him, first of all, full liberty to do this and to launch the hypothesis of general retrogressive development as a competitor with that of universal progressive development. It requires but a few words of explanation and an example, for which Dr. Dohrn has selected the possible relations of the Ascidians to the Vertebrata, to show that retrogressive development is not only a possibility, but *must* be going on and has been going on—on a very large scale—and in any doubtful case is as much entitled to consideration as the hypothesis of progressive development. A less important portion of the pamphlet is that which precedes the development of the author's Hypothesis of Degradation, and illustrates the application of what he calls the "principle" of the Succession of Functions. To put it in the form of a hypothesis it comes to this:—"Organs do not arise *de novo* in organisms, but are formed by the gradual change of function and accompanying change of structure of pre-existing organs." That this is true, or at any rate that it is the hypothesis which, according to the "principle of uniformity," must be preferred to its converse, namely, "that organs *are* formed *de novo*" must be admitted by everyone. In fact, most of Dr. Dohrn's readers will feel that there really is not much novelty in this proposition, since it is already involved in the doctrine of homologies to a very large extent. Dr. Dohrn admits this in his pamphlet, but we conceive that his view differs from that implied in the generally recognised doctrine of homologies, in that the latter is not absolute; it would merely assert that *many* or *some* organs do not arise *de novo*, but are formed by the gradual change of function and accompanying change of structure of pre-existing organs. Dr. Dohrn raises this into a hypothesis of *universal* application, and proposes to apply it stringently in speculations as to the genealogical relationships of organisms. He illustrates its application in an attempt to explain the genealogical affinities and mode of development of Ascidians, Amphioxus, Lampreys, and Sharks. We are very much disposed to believe that here, as in his advocacy of the hypothesis of degradation, Dr. Dohrn has grasped and emphasised a truth which has been floating before the eyes of other people but has not been appreciated at anything like its real importance by them. We believe that the hypotheses of degradation and of continued homologies put before naturalists in the present pamphlet will have a very important and powerful influence on the rapidly progressing reconstruction of the animal pedigree with which so many zoologists are busy.

At the same time it is necessary to point out that the particular speculative conclusions at which Dr. Dohrn arrives as to the new Vertebrate mouth which has replaced the ancestor's mouth as well as the new Ascidian mouth, which has done the same thing—further, the conclusion as to the secondary character of the Vertebrates' anus, and the development of Vertebrate gill-slits from segment organs and of Vertebrate limbs from annelidan gill-supports—all this and more besides is ingenious and healthy hypothesis, but has no value unless Dr. Dohrn or some one else (which is not a thing he should rely upon) will bring it to bear upon the facts and seek to establish it by new observations. We must confess that although we are inclined to entertain some of Dr. Dohrn's suggestions as hypotheses, yet we feel that he has given us rather a large supply, which, in justice to his reputation as an observer, he should hasten to balance by a fair amount of new investigation. Such a speculation as that which he gives us relative to the origin of Vertebrates, can from his hands only be regarded as a sort of programme or announcement of the work which he intends to do during the next decade at the Zoological Station. We shall look most anxiously for the first instalment of results.

Lastly, we shall not shrink from pointing out that Dr. Dohrn urges the hypothesis of degradation to a degree which would be regrettable were it quite evident that he is serious and not merely anxious to engage the attention of his reader by letting imagination have its full swing. Supposing, says Dr. Dohrn, that the Ascidians are the degenerate descendants of a half-worm- half-fish-like ancestor—and the mere consideration of their individual development is enough to make this probable—then we have to admit an amount of degeneration which covers very wide possibilities. For the compound Ascidians, with their various encrusting species, are included in the series; and, moreover, many forms which have ceased in their individual development to give any indication of the affinities which are indicated by the larvæ of other forms. If so large, so abundant, and varied a group can thus take its rise by degeneration, what is to prevent the simpler worms from having originated in the same way? Why may not the Cœlenterata have acquired histological and general simplification in a parallel manner by degeneration accompanying a fixed life? And the Protozoa, the whole series of unicellular animals, why are they not to be considered as degenerated from multicellular forms by a process of simplification? In fact, in a few sentences Dr. Dohrn suggests doubts which land him in a theory which is almost identical with that of Aristotle.

"Thus then," he says, "the animal kingdom has quite a new aspect for us when we look at it from the point of view developed in this essay. Instead of having before us a large mass of forms which from the first commencement of organic life have made little or no progress, whilst a few favoured stems have developed themselves to the highest perfection, we obtain the conception of one single stem, which bore within itself the germ of all other higher, highest but also lowest forms, whose descendants on the one hand in thought and fancy embrace the universe and recognise themselves within the universe as individualities, whilst others lead a senseless inert existence and give rise to the belief that a non-living nature might be able now or at any time to originate such things." Finally, the author argues that the development

of this single stem is not to be assigned to either chance or to chemico-physical, but to an "Entwickelungs-gesetz" yet to be discovered. This, we confess, is to us a disappointing termination to a clever and spirited essay. Surely Dr. Dohrn would not expect a scientific man to understand by the word "chance" anything but a periphrasis for the operation of hidden cause. And what can he expect any law of development to be, if not an expression of the operation of chemico-physical causes?

As to the original form under which life made its first appearance, Dr. Dohrn's words would almost lead to the impression that he believes in the creation of a "type-form" something like the Cherubim, with an account of which Archdeacon Freeman favoured Section D of the British Association when it met at Exeter in 1869. His language is, however, sufficiently vague to warrant the supposition that, as an orthodox physical philosopher, he holds the doctrine of the evolution of organic forms subject to the larger doctrine of general evolution, and consequently we may suppose that he would hold that the single stem which has blossomed in man, and from which all other forms have descended by retrograde development, *did* take its origin from simple protoplasm, which had naturally been evolved from carbon compounds. If the animal pedigree did originate from these very simple beginnings, we suppose Dr. Dohrn would say that all trace of them is gone, what is simple *now* in the way of organisms is not the simplicity of the original stock, but a simplicity attained by degeneration. We do not see any reason to accept this hypothesis of *universal* degradation (man alone being excepted from its influence), any more than we can see reason to accept the competing hypothesis of *universal* progress. We are very strongly inclined to think that neither hypothesis can have the whole field to itself. We should expect to find in some directions progress, in others retrogression.

The extent to which each of these processes has gone on in past ages in connection with the family history of the animal kingdom is the great problem for zoological research. E. R. L.

THE NEW METAL GALLIUM

THE discovery, by M. Lecoq de Boisbaudran, of a supposed new element in a blende from the Pierrefite mine in the Argeles Valley, Pyrenees, was made known in our "Notes" of last week. This element, which the discoverer proposes to name *Gallium*, has revealed itself by the following chemical reactions:—

The oxide, or possibly suboxide, is precipitated by metallic zinc from a solution containing chlorides and sulphates.

In a mixture of the chlorides of the new metal and of zinc, ammonia throws down the new element first if added in a quantity insufficient to precipitate the whole of the metals present. Nearly the whole of the gallium is thus thrown down in the first fraction.

Under conditions competent to peroxidise the new metal, the oxide is soluble in excess of ammonia.

Ammonium sulphydrate produces a precipitate insoluble in an excess of the reagent. The sulphide appears to be white.

Sulphuretted hydrogen produces a precipitate in presence of ammonium acetate and excess of acetic acid. In presence of zinc salts the new substance concentrates itself in the sulphides first deposited, but six fractional precipitations were requisite to remove the greatest part of the zinc sulphide. In presence of hydrochloric acid no precipitate is formed.

The oxide, like that of zinc, dissolves in excess of ammonium carbonate.

The salts of gallium are readily precipitated in the cold by barium carbonate.

The chloride may be frequently evaporated with great excess of *aqua regia* without undergoing any loss by volatilisation.

When hydrated zinc chloride containing a trace of the new substance is heated to the point when zinc oxychloride begins to form, the gallium remains in an insoluble condition, possibly as oxychloride.

The quantity of the substance procured was too small to attempt its isolation. Some drops of zinc chloride solution in which the new metal had been concentrated were examined spectroscopically by the electric spark. The spectrum is composed chiefly of a violet line about wave-length 417, and a feeble line about 404.

In his communication to the French Academy, the author states that he obtained the first indications of the new metal on Friday, Aug. 27. It is to be hoped that a good supply of the mineral will be procurable, so that the new element may be isolated, its atomic weight determined, and its reactions studied in detail. This now makes the fifth terrestrial element which the spectroscope has been instrumental in bringing to light.

R. MELDOLA

UNPUBLISHED LETTERS OF GILBERT WHITE

AT the meeting of the Norfolk and Norwich Naturalists' Society, held on the 28th inst., the secretary read an interesting series of ten unpublished letters, written by Gilbert White, of Selborne, to Robert Marsham, F.R.S., of Stratton Strawless, Norfolk, and communicated by the Rev. H. P. Marsham, great-grandson of the latter. The letters, which are dated between August 13, 1790, and June 15, 1793, are excellent examples of Gilbert White's delightfully discursive style, their contents being of a very varied nature. Mr. Marsham, to whom they were addressed, was a great planter, and communicated his experiments on growing trees to the Royal Society; the beauty and great size of the timber at Stratton bear testimony at the present day to his judgment and successful treatment. As might be expected, under these circumstances, a large portion of the correspondence is devoted to forest-trees, the love for which was shared in an almost equal degree by both correspondents. The "Indications of Spring," of which Mr. Marsham left such a remarkable register, and which have been continued by his family, with one slight interruption, from the year 1736 to the present time (see "Philosophical Transactions" for 1789, and the "Transactions" of this Society for 1874-5), of course form an annual topic, as well as the rainfall; but perhaps the most valuable part of the correspondence is the gossip about birds, some of which is of very great interest. On the 30th October, 1792, Marsham writes to White: "My man has just shot me a bird which was flying about my house; I am confident I have never seen its likeness before." On reference to his Willoughby, he declares it to be "the Wall-creeper, or Spider-catcher," and a description, endorsed by him on one of White's letters, as well as a manuscript note in his copy of Willoughby's "Ornithology," still in the possession of the Marsham family, places it beyond doubt that the bird was a veritable *Tichodroma muraria*. White, after saying he is persuaded that the bird is the "very *Certhia muraria*," continues: "You will have the satisfaction of introducing a new bird of which future ornithologists will say, 'Found at Stratton, in Norfolk, by that painful and accurate naturalist, Robert Marsham, Esq.,'"—a prophesy which, after an interval of eighty-two years, will at length be fulfilled. Nearly a whole letter is devoted to an extract from an unpublished "Natural History of Gibraltar," by Gilbert White's brother, the Rev. John White, who resided many years on the "Rock." By this it is shown that John White, who went to reside there in 1756, soon discovered the Crag Swallow

(*Cotyle rupestris*) to be distinct from the Sand Martin, for which it was then mistaken. He gives an interesting account of its habits, and names it *Hirundo hyemalis*, from its great abundance at Gibraltar in the winter months. The last letter of the series, dated June 15, 1793, has a special interest attached to it from the fact that it was written only eleven days before the death of this estimable man and ardent naturalist. The whole of this interesting series will be published in the Transactions of the Society, and it is hoped, through the kindness of Prof. Bell, in whose hands they now are, that Marsham's letters to White may be added.

NOTES

DURING the last week there has been a goodly talk about education, and Mr. Cross has come to the front in a most unexpected manner, while the modern English Cardinal has been acting as his foil. Cambridge, too, in the shape of Mr. James Stuart, has been active at Nottingham, and the world thinks that the University is active. The truth is, however, that the University is too poor to do anything, and that the Colleges are simply looking on while a private benefactor is providing both with those means of teaching which third-rate institutions on the Continent have possessed to a greater or less extent any time during the present century. Mr. Cross not only foreshadows compulsion, but he shows that we have now a Minister who knows the difference between Education and Instruction. "It is not mere book learning that I am talking of. That is not the object of these schools. It is the school discipline, the training of the mind of the child, the teaching him how to teach himself, the self-control and the self-respect which he gets at school, which do more for him than all the book learning that you put into his head." The Cardinal, on the other hand, defines "Secular Education" as "secular knowledge," and then adds: "Education means the full possession and understanding and enjoyment of the inheritance of faith, which the child has by virtue of his regeneration in baptism." It is clear that the Cardinal, if he means anything, confounds instruction with education as successfully as ninety-nine out of every hundred who talk on the subject confound education with instruction.

AT a meeting of the Entomological Club of the American Association for the Advancement of Science, Mr. C. V. Riley, the secretary, read a paper on "Locusts as Food," in which he gave his own experience in cooking and eating them. On one occasion he ate nothing else for a whole day. He found them to have an agreeable nutty flavour, and especially recommended them deprived of their legs and wing-cases, and fried in butter, and also spoke very highly of a soup made from them. He referred to John the Baptist, who had often been pitied for the scantiness of his fare, locusts and wild honey, and expressed his opinion that he was rather to be envied than otherwise. The writer regarded it as absurd that parties should actually die of starvation, as some had done in the districts where this locust plague had prevailed, while surrounded by such an abundance of nutritious and palatable food.

FROM different settlements on the West Coast of Africa young living gorillas have several times been shipped for Europe under auspices apparently the most favourable. On one occasion, about six years ago, a Dutch merchant at St. Paul de Loanda took the trouble to keep a young male in company with a black boy for some considerable time on the coast, and when the two had become good friends, took passages for them both to Holland. The animal only survived a fortnight from the date of its embarcation, dying rather suddenly, as most others seem to have done, from a kind of depression or home-sickness, not from any well-marked disease. No gorilla, exported as such, has reached Europe alive. Quite recently, within the last month or so, one destined for Hamburg arrived within two days of its journey's end, when it shared the fate of its predecessors. This specimen was, immediately after its death, placed into spirit, and will, we believe, form the subject of a monograph by Dr. Bolau, of the Zoological Museum of Hamburg, from whom we may expect the settlement of several important and doubtful points in the anatomy of the greatest of the anthropoid apes. In about the year 1852, in one of Wombwell's travelling menageries, there was exhibited for some months a monkey very like a chimpanzee. The animal was expert at tricks, and was clad in a grotesque costume. From a daguerreotype photograph in the possession of Mr. A. D. Bartlett, resident superintendent of the Zoological Gardens in Regent's Park, that gentleman was enabled to identify the specimen as one of a young gorilla, and not a chimpanzee. Its face was dark, its arms and legs proportionately larger, its ears very much smaller, and the distance between the eyes greater than in the chimpanzee. A still more interesting instance of the same kind has, however, recently occurred. For the last two years there has been a female "chimpanzee" at the Zoological Gardens at Dresden, named Mafota, which has attracted considerable atention. She was purchased by Herr Schöpff, the Director of the Dresden Gardens, in a very unpromising condition, being much denuded of hair, and covered with an unhealthy skin eruption. Since the animal has been under Herr Schöpff's skilful care, it has become quite a different creature. It has grown very rapidly; surprisingly so. The hair now forms an abundant covering, and the skin is in a perfectly healthy condition. It is quite tame with its keepers, whose boots it is in the habit of taking off and replacing for the amusement of visitors. It performs many other tricks, showing great intelligence. Herr Carl Nissle, an artist, we believe, whilst studying the figure and movements of Mafota, became rapidly impressed with the idea that she is not a chimpanzee at all. Her great size, the numerous black spots on the naked skin of the face, which in the chimpanzee is simply flesh-colour, the black instead of pink hands, the slight webbing between the fingers, and the different expression, with a broader nose, all led him to the conviction that she is a gorilla. He carefully studied the stuffed specimens of the gorilla and chimpanzee, both at Berlin and Lubeck, and, what is more, has had the opportunity of seeing the new Hamburg spirit specimen above referred to. These all confirmed his surmise, towards the complete verification of which we have the affirmative opinion of Prof. R. Hartmann, prosector to the Anatomical Museum of Berlin. So there is strong reason for the belief that Mafota is a gorilla, the first living specimen recognised as such in this continent.

THE following are the hours of the various Introductory Lectures at the London Medical Schools, which will be delivered to-morrow (Oct. 1st), with the names of the respective lecturers:—

HOSPITAL.	LECTURER.	HOUR.
Charing Cross	Mr. Fairlie Clarke	4 P.M.
St. George's	Dr. Barnes	4 ,,
Guy's	Dr. Stevenson	2 ,,
King's College	Dr. Curnow	4 ,,
London	Dr. B. Woodman	3 ,,
St. Mary's	Dr. Randall	3·30
Middlesex	Mr. Lowne	3 ,,
St. Thomas's	Dr. Payne	3 ,,
University College	Dr. Corfield	3 ,,
Westminster	Mr. R. Davy	3 ,,

DR. JAMES BELL PETTIGREW, F.R.S., Lecturer on the Institutes of Medicine at the Royal College of Surgeons, Edinburgh, has been appointed to the Chair of Medicine in the University of St. Andrews, vacant by the death of the late Dr. Oswald Home Bell.

THE following is a list of candidates who have been successful in obtaining Royal Exhibitions of 50*l.* per annum each for three

years, and free admission to the course of instruction at the Royal School of Mines, London, and the Royal College of Science in Dublin :—1. School of Mines: John Gray, 21, engineer, Strichen, N.B.; Frederick G. Mills, 14, student, London; Thomas E. Holgate, 20, farmer, Blackburn. 2. College of Science: C. C. Hutchinson, 21, engineer, Leeds; Henry Hatfield, 20, student, Stockport; Thomas Whittaker, 18, clerk, Accrington.

THE term of office of the present Lord Rector of Aberdeen University—Professor Huxley—having nearly expired, the students are already looking out for a successor. Mr. M. E. Grant Duff, M.P., Dr. W. B. Carpenter, Mr. Robert Lowe, and Dr. Alexander Russel, editor of the *Scotsman*, are proposed for election. A report in the *Times* states that the feeling of the majority seems to be in favour of Dr. Carpenter.

THE preliminary North-west African Expedition is expected to leave England for the coast of Africa early in November. General Sir Arthur Cotton and several scientific gentlemen are expected to accompany it. The object in view is to make a survey of the coast of Africa opposite the Canary Islands for the purpose of finding a suitable position for a harbour and commercial and missionary station; to enter into commercial arrangements with the native tribes, and to inquire into their present means of commerce, and the resources of the countries through which it is proposed to pass. To examine as far as practicable the sand bar across the mouth of the River Belta, which it is supposed keeps back the waters of the Atlantic Ocean from flowing into the dry bed of the ancient inland sea, to obtain levels and other necessary information. Mr. Mackenzie, the director of the party, expects to get the friendly support of the most powerful chief of the tribes on the north-west coast of Africa.

THE celebration of the fiftieth anniversary of the opening of the first railway between Stockport and Darlington is attracting the notice of the French papers. A curious fact connected with French railways is that Baron Charles Dupin, who published his celebrated work on Great Britain in 1826, described railways at full length, but abstained from saying a word about motive-power. Baron Dupin, a great geometer and mechanician, declared to the Institute that locomotives could never move, owing to the weakness of their hold on the rails, and that the use of horses could not be dispensed with. Baron Charles Dupin's reputation was so great that the truth of the statement was taken for granted, and in the École des Ponts et Chaussées, the public institution where State engineers are educated at the expense of the Government, in a course of lectures given after 1830, it was said that horses could never be dispensed with. The advantages of locomotion were lectured upon in a free institution which was opened at that time, called the École Centrale des Arts et Manufactures. The professor was the celebrated railway engineer, Perdonnet. Arago was opposed to the boring of tunnels as endangering the health of travellers, owing to the great cold which he anticipated would be felt.

M. LEVERRIER has addressed a circular to the Presidents of the Meteorological Commissions of the departments with reference to the Meteorological Atlas in course of publication for the years 1872, 1873, and 1874. It is intended that this important work shall contain instructions relative to meteorological observations and tables for their reduction; a discussion of thunderstorms which have occurred in the different river-basins as well as over France generally; a *résumé* of the observations made during the three years at the departmental stations; hail charts; the rainfall for the whole of France, by M. Belgrand; and lastly, a series of memoirs on special subjects by French and foreign meteorologists. The price for the large or folio volume will be only eight shillings, representing the price of paper and printing, the printing being undertaken by the Government, and the compilation having been done by the Meteorological Service at the Observatory. The number of copies printed being necessarily limited, persons wishing to purchase the work are required to send a money order to the Secretary of the Association Française, 11, Quai Voltaire, Paris.

DR. GUSTAVUS HINRICHS, Director of the Laboratory of the Iowa State University, Iowa city, has issued a circular, dated August 1875, with the view of organising a system of rainfall observation for the whole of the State of Iowa. He is confident of a start with one rain-gauge in each county of the State, and hopes in a few years to secure the erection of four or five gauges in each county. Printed forms on addressed postal cards will be issued to the observers, who are requested to mail them on the 1st, 11th, and 21st of each month. Thrice a month Dr. Hinrichs will prepare a statement of the rainfall of Iowa for the corresponding ten days, comparing it at the same time with past averages, and forward it to the daily press for publication. Other States will doubtless soon follow the example.

THE Upsala Observatory has published a Circular (No. 6) giving an elaborate discussion by Dr. Cronwall, of the observations made over Sweden to determine the annual periods of the duration of ice. The six coloured maps, which illustrate the paper, showing, by lines passing through equal times and periods, the beginning, end, and number of days' continuance of the ice over the different districts of the country during the winters of 1871-72 and 1872-73, are valuable contributions to the climatology of Sweden. Their great value lies in illustrating in a precise as well as striking manner the influence of its adjoining seas, its lakes, its mountains and lesser elevations, and latitude, in determining the times of occurrence and termination of this element of the climate of Sweden. These discussions, begun by Dr. Hildebrandsson for the winter of 1870-71, cannot fail to be of great benefit to agricultural and other public interests.

SINCE our last issue we have received telegraphic intelligence of frightful floods and consequent loss of property in Texas. At Indianola the storm began on the 15th. The east wind which prevailed next morning increased to a gale. The water soon became six feet deep in the streets. On the 17th the wind veered to the north-west. The waves became chopped. The houses were washed away or tumbled down. Toward the morning of the 18th the wind lulled and the water receded; wind veered to the north. When daylight broke an awful destruction became visible. The town could not be recognised. The ruin was almost total. Seventy bodies were found in a brief period and buried. Men and women were discovered who had floated on doors or anything obtainable. Some were imprisoned beneath roofs. Hundreds had miraculous escapes. The loss of life may reach 200. Every business house but five has been destroyed. Every pilot but one has been drowned. The city of Sabine has been submerged and greatly damaged, but without loss of life. Matagorda, at the entrance of Matagorda Bay, has been swept away; but two houses are standing. Cedar Lake is also destroyed. All the inhabitants are reported lost at East Bay. In a village containing twenty-eight people, all but five are lost.

A CORRESPONDENT of the *Daily News*, writing from Christiania, says: "I translate the following from the *Finmarken-post*, a newspaper published in Europe's northernmost city—Hammerfest:—' On the 3rd instant arrived at Hammerfest the schooner *Regina*, Capt. Gundersen, belonging to the firm of O. J. Finckenhagen, from a voyage in the Arctic regions and the north coast of Nova Zembla. Capt. Gundersen discovered in Nova Zembla a journal, kept by the Dutch Arctic voyager, Barent, apparently giving an account of his doings from the 1st of June to the 29th August, 1580, as far as Capt. Gundersen was able to make out, being unacquainted with Dutch and Dutch writing of 300 years ago. The paper is in excellent preservation,

and the writing distinct. Barent passed the winter 1596-97 in the Arctic regions. This journal, therefore, relating presumably to 1580, will give no information of his stay, but will, nevertheless, be of great interest.'"

WE learn from *Harper's Weekly* that the Kirtland School of Natural Sciences, established in Cleveland, Ohio, for summer instruction in natural history, concluded its course on the 9th of August last. The school consisted of twenty members, of whom thirteen were ladies, and lasted for five weeks, during which time gratuitous instruction was given by lectures and otherwise, and short excursions were made in connection with the subjects of study. Dr. Newberry, Prof. Theodore B. Comstock, Prof. Albert Tuttle, and Dr. William K. Brooks were the instructors. The operations of the school were mainly conducted by Prof. Comstock. Facilities were extended by railroad and steamboat companies in the transportation of the school and in various interesting excursions.

IN a recent number of the *Philadelphia American Times*, Dr. W. W. Keen proposes the employment of a solution of chloral as a preservative for objects of anatomy and natural history, its special advantage being said to be that the colour of objects is perfectly preserved, and all the parts retain their natural consistency, at the same time that no special precaution is necessary in stoppering the bottles containing the preparations. It is used by injecting it into the blood-vessels, or by immersion.

IN a recent number of the *Journal de la Société centrale d'Horticulture de France*, there is an article by M. Ch. Royer, "On the Causes of the Sleep of Flowers." The sleep of flowers has been attributed to various causes, including heat, light, moisture, dilatation of the epidermis of the inside of the perianth, contraction of the outside of the perianth, &c. The writer of the article in question endeavours to prove that expansion of the flowers in the morning is due to a turgescence of the parenchyma of the flower, brought about by heat, certainly; but the same agent indirectly causes the same flowers to close up again, after the disappearance of the swelling through evaporation. This, he contends, accounts for the early closing of flowers under a high temperature, or in dry soils. We have always understood that this phenomenon was governed by the hygrometrical conditions of the atmosphere.

THE *Revue des Eaux et des Forêts*, 1875, gives some statistics of the constituents of the forests of Denmark. The beech is now the most universal, having gradually succeeded in displacing the oak and pine. Next in order are the birch, alder, aspen, hazel, &c. Although at a very remote period pines appear to have formed the principal forests of Denmark, they are not now indigenous, nor have they been for many centuries; indeed, they do not thrive when introduced. According to the celebrated Danish geologist, M. Forchhausmer, the beech grows best in the formation which he calls *argile caillouteuse*, or *argiles à blocs erratiques*; whereas the oak prefers the *sable caillouteuse*, or *sable à blocs erratiques*. An examination of the vegetable remains in the bogs so common in Denmark reveals the fact that the earliest forests were composed of pines, followed by the sessile-fruited variety of the oak, now to a great extent superseded by the beech, &c. It is supposed that the pine forests flourished during the *âge de la pierre à éclats*; and the oak was at its greatest development at the commencement of the bronze age.

AMONGST the several ameliorations which are in preparation at the Ministry of Public Instruction in France, is the remodelling of the *baccalaureat* in a manner which is likely to benefit the study of medicine and the spread of the study of science. The *baccalaureat* of sciences is to be required as formerly from students in medicine; but after having passed a general examination for their first *baccalaureat* they will be examined in a second *baccalaureat* of *sciences physiques*, which includes not only physics, but general notions of botany, zoology, mineralogy, &c. The general *baccalaureat* is common to students in medicine and in mathematics, the students of the latter branch having to pass a special examination of their own entitled *Baccalaureat des Sciences Mathematiques*.

WE believe that the Belgian Government is about to establish tide gauges on the Escault, and to undertake complete researches on the tides and currents of the coasts of Belgium generally. Prof. Van Rysselberghe, the inventor of the self-recording meteorograph, to which we have already called attention, has been attached to the Hydrographic Department, with a view of aiding in these researches.

WE would direct the attention of our biological readers to a translation from the *Berliner Klinische Wochenschrift*, in the current number of the now monthly *London Medical Record*, of a paper by Dr. Scheele, of Dantzig, on two cases of complete transposition of the viscera, together with valuable observations and references on the subject generally.

AN interesting ceremony recently took place at Estagel, a small country town in the Department of the Pyrenees, where the great Arago was born. The local authorities and an immense number of people have celebrated the tenth anniversary of the erection of a statue of that astronomer. No scientific speaker was present, and Arago was merely eulogised in general terms for his science as well as for his patriotism.

THE vanilla plant has lately been attacked by a disease which has greatly interfered with its cultivation. Chemistry has been brought to bear in the production of a new substance from which the "vanilla essence" is produced. Messrs. Hartig and Kubel, two German chemists, have found in the *cambium* of conifers a species of resin which, after certain processes, produces an aroma exactly similar to that of the vanilla, and which possesses the same composition as that of the true vanilla essence itself. This *pseudo* vanilla is sold largely in Germany for the real article; its price is about two-thirds that of the true vanilla essence.

ON Tuesday last there was a private view of the works of the Westminster Aquarium and Winter Garden. From their unfinished state it was not possible to form an accurate idea of the contemplated arrangements, but the considerable area already occupied or to be covered with buildings struck everybody. At the luncheon subsequently given the Managing Director made a speech, in which much was said about science and intellectual enjoyment. Undoubtedly the Company will have a powerful engine at its disposal either for instruction or amusement.

NO. 3, vol. iv., of the Proceedings of the Geological Association, contains, besides pleasant descriptions of some excursions, the following papers:—"On the deposits now forming in British seas," by G. A. Lebour; "Notes on specimens of Phosphorate from the Department of the Lot, France," by F. W. Rudler; "A probable origin of the perforation in sharks' teeth, from the Crag," by H. A. Burrows; and "On the conditions of animal life in the Deep Sea bottom," by Dr. W. B. Carpenter.

THE additions to the Zoological Society's Gardens during the past week include two Bonnet Monkeys (*Macacus radiatus*) from India, presented by Mr. Turnbull; a Macaque Monkey (*Macacus cynomolgus*) from India, presented by Mrs. Knight; two Common Wolves (*Canis lupus*) from Russia, presented by Mr. Charles Bell; a Chinese Mynah (*Acridotheres cristatellus*) from China, presented by Mr. J. R. France; two Rattlesnakes (*Crotalus durissus*) from N. America, a Long-nosed Crocodile (*Crocodilus cataphractes*) from W. Africa, received in exchange; five Russell's Vipers (*Vipera russelli*) born in the Gardens.

SOME LECTURE NOTES UPON METEORITES

NOWHERE in the "Cosmos" does Alexander von Humboldt show more vividly his keen appreciation of all the grander operations of nature than in those passages in which he discusses the subject of meteors, and in which he gives us a forecast of the connection of those striking and still not entirely explained phenomena with other celestial spectacles, such as the apparition of comets and the fall of meteorites.

Thus Humboldt dwells with a lingering interest on the subject of the meteoric showers which in their grandest form, on at least one, and generally on some successive Novembers in every generation, and in a less brilliant degree on every 10th of August, illuminate the sky with countless lines of momentary light. And while bringing the occurrence of these swarms of meteors with much vividness before our eyes, he treats them as a special form of the same display presented by the single meteor, that, gliding down the sky, leaves its thread of light to illuminate a few degrees of the great arc described on the dome of heaven by the meteor; nor does he hesitate to link these phenomena into one series with those larger meteoroids that we call fireballs, and which sometimes light up the whole heavens, and may occasionally be seen over half a continent. And we may go on with Humboldt to connect with these greater meteors a class of still more striking phenomena accompanying the descent generally out of a dark cloud when seen in daylight, or with a bright flame, when seen by night, of meteoric stones, heralded by sounds as of thunder.

Within the last few years the cases of recurring periods of meteoric showers have been considerably multiplied, while these and the comets have been recognised by astronomers as belonging to the same order of celestial objects: and we are now enabled to group the whole of the phenomena we are considering under a single category with a confidence far greater than that on which Humboldt built his surmise regarding them.

It is with the meteoric bodies that fall from out of a cloud when seen by day, and in fiery mass where the light can be distinguished, and accompanied by detonations like cannon, that we are going more immediately to deal here; and it may be well therefore, without recalling the descriptions that may be found in many treatises of some of the more familiar meteoric falls, such as those of L'Aigle and of Braunau, to recount the evidence of eye-witnesses of these events on other occasions. The following is a contemporary account of the fall of a shower of stones in the county of Limerick, at Adare, on Sept. 10, 1813:—

"Friday morning, the 10th September, 1813, being very calm and serene, and the sky clear, about 9 o'clock, a cloud appeared in the east, and very soon after I heard eleven distinct reports, appearing to proceed thence, somewhat resembling the discharge of heavy artillery. Immediately after this followed a considerable noise not unlike the beating of a large drum, which was succeeded by an uproar resembling the continued discharge of musketry in line. The sky above the place whence this noise appeared to issue became darkened and very much disturbed, making a hissing noise, and from thence appeared to issue with great violence different masses of matter, which directed their course with great velocity in a horizontal direction towards the west. One of these was observed to descend; it fell to the earth, and sank into it more than a foot and a half, on the lands of Scagh, in the neighbourhood of Patrick's Well, in the county of Limerick. It was immediately dug up, and I have been informed by those that were present, and on whom I could rely, that it was then warm, and had a sulphurous smell. It weighed about 17 lbs., and had no appearance of having been fractured in any part, for the whole of its surface was uniformly smooth and black, as if affected by sulphur or gunpowder. Six or seven more of the same kind of masses, but smaller, and fractured, as if shattered from each other or from larger ones, descended at the same time with great velocity in different places between the lands of Scagh and the village of Adare. One more very large mass passed with great rapidity and considerable noise at a small distance from me; it came to the ground on the lands of Brasky, and penetrated a very hard and dry earth about two feet. This was not taken up for two days; it appeared to be fractured in many places, and weighed about 65 lbs.! Its shape was rather round, but irregular. It cannot be ascertained whether the small fragments which came down at the same time corresponded with the fractures of this large stone in shape or number, but the unfractured part of the surface has the same appearance as the one first mentioned. There fell also at the same time, on the lands of Faha, another stone, which does not appear to have been part of or separated from any other mass; its skin is smooth and blackish, of the same appearance with the first-mentioned; it weighed above 74 lbs.; its shape was very irregular. This stone is in my possession, and, for its volume, is very heavy.

"There was no flash of lightning at the time of, or immediately before, or after the explosion; the day continued very calm and serene, was rather close and sultry, and without wind or rain. It is about three miles in a direct line from the lands of Brasky, where the very large stone descended, to the place where the small ones fell in Adare, and all the others fell intermediately; but they appeared to descend horizontally, and as if discharged from a bomb and scattered in the air."

The next account is that of a stone that fell at Durala, or Dooralla, on February 18, 1815.

Extracts from a Letter from Capt. G. Bird.

"Loodiana, April 5, 1815.

"On the 18th February last, some people who were at work in a field about half a mile distant from the village of Dooralla were suddenly alarmed by the explosion of what they conceived to be a large cannon, 'the report being louder than that of any other gun they had ever heard,' which report was succeeded by a rushing noise like that of a cannon ball in its greatest force. When looking towards the quarter whence the noise proceeded, they perceived a large black body in the air, apparently moving directly towards them, but, passing with inconceivable velocity, buried itself in the earth at the distance of about 60 paces from the spot where they stood. The Brahmins of the village, hearing of it, proceeded to the spot with tools for digging it up. They found the surface broken, and the fresh earth and sand thrown about to a considerable distance, and at the depth of rather more than 5 ft. in a soil of mingled sand and loam they found the stone, which they cannot doubt was what actually fell, being altogether unlike anything known in that part of the country. The Brahmins conveyed it to the village, covered it with wreaths of flowers, and started a subscription for the purpose of raising a small temple over it. It fell on the 18th of February, about mid-day, in a field near the village of Dooralla, which lies about lat. 30° 20′, long. 76° 41′, within the territory belonging to the Pattialah Rajah, 16 or 17 miles from Umballa, and 80 from Loodiana. The day was very clear and serene, and, as usual at that season of the year, not a cloud was to be seen, nor was there in the temperature of the air anything to engage their attention; the thermometer of course may be stated about 68° in the shade. The report was heard in all the circumjacent towns and villages, to the distance of 20 coss, or 25 miles, from Dooralla. The Rajah having been led to consider it as a messenger of ill omen, according to my wish gave immediate orders for its conveyance to Loodiana, but with positive injunctions that it should not approach his place of residence. It weighs rather more than 25 lbs., and is covered with a pellicle thinner than a wafer, of a black sulphureous crust, though it emits no smell of sulphur that I can discover. It is an ill-shapen triangle, and from one of the corners a piece has been broken off, either in its fall or by the instruments when taken out of the ground. This fracture discloses a view of the interior, in which iron pyrites and nickel are distinctly visible. No Hindoo ventures to approach it but with closed hands in apparent devotion, so awful a matter is it in their eyes."

This aërolite was brought from India by Lieut.-Col. Pennington, and presented to the Hon. East India Company. It is now in the British Museum.

The next description is that of the fall of a stone at Manegaum, in Kandeish, on June 29, 1843. The account is given by two Hindoo eye-witnesses:—

"On the day the aërolite fell we were both seated, about 3 o'clock in the afternoon, on the outskirts of the village, in a shed belonging to Ranoo Patel. There was at the time no rain, but heavy clouds towards the northward. There had been several claps of thunder for two hours previously, and some lightning. Suddenly, while we were seated in the shed, several very heavy claps of thunder occurred in quick succession, accompanied with lightning, on which we both went out to look around us, when, in the middle of a heavy clap, we saw a stone fall to the ground in a slanting direction from north to south, preceded by a flash of lightning. It fell about 50 paces from us. On going up to it we found that it had indented itself some four or five inches into the ground; it was broken in pieces, and, as far as we could judge, appeared to be about fifteen inches long, and three inches in diameter, of an oblong shape, somewhat similar to a Chouthe grain

measure; it was of a black vitreous colour outside, and of a greyish yellow inside; it was then of a mouldy texture, and hardened to the consistence of the present specimens afterwards.

"Only one stone fell. No rain had fallen for eight days previously, nor did it for four days after the fall of the stone. It had been warm all day before, but not much more so than usual. From mid-day till the time the stone fell (3 P.M.) it was very cloudy towards the northward; after its fall the thunder ceased, and the clouds cleared away. No stone of a similar description had ever fallen near our village before. The pieces of the stone were immediately after carried off by the country people. Our village is situated on the banks of the small river, the Poorma. There are no hills in its vicinity, the nearest being 3 coss (or 6 miles) off."

Finally, we may extract from the contemporary notices published in the United States, the more remarkable circumstances attending the fall of a great number of aërolites at New Concord, U.S.A.:—

"About fifteen minutes before one o'clock, May 1, 1860, the people of South-eastern Ohio and North-eastern Virginia were startled by a loud noise. . . . . The area over which the explosion was heard was probably not less than 150 miles in diameter. . . . . An examination of all the different directions leads to the conclusion that the central point from which the sound emanated was near the southern part of Noble County, Ohio. . . . .

"Twenty-three distinct detonations were heard, after which the sounds became blended together, and were compared to the rattling fire of an awkward squad of soldiers, and by others to the roar of a railway train. These sounds, with their reverberations, are thought to have continued for two minutes. The last sounds seemed to come from a point in the south-east, 45° below zenith. The result of this cannonading was the falling of a large number of stony meteorites upon an area of about ten miles long by three wide. The sky was cloudy, but some of the stones were seen first as 'black specs,' then as 'black birds,' and finally falling to the ground. A few were picked up within twenty or thirty minutes. The warmest was no warmer than if it had lain on the ground exposed to the sun's rays. They penetrated the earth from 2 ft. to 3 ft. The largest stone, which weighed 103 lbs., struck the earth at the foot of a large oak tree, and after cutting off two roots, one 5 in. in diameter, and grazing a third root, it descended 2 ft. 10 in. into hard clay. This stone was found resting under a root which was not cut off. This would seemingly imply that it entered the earth obliquely. It is said that other stones which fell in soft ground entered the earth at a similar angle. They must have been flying in a north-west direction. This fact, added to the other facts, that the detonations heard at New Concord came lower and lower from the zenith toward the south-east, and that the area upon which the stones fell extends with its longer axis in a south-east and north-west direction, would imply that the orbit of the meteor, of which these stones are fragments, extended from south-east to north-west. This conclusion is confirmed by the many witnesses who saw at the time a luminous body moving in the same direction. It is a fact of some interest that the larger stones were carried by the orbital force further than the small ones, and were found scattered upon the north-west end of the area referred to.

. . . .

"Prof. Evans computes, from data supplied by several reliable witnesses, the altitude of the meteor when first seen to range between thirty-seven and forty-four miles.

. . . .

"A train accompanying the stones is described as a cone, having its base upon a fire-ball. As seen from near Parkersburg its length was estimated at twelve times the diameter of the ball. The part next the base appeared as a white flame, but not so bright as to render the outline of the ball indistinct. About half way toward the apex it faded into a steel blue.

. . . .

"Near McConnellsville several boys observed a huge stone descend to the earth which they averred looked like a red ball, leaving a line of smoke in its wake." McConnellsville is twenty-five miles south of Concord.

. . . .

Another observer at Berlin saw a ball of fire flying in a northerly direction with great velocity. It appeared as white as melted iron, and left a bright streak of fire behind it which soon faded into a white vapour. This remained more than a minute, when it became crooked and disappeared. Berlin is about 80 miles south-west of Concord.

Now, these and other descriptions of similar events witnessed by people in different parts of the world substantially agree. In some minute circumstances they naturally differ, as doubtless do also the events themselves or the conditions under which they are witnessed. The appearance of a cloud at a great elevation, its rapid motion, the emanation from it of masses of matter ultimately falling to the earth, the association with these appearances of a fiery light forming a splendid spectacle that lights up the heavens by night and in twilight, and is often also seen by day; the trail that follows the great meteoroid mass, and lingers on the air in the form of a long-drawn film of cloud that remains luminous by night for some short period after the passage of the luminous ball or cone,—are phenomena to which witness is borne in many cases besides the last above recorded. Testimony is also concurrent on the loudness and repetition of detonations that accompany these phenomena, irrespectively of their multiplication by the effect of echo. In the case of a group of meteorites that fell at Butsura, in India (near Goruckpore), on May 12, 1861, we have evidence of three different explosions.

Now, for some parts of the phenomena thus recorded we can offer satisfactory explanations, though of other parts of them the explanations hitherto offered may seem not quite so complete.

First, we have the enormous velocity with which such a body comes into our atmosphere, sufficient in some cases to bear the meteorite through the distance from London to Edinburgh in as many seconds as an express train takes hours; and where the body enters our atmosphere that medium is so rare that we can hardly conceive it presenting any resistance; yet even at that enormous elevation—certainly in many cases as much as forty miles above the earth, where the meteor enters this fine atmosphere—there cannot be a doubt that the atmospheric resistance at once called into play is sufficient to impede the body that enters it with so enormous a velocity. And by virtue of a principle which is now an axiom of science, this arresting of the velocity of the meteorite means calling into activity intense heat that is largely imparted to the meteorite itself—heat, in fact, that is proportional to the velocity for which it is exchanged.

Now, these meteoric masses must often come into our atmosphere, not individually, but in swarms. From the rapidity with which the heat is developed, and partly also as a consequence of the low conductivity for heat of the stony masses, their surface only has time to experience the effects in the few seconds of transit, and therefore only the surface fuses; and, as a consequence of this fusion, there arises a sort of spray of meteoric dust flung off from the meteorite or from the meteoric swarm; and this forms a cloud, such as may be seen lingering on the track of almost any large meteor that is visible by daylight. To the material nature of such a cloud as it rests, or rather, though rapidly falling, seems to rest, poised in the air, the writer can bear personal testimony, having witnessed it in the train of a fine meteor many years ago, about sunset. When the ordinary clouds had long ceased to be tinted by the rays of the evening sun, as in the after-glow on the Alps, the long line of meteoric cloud became lit up with rose-tinted hues, and bending into a curve towards the east before an upper current of air, offered proof beyond question of the material nature of this cloud, and at the same time of its great elevation and the fine state of division of its dust-like particles, which undoubtedly resulted from the disintegration of the meteoric mass in its passage through the air. The same cloud of dust is often visible as a luminous trail by night, in consequence partly of its retaining its incandescence for a certain time, but probably also in part from the phosphorescence of its material. We are thus able to offer an undoubtedly true explanation of one part of the spectacle.

The existence in the crust of a meteorite of projecting particles of unoxidised meteoric iron, and, in the case of the Busti meteorite, of calcium sulphide unaltered, is explained by the momentary character of the process which during the flight of the meteorite perpetually removes the outer surface and exposes a fresh one, which, however, is always screened by a protecting glaze of fused silicate from the immediate action of the air, so long as there is velocity enough left to the mass thus to fuse and to throw off in its wake fresh portions of its surface; while in the later stage of its flight the glaze accumulates into a denser crust highly charged with magnetic iron oxide, mainly the result of the oxidation of the iron of the silicates.

The cause or causes of the explosions are more difficult to demonstrate. They have been accounted for in two separate ways, which, though different, are not inconsistent, and are both probably involved in a complete explanation of the disruption and detonations. Why should a meteorite explode with a repor

which could be heard forty or fifty miles away? Nay, why should it explode at all?

One answer is this. The aërolite comes into our atmosphere from regions in which the temperature, "the cold of space," may range as low as 140° below zero Centigrade; and though the mass, from the absorption of solar heat, would possess a temperature much above this, it would nevertheless be intensely cold, and consequently more brittle than at ordinary temperatures; and hence, on its entering our atmosphere, the heat it instantaneously acquires on its outer portion expands this, and tends to tear it away, so as to dissever the exterior from the interior, which continues to be relatively contracted by the intensity of the cold which the aërolite brings with it from space. The consequence is, first, that little bits of the stone spring out all over it, leaving those curious little holes or pit marks which are characteristic of a meteorite; and every now and then, as the heat penetrates, larger masses split away, of which interesting evidence is afforded by the meteorite, for instance, that fell at Butsura on May 12, 1861. Fragments of this stone were picked up three or four miles apart; and by supplementing them by a small piece modelled to fill up one lacuna, one is able to build up again with much certainty the original meteorite, or at least the portion of it represented by the fragments of it which were found. Important portions of this stone are in the British Museum, presented some years ago by the liberality of that invaluable institution, the Asiatic Society of Calcutta. Now, it is remarkable that these fragments, which in other respects fit perfectly together, are, even on the faces of junction, now coated with a black crust. On the other hand, another of these fragments not thus coated fits like the former to a part of the meteorite that was found some miles away rom it, and is also not incrusted at the surface of fracture. Hence we can assert that this aërolite acquired after coming into our atmosphere a scoriated and blackened surface or incrustation. The first explosion drove the fragments first alluded to asunder, and these became at once incrusted on their broken surfaces; but others that were separated afterwards, probably on the last of the three explosions, had not sufficient velocity left to cause their incrustation in the same manner as was the case with the fragments previously severed. Now, this successive incrustation of the fragments of the meteorite confirms the idea that the disruption of the mass, and the explosions heard for so vast a distance as Goruckpore (some sixty miles), are parts of the same convulsion; and sixty miles is by no means an uncommon distance for the sound of such a meteoric explosion to be heard.

The late W. von Haidinger (to whom we are indebted for a collation of the facts and for valuable suggestions bearing on this subject) threw out the notion that what really produced the detonation was not the disruption of the mass (which he held not to be a sufficient cause for so loud a report) so much as the collapse of the air into a vacuum which, after following the meteorite as it pursued its rapid course, suddenly ceased to exist as the velocity of the meteorite became practically reduced to zero.

But it still would remain to be explained why at one time more than another this collapse of the vacuum should take place, or how it could be repeated; of this, however, a sufficient explanation would seem to be afforded by the actual bursting asunder of the meteorite from the cause before assigned, since this explosion, by disturbing the conditions on which the persistence of the vacuum depends, would permit the collapse of the air and consequent detonation.

(To be continued.)

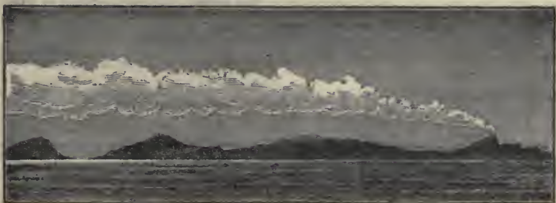
OBSERVATIONS ON A REMARKABLE FORMATION OF CLOUD AT THE ISLE OF SKYE*

THE resistance offered by the earth's surface to the wind is known to reduce its velocity and to cause deviations in its direction both horizontal and vertical, as well as to retard the progress of the storm itself. This friction to which aërial currents are subjected is probably least for a surface of water such as the sea—greater for plains of loose sand, where, as in the Nubian deserts, lofty sand pillars are produced—and greater still where the surface is immoveable, as in the case of solid land; but the greatest resistance of all is due to the obstruction offered by rugged hills and lofty mountain-ranges.

In an account of the Morayshire easterly storm of September 1871; published in the *Scottish Meteorological Journal*, I suggested that the great amount of rainfall which fell on that occasion at and near the Morayshire coast, and on the sea-coasts of the counties of Fife and East Lothian which also fronted this storm, was due to the sudden increase of friction which the wind encountered when it reached the land. The in-shore stream of air being checked by the unyielding nature of the shore, even though it was, as in this case, of no great elevation, would form a pillow of obstructed or perhaps nearly stationary air, which would produce vertical deflection on the strong currents coming in from the sea. The stream of air thus projected upwards to a height where the temperature is lower would be condensed into vapour and rain.

This sudden change of resistance to in-shore winds is probably one of the causes of the well-known peculiarity of seaside climates.

On the 27th July last, about 11.30 A.M., when in the steamer of the Northern Lighthouses off the Sound of Harris, I saw a beautiful example of the genesis of clouds—due, however, not to



a low foreshore, but to hills of about 900 feet high. The sky was perfectly clear, with a steady but very slight breeze from the S.W., which came straight upon the south-western extremity of the Island of Skye, distant about twelve miles from the ship. A small portion of the most southerly projection of the island, which was considerably lower than the more inland parts, was perfectly free from vapour, but at a short distance inland from the shore, there was an abrupt face of hill, from the top of which there rose a very slender column of white vapour which gradually expanded as it ascended into the air, presenting exactly the appearance of the escape of steam from the spiracle of a volcano. The cloud thus formed not only extended as far as the northern extremity of Skye—itself a distance of twenty-eight miles—but was visible as a well-defined stratum of cloud for a long distance beyond Skye, so that its whole length must have considerably exceeded forty miles, beyond which distance it became more diffuse and attenuated. Had I not known to the contrary, I should undoubtedly have believed that what I saw was due to volcanic eruption.

The vapour caused by the lower temperature of the atmosphere at the level of the top of the bluff face was obviously carried away by the breeze gradually as it was formed, thus producing by a continuous process of generation the long extent of cloud which I have described. This fact shows that clouds may be due to deflections produced by irregularities on the earth's surface far remote from the place where we actually see them. I may mention, in proof of the steady nature of the breeze and of the entire absence of any vertical disturbance in

* By Thomas Stevenson, F.R.S.E.

the atmosphere, that later in the day we traced the smoke from the steamer's funnel for a distance of nearly fifteen miles.

The accompanying woodcut is from a sketch which I made on board the vessel at the time, and I doubt not will be interesting to your readers.

SCIENTIFIC SERIALS

Zeitschrift der Oesterreichischen Gesellschaft für Meteorologie, August 15.—This number contains a description, with diagrams, of Theorell's printing meteorograph, a very ingenious instrument, likely to be of much service in meteorology. It differs from other meteorographs in this, that instead of tracing curves, which have to be afterwards translated into figures, it prints the figures at once, thus saving much future trouble. One of the three already made has been in use at the Royal Observatory of Vienna since September 1874, and has been so adapted as to record, by electric communication, the state of the following instruments, placed in any situation: anemometer, vane, wet and dry thermometers, and barometer, once in every quarter of an hour. The moving force is a galvanic current connected with a clock. Dr. Theorell's account of the instrument referring to the plates will be continued in the next number of the *Zeitschrift*. In the "Kleinere Mittheilungen" Prof. Hoffmann, of Giessen, compares the sum of the daily maxima of solar radiation in several years with the time of the flowering of certain plants. His results in 1875 bear out his expectations derived from four previous years' observations, 1866-69, and in certain cases his forecast of the time of flowering was nearly correct.—There is besides a paper by Dr. Schreiber on a new registering air thermometer; also a letter from Mr. Ferrel on the theory of storms.

Jahrbuch der Kais.-kön. Geologischen Reichs-Anstalt, Band 24, heft iv.—Nearly all this part of the *Jahrbuch* is occupied by the second part of Dr. Guido Stache's elaborate memoir on the Palæozoic regions of the eastern Alps. In this part he summarises all that is known respecting the geology of the western slopes (Cadoric Alps) of the area embraced in his review.—The only other paper is one by M. V. Lipold—"Explanation of the geological map of the environs of Idria, in Carniola." A coloured map and plate of horizontal sections accompany the paper.—In Dr. Tschermak's "Mineralogische Mittheilungen" Dr. R. v. Drasche concludes his paper, entitled "Petrographic-geological Observations on the West Coast of Spitzbergen." The editor describes the *Labradorite* of Verespatak; and a notice of two other minerals, *Famatinite* and *Wapplerite*, is given by A. Frenzel.

THE *Boletin de la Academia Nacional de Ciencias exactas en la Universitad de Cordova* (*South America*), Entrega iii., 1874, contains some papers of interest. We note the following:—On the chemical composition of the water of the La Plata River, by Señor Kyle.—On the formation of saline deposits, by D. Fred. Schickendantz.—On the chemical and physical action which took place in the formation of the pampas of Cordova, by Dr. A. Doering.—Critical notices on some entomological publications, by Dr. D. C. Berg.

THE *Annali di Chimica applicata alla Medecina* (August) contain the following papers of note:—On salicylic acid, by Dr. D. Gibertini.—Note on chloral-santonine, by C. Pavesi.—On the health of smokers, by Dr. Bertherand.—On the substitution of iron shot for lead shot for the purpose of cleaning bottles in hospitals, barracks, &c., by Sig. Fordos.—On the comparison of human milk with cows' milk with regard to the nutrition of infants, by Ph. Biedert.—A number of papers of minor interest.

SOCIETIES AND ACADEMIES

VIENNA

Imperial Academy of Sciences, July 15.—On the solubility of calcic chloride in water, by H. Hammerle.—On the decrease in the temperature of the maximum of density of water through pressure, by C. Puschl.—On the system of vessels of the tube-bones, with notes on the structure and development of bones, by C. Langer.—Researches on the capacity of gas-mixtures for conducting heat, by J. Plank.—On the theory of the composite eyes and the seeing of motions, by Dr. S. Exner.—On the graduation of induction apparatus, by Dr. E. Fleischl.—Researches on the motion of the imbibition-water in wood and in the membrane of the vegetable cell, by Prof. Wiesner.—On the morphology and biology of Lenticellæ, by G. Haberlandt.—Meteorological observations made at Hohe Warte, near Vienna.

July 22.—(Last meeting before holidays).—Remarks on the variations in the velocity of light passing through quartz which is subjected to pressure, by J. Merten.—The Crustacea, Pygnogonida, and Tunicata of the Austro-Hungarian North Polar Expedition, by C. Heller.—On the finer structure of bone substance, by Prof. von Ebner.—On the construction of the reflection goniometer, by Prof. von Lang.—(The next meeting will take place on Oct. 14.)

K.K. Geologische Reichsanstalt, May 31.—Report from Dr. O. Lenz on his travels in Africa.—On the occurrence of marine petrefacts in the Ostrau layers, by D. Stur.——On the coal deposits of Drenovec, by Dr. R. Hörnes.

June 30.—On the Island of Kos, by Dr. M. Neumayer.—On fresh-water strata amongst the Sarmatic deposits near the Sea of Marmora, by Dr. R. Hörnes.—On the landslip near Unterstein, on the Salzburg-Tyrol Railway, by H. Wolf.

July 31.—On some fossil plants from India, by O. Feistmantel. On the formation of the terra rossa, by Th. Fuchs.—On mountain folds, by the same.—On secondary infiltrations of carbonate of lime into loose and porous formations, by the same.—Report by D. Stur on his travels in Silesia.—On the fauna of the Schliers of Ottnang, in Upper Austria, by R. Hörnes.

STOCKHOLM

Kongl. Vetenskaps Akademiens Förhandlingar, March 10.—The following papers were read:—Genera et species Lithobioidarium disposuit, by A. Stuxberg.—Review of all Lithobioidæ hitherto known in North America, by the same.—Report on the bryological researches in Norway during 1874, by C. Hartman.—On the moss flora of Lulea (Lappmark), by P. J. Hellbom.—On the observation of two crossing rainbows, by O. Gumaelius, with some remarks on the same, by R. Rubenson.

April 14.—On the marine Entomostraca collected during the Swedish Scientific Exhibition to Spitzbergen, by W. Lilljeborg.—On the formation of the smaller bays, of the river valleys, of lakes, and of sea banks, by A. Helland.

GÖTTINGEN

Nachrichten von der königl. Gesellschaft der Wissenschaften, Aug. 7.—The following papers were read:—On lens fibres, by Prof. J. Henle.—On the linear differential equations of the second order which possess algebraic integrals, and on a new application of the "invariant" theory, by Prof. L. Fuchs.

THURSDAY, OCTOBER 7, 1875

THE ASTRONOMY OF THE BABYLONIANS

THE astronomical science of the ancient Babylonians and their pupils, the Assyrians, was neither so profound nor so contemptible as has often been maintained. Now that we are able to read the native records written in the cuneiform or wedge-shaped character, we find that the progress made at a very early period in mapping out the sky, in compiling a calendar, and above all in observing the phenomena of the heavens, was really wonderful, considering the scanty means they possessed of effecting it. Certainly their astronomy was mixed up with all kinds of astrological absurdities, but this did not prevent them from being persistent and keen observers, whose energy in the cause of knowledge is not undeserving of imitation even in the present day.

The originators of astronomy in Chaldea, as indeed of all other science, art, and culture there, were not the Semitic Babylonians, but a people who are now generally termed Accadians, and who spoke an agglutinative language. They had come from the mountains of Elam or Susiana, on the east, bringing with them the rudiments of writing and civilisation. They found a cognate race already settled in Chaldea, and in conjunction with the latter they built the great cities of Babylonia, whose ruins still attest their power and antiquity. Somewhere between 3000 and 4000 B.C. the Semites entered the country from the east, and gradually contrived to conquer the whole of it. It is probable the conquest was completed about 2000 B.C. At all events, Accadian became a dead language two or three centuries later, but as the Semitic invaders owed almost all the civilisation they possessed to their more polished predecessors, it remained the language of literature, like Latin in the Middle Ages, down to the last days of the Assyrian Empire.

Astronomy was included in the branches of science borrowed by the Semitic Babylonians from the Accadians. Consequently their astronomical records contain many words which belong to the old language, while most of the stars bear Accadian and not Semitic names. Even where the Assyro-Babylonians had a technical term of their own, like *kasritu*, "conjunction," they continued to *write* the old Accadian word *ribanna*, of which *kasritu* was a translation, though they probably *pronounced* it *kasritu*, just as we pronounce *viz.* "namely."

The oldest Chaldean astronomical records of which we know are contained in a great work called "The Observations of Bel," in 70 books, compiled for a certain King Sargon of Agané, in Babylonia, before 1700 B.C., and of which we possess later copies or editions, made for the Library of Sardanapalus at Nineveh. The catalogue of this work shows that a great part of it was purely astrological; other books, however, were more scientific. Thus there was one on the conjunction of the sun and moon, another on comets, or, as they are called, "stars with a corona in front and a tail behind," a third on the movements of Mars, a fourth on the movements of Venus, and a fifth on the Pole-star.* The catalogue concludes with a curious intimation to the student, who is told to write down the number of the tablet or book he wishes to consult, and the librarian will thereupon hand it to him. The larger portion of the work itself has been recovered, though some of the tablets belonging to it still lie under the soil of Kouyunjik, and a good part of the details which follow is extracted from this primitive Babylonian treatise.

The Accadians seem to have begun their astronomical observations before they left Elam, since the meridian was placed in that country, while the old mythology made "the mountain of the East" the pivot on which the sky rested. This will account for the large number of eclipses recorded in the "Observations of Bel," which imply a corresponding antiquity for the commencement of such records. These records were carefully kept, as there were State Observatories in most of the Babylonian and Assyrian towns—at Ur, Agané, Nineveh, and Arbela, for instance—and (at all events in later times) the astronomers royal had to send fortnightly reports to the King.

It is to the Accadians that we owe both the signs of the Zodiac and the days of the week. The heaven was divided into four parts, and the passage of the sun through these marked the four seasons of the year. A tablet brought home by Mr. Smith informs us that the spring quarter lasted from the 1st of the month Adar to the 30th of the month Iyyar (that is, from the 1st degree of Pisces to the 30th degree of Taurus), the summer quarter from the 1st of Sivan to the 30th of Ab (the 1st degree of Gemini to the 30th of Leo), the autumn quarter from the 1st of Ebul to the 30th of Marchesvan (the 1st degree of Virgo to the 30th of Scorpio), and the winter quarter from the 1st of Chisleu to the 30th of Sebat (the 1st degree of Sagittarius to the 30th of Aquarius). The fact that the spring quarter did not commence with the beginning of the year in Nisan or March, shows that the scheme was subsequent to the formation of the calendar.

The year was divided into twelve lunar months and 360 days, an intercalary month being added whenever a certain star, called "the star of stars," or *Icu*,* which was just in advance of the sun when it crossed the vernal equinox, was not parallel with the moon until the 3rd of Nisan, that is, two days after the equinox. This, however, did not always suffice to keep the seasons in order, and the calendar had more than once to be rectified by the intercalation of other so-called months, consisting of a few days each. Cycles of twelve solar years were also in use, during which the same weather was expected to recur. The day was divided into twelve *casbumi*, or "double hours," each of these being further subdivided into sixty minutes and sixty seconds. The month, too, was cut into two halves of fifteen days, each subdivided into periods of five days, though a week of seven days was also employed from the earliest times. The days of the week were named after the sun, moon, and five planets; and since the 7th, 14th, 19th, 21st, and 28th of the month were termed "days of rest" on which certain works were forbidden to be done, it is clear that the origin of our modern week must be referred to the ancient Chaldeans. The names of the months were taken from the corresponding signs of the Zodiac, and as the Zodiac

* That is, α Draconis.

* Called *Dil-gan*, or "messenger of light," in Accadian. It must be identified with τ Arietis, and at a later time with α Arietis.

began with Aries and the year with Nisan, neither the Zodiac nor the Calendar of the Accadians could be earlier than 2540 B.C. This is also indicated by the fact that even as late as the composition of the "Observations of Bel," time is calculated in the case of eclipses, not by the *casbu*, or "double hour"—a word which is Accadian, and not Semitic—but by the older division into three watches. These consisted of four hours each, beginning at 6 P.M. and ending at 6 A.M., and they were called respectively the "evening," "middle," and "morning" watches. Something like an accurate measurement of time was attained by the invention of the clepsydra.

Eclipses of the moon were observed from a very early epoch; but numerous as are the records of them in the great astronomical work of Sargon's Library, the vague and unscientific way in which they are recorded renders them of little value. The usual formula is: "In the month so and so, on the 14th day, an eclipse takes place, beginning on the east and ending on the west: it begins in the middle watch [10 P.M. to 2 A.M.], and ends in the morning watch, the shadow being eastward from the commencement to the cessation of the eclipse." In subsequent times, however, the language of the observatory reports becomes more precise and the gradual progress of an eclipse is carefully described. Long before the reign of Sargon of Agané, the discovery had been made that lunar eclipses recur after a cycle of 223 lunations, and records of them incorporated into the "Observations of Bel" generally begin with the words "According to calculation," or (it may be) "Contrary to calculation, the moon was eclipsed." One of the most curious tablets now in the British Museum is one of lunar longitudes, which seems to have formed part of the great Babylonian work on Astronomy, but, since it is written in Accadian, must be older than 2000 B.C. As a translation of it has not been made before, it is here given in full:—

1.	The 1st day (the moon) advances	5 deg.
2.	The 2nd day ,, ,, ...	10 deg.
3.	The 3rd day ,, ,, ...	20 deg.
4.	The 4th day ,, ,, ...	40 deg.
5.	The 5th day ,, ,, ...	80 deg.
6.	The 6th day ,, ,, ...	96 deg.
7.	The 7th day ,, ,, ...	112 deg.
8.	The 8th day ,, ,, ...	128 deg.
9.	The 9th day ,, ,, ...	144 deg.
10.	The 10th day ,, ,, ...	160 deg.
11.	The 11th day ,, ,, ...	176 deg.
12.	The 12th day ,, ,, ...	192 deg.
13.	The 13th day ,, ,, ...	208 deg.
14.	The 14th day ,, ,, ...	224 deg.
15.	The 15th day ,, ,, ...	240 deg.
16.	The 16th day for 224 deg. of advance it retrogrades*	16 deg.
17.	The 17th day for 208 deg. ,, ,,	32 deg.
18.	The 18th day for 192 deg. ,, ,,	48 deg.
19.	The 19th day for 176 deg. ,, ,,	64 deg.
20.	The 20th day for 160 deg. ,, ,,	80 deg.
21.	The 21st day for 144 deg. ,, ,,	96 deg.
22.	The 22nd day for 128 deg. ,, ,,	112 deg.
23.	The 23rd day for 112 deg. ,, ,,	128 deg.
24.	The 24th day for 96 deg. ,, ,,	144 deg.
25.	The 25th day for 80 deg. ,, ,,	30 deg.
26.	The 26th day for 32 deg. ,, ,,	56 deg.
27.	The 27th day for 23 deg. ,, ,,	12 deg.
28.	The 28th day for 15 deg. ,, ,,	26 deg.
29.	The 29th day for $5\frac{1}{20}$ deg. ,, ,,	$4\frac{2}{3}$ deg.
30.	The 30th day the moon is the god Anu.	

The fractions at the end of the tablet are hard to explain, and it is unfortunate that the month is not named during which the observations were made, and that we have no other tablet of a similar kind to compare with it. It will be noticed that here, as everywhere else in Babylonian mathematics, the soss or 60 was the unit, and also that the path of the moon was divided into 240 (60×4) degrees. This corresponds with an analogous division of the equator into 240°, η Piscium being 60°, γ Piscium (or rather α Pegasi) 80°, and so on. An inner circle was drawn within the equatorial and divided into 120 (60×2) degrees, a line passing through η Piscium being 30°, and 10° being marked for every 20° of the equator. The ecliptic, "the yoke of the sky" as it was picturesquely called, was divided into 360°, 30° for each sign.* It is curious that no trace is to be found of the 28 *nakshatras* or lunar mansions of Hindu and Chinese astronomy which have been so confidently assigned to a Babylonian origin. Should M. Biot, however, be right in holding that there were primarily but 24 of these, the four additional ones being added by the Chinese sage, Cheu-kung (B.C. 1100), it is possible that they might be connected with the 24 zodiacal stars which, according to Diodorus, were called "judges" by the Babylonians, 12 being north and 12 south.

The problem of calculating solar eclipses by tracing the shadow as projected on a sphere had also presented itself at an early period. Like eclipses of the moon, eclipses of the sun are spoken of as occurring either "according to calculation" or "contrary to calculation." In a report sent in to one of the later kings of Assyria by the State Astronomer, Abil-Istar states that a watch had been kept on the 28th, 29th, and 30th of Sivan, or May, for an eclipse of the sun, which did not, however, take place after all. The shadow, it is clear, must have fallen outside the field of observation. Besides the more ordinary kind of solar eclipses, mention is made of annular eclipses, which, strangely enough, are never alluded to by classical writers. It is interesting to find that observations were made as early as the time of Sargon of Agané on the varying colour of the sun, especially at the beginning of the year on the 1st of Nisan. Thus in one place we are told that the sun on that day was "bright yellow," in another place that it was "discoloured" (or rather "spotted").

Of the planets, only Mercury, Venus, Mars, Jupiter, and Saturn were known, besides the earth. These, however, excited great attention, and their phenomena were carefully studied. The movements of Venus and Mars especially attracted notice. Among the names given to Mars was that of "the vanishing star," in allusion to its recession from the earth, just as Jupiter was frequently called "the planet of the ecliptic," from its neighbourhood to the latter. The title of Mars just alluded to, however, raises the very interesting question whether the Babylonians had observed the phases as well as the movements of Venus and Mars. Now a report, taken from the "Observations of Bel," distinctly states that Venus "rises, and in its orbit duly grows in size," and this, in combination with the name of Mars as "the vanishing star," shows plainly that the phases of the two planets must have been noticed. Such a fact necessitates the existence of some kind of telescope,

* Literally, "becomes obscure."

* The Babylonian symbol for a degree was the star ✳).

however rude; and Mr. Layard's discovery of a crystal magnifying lens at Nineveh indicates that such an instrument may have actually been in use.*

The portion of Chaldean astronomy which was concerned with the planets was unnecessarily complicated by the habit of naming them from the fixed stars near which they happened to be at different times of the year, so that the same planet is often spoken of under varying names. Thus *Nibatanu* was properly Altair, but became a very common title of Mars. The number of the fixed stars observed by the Chaldeans was very great, and again suggests the use of something more than the naked eye. The principal stars had individual names, the rest being included in the constellations to which they belonged. In this way the heavens were mapped out long before the idea of a terrestrial atlas had suggested itself. The identification of the Chaldean constellations and fixed stars is of course a work of considerable difficulty, but the modern representatives of several of them have now been determined, and with the help of these and fresh astronomical texts, there is every reason to hope that our knowledge of the celestial globe of the Babylonians will be as complete as it is in the case of the Greeks and Romans.

A. H. SAYCE

COMTE'S PHILOSOPHY

The Positive Philosophy of Auguste Comte, freely translated and condensed. By Harriet Martineau. In Two Volumes, 8vo. Second Edition. (London: Trübner and Co., 1875.)

THE first edition of Miss Martineau's version of the "Positive Philosophy" was published in the autumn of 1853. The considerable space of time which has since elapsed cannot have been due to any defect in the adapter's work. So excellently were the translation and condensation accomplished by Miss Martineau, that Comte substituted her two volumes for his own six volumes, and since Comte's death the work has actually been retranslated into French. It does not give us a great idea of the demand for Comte's works in England, when we find that twenty-two years intervene between the first and second editions. At last, however, the work is re-issued in two handsome volumes, but we are not informed that any alteration at all has been made either in the matter or language of the work, and I have not been able to detect a difference even in a word. The appearance of this new edition nevertheless affords an opportunity for a few remarks upon the value and pretensions of the "Positive Philosophy."

It has been asked "What's in a name?" As regards the positive philosophy, it may be answered that there is a great deal in the name. The name Positive is an admirable *question-begging epithet*. Everything which Comte wished to stamp with his approval, and make a part of his system, he called positive, and a formidable list of new names was invented. We have Positive Philosophy, Positivism, Positivity, Positive Method, Positive Polity, Positive Morality, and even Positive Practices. It would be much more correct to say Comte's Philosophy, Comtism, Comte's Method, Comte's Polity, Comte's Practices, because I believe it is impossible to attribute any invariable meaning to the word Positive, as used by Comte, except that it meant what belonged to his system. Nevertheless, the word was of inestimable value to Comte, because it enabled him to represent all his own views, some being of the most peculiar character, as the natural outcome of the Baconian Philosophy.

We frequently find Comte stating, in the frankest manner, that there was nothing new in the idea of a positive philosophy. Bacon and Descartes (vol. ii., pp. 381, 386, &c.) were the two great legislators of the philosophy. Even the common sense of ordinary thinkers contains all the elements of Positivism, provided that absurd metaphysical and theological ideas do not obscure them. Through Hume, Brown, and a few other philosophers, the pure method of positivism descended to Comte, whose mission it was to develop a complete system of positive thinking. When we attempt to find a clear definition of what the positive method is, it appears to be simply synonymous with the scientific method of induction, resting upon facts. Having thus invested himself with the prestige of whatever is best in the results of modern science, Comte proceeds to deliver at full length his own ideas of the origin and progress of civilisation, the grounds of morality, the best form of government, and the coming system of religious worship. All these ideas, being called positive, are of course the necessary outcome of the pure scientific method.

The following is one of the clearest statements, which I can find, of the nature of the positive method (vol. ii. p. 424):—"The Positive Philosophy is distinguished from the ancient . . . by nothing so much as its rejection of all inquiring into causes, first and final; and its confining research to the invariable relations which constitute natural laws. . . . We have accordingly sanctioned, in the one relation, the now popular maxim of Bacon, that observed facts are the only basis of sound speculation; so that we agree to what I wrote a quarter of a century ago,—that no proposition that is not finally reducible to the enunciation of a fact, particular or general, can offer any real and intelligible meaning. On the other hand, we have repudiated the practice of reducing science to an accumulation of desultory facts, asserting that science, as distinguished from learning, is essentially composed, not of facts, but of laws, so that no separate fact can be incorporated with science till it has been connected with some other, at least by the aid of some justifiable hypothesis." Now this passage not only contains very good sense, but it may be regarded as a most clear statement of what correct scientific method aims at, the ascertainment of general laws. But there is nothing whatever in this to distinguish the positive method from that pursued by all scientific inquirers who have any share of the spirit of Galileo, or Gilbert, or Newton, or Hooke, or Lavoisier, or Laplace, or Faraday. The question really is, then, whether Comte, having properly formulated the method of scientific inquiry, knew how to apply it in regions where he was not led by greater minds. There is no

* A broken tablet I have come across seems to record a transit of Venus across the sun. It is to be hoped that Mr. Smith will before long succeed in bringing to England the remainder of the Kouyunjik Library. At present a tablet is often broken off at its most interesting part, while the corresponding fragment is still lying under the soil on the banks of the Tigris.

doubt that Comte possessed a remarkably extensive and generally accurate knowledge of mathematics, astronomy, and many portions of physics and chemistry, as developed in his day. The first part of his work is therefore comparatively free from objection, and consists to a great extent of an interesting and able review of the progress of physical science.

Incidentally I may remark, that Comte, while continually sheltering himself under Lord Bacon's great name, appears to have known little or nothing of Bacon's works. If there was one thing which Comte abjured, it was the inquiry into causes, whereas Bacon quotes approvingly the old dictum that "truly to know is to know by causes." Every reader of the "Novum Organum" must be aware that Bacon deals not only with causes, but with still vaguer ideas, Forms, Natures, Essences, terms so metaphysical that even the editors of Bacon hardly pretend to make out clearly what they mean. The following is a characteristic extract from the second book of the "Novum Organum" (Aphorism iv.) :—"The true form is such that it deduces the given nature from some source of essence which is inherent in things, and is better known to nature, as they say, than Form is. And so this is our judgment and precept respecting a true and perfect axiom for knowledge, that another nature be discovered which shall be convertible with the given nature, and yet be a limitation of a more general nature, like a true genus." It is possible that Bacon knew what he meant, but his own employment of his "true and perfect axiom" was no more happy than I hold Comte's application of his positive method to be.

It is of course impossible to show in a single brief article how crude and unscientific were Comte's results when he applied his method to new fields of research, especially in Sociology. One of his supposed greatest discoveries was the philosophical law of the succession of three states : the primitive theological state, the transient metaphysical, and the final positive state. This is one of those vague and hasty generalisations which have the worst scientific vice of being incapable of precise verification. The theory can be stretched, like india-rubber, to cover any difficulties. If we object that the Hebrews were from the earliest historical times Monotheists, and have so continued to the present day, we are told that they were *prematurely monotheistic*, and are left to imagine that they will ultimately become positivists. What sufficiently condemns Comte's laws of evolution is that they led him away from the doctrines of evolution as now established by Darwin and Spencer, and their followers. Comte was well acquainted with Lamarck's views, which he discusses in Book V. chap. 3, coming to the unfortunate conclusion (vol. i. p. 345) that in every view Lamarck's conception is to be condemned, and "that species remain essentially fixed through all exterior variations compatible with their existence." In the beginning of the fifth chapter of the sixth book, too, we find a passage which entirely cuts Comte off from any share in the sociological doctrines of Spencer. "Gall's cerebral theory," he says (vol. ii. p. 105), "has destroyed for ever the metaphysical fancies of the last century about the origin of man's social tendencies, which are now proved to be inherent in his nature, and not the result of utilitarian considerations." It is highly remarkable that, though the germs of the new philosophy of evolution had been put afloat by the elder Darwin, Lamarck, Malthus, and others, both Comte and his admirer, John Stuart Mill, entirely failed to appreciate their value.

There is no doubt that Comte had very wide and general views as to the possibility of creating great bodies of social science, described by various combinations of the adjective Positive, such as Positive Morality, Positive Polity ; but I quite deny that he had any true conception of the proper way of going about the work. It is impossible that he should have, because he altogether abjured and ridiculed that branch of mathematical science, namely, the theory of Probability, by which alone we can approach the scientific investigation of the complex condition of a nation. He says (vol. ii. p. 416) : "Mathematicians drop the supposition of natural laws as soon as they encounter phenomena of any considerable degree of complexity, and especially when human action is in any way concerned ; as we see by their pretended calculation of chances, through a special application of analysis—an extravagance which is wholly incompatible with true positivity, but from which the vulgar of our algebraists still expect, after a century of wasted labour, the perfecting of some of the most difficult of human studies." It becomes hardly possible to treat Comte's pretensions seriously, when we contemplate this intellectual freak by which he rejects the theory which is becoming more and more the basis of all exact science. The more exact and perfect, in fact, a science becomes, the more complete is the application of the rules derived from the theory of probability. In the computations at Greenwich and other astronomical observatories, they are used in almost every reduction. Nothing is more accurate than a good trigonometrical survey, and yet there is no work to which the theory of chance is more elaborately applied. In proportion as chemistry and physics become exact and methodical sciences, they also resort to the theory of chance, as we see in the researches of Sir B. C. Brodie, or the elaborate labours of Prof. W. H. Miller on standard weights and measures.

As to social science, the Method of Means and the law of divergence from an average, founded on the theory of probability, are simply the alpha and omega of scientific method. We cannot stir a step in any branch of statistical inquiry without drawing an average, and we cannot do this unless we accept the theory which Comte ridiculed. Quetelet is the true founder of exact social science, and his long labours consisted in the unwearied application of the doctrine of chance to vast bodies of statistical facts. In Mr. Francis Galton's works we find the same true method carried out with perfect appreciation of its value.

I might go on to point out, again, that the one branch of social science which most early assumed a partially scientific form, namely, political economy, was that to which Comte entirely refused his *imprimatur*. He never would allow it to be called Positive, though he predicted that in the positive era the world would be governed by bankers. Criticism, however, is disarmed when we consider the vagaries to which the positive method is supposed to have led its great expositor.

W. STANLEY JEVONS

INTERNATIONAL METEOROLOGY

Report on Weather Telegraphy and Storm Warnings to the Meteorological Congress at Vienna, by a Committee appointed at the Leipsig Conference.—Report of the Proceedings of the Conference on Maritime Meteorology, held in London, 1874. (Published by authority of the Meteorological Committee, 1875.)

THE first of these reports is a clear and admirable statement drawn up by Dr. G. Neumayer, of Berlin, secretary to the Committee, of the present position of Meteorology with reference to storm warnings. In this light we recommend it, as well as the appendix which gives the opinions of nearly all our best meteorologists on this important question, for attentive perusal. It is a significant fact, as marking the change of opinion which has taken place since the Dundee meeting of the British Association, that the Committee declare it to be desirable that in all countries in which up to the present time systems of storm warnings have not been organised, steps leading to such an organisation should be taken as soon as possible. What is now required is the further development of the system as regards the principles on which it is based, and its practical application to other public interests than those of commerce and navigation.

The Maritime Conference which met in September 1874 did some goodwork towards securing for meteorology greater exactness and uniformity in observations made at sea—not the least important consideration being the number of countries represented at the Conference, all of which, it may be inferred, will be guided by the decisions arrived at. Of the improvements effected on the Brussels Abstract Log may be noted the recording of the direction and force of the wind as at the time of observation, and not as estimated for a certain number of previous hours, and the recording of the upper and lower clouds in separate columns. The notation of clouds from 0, a clear sky, to 10, an entirely clouded sky, is also an improvement as being in accordance with the procedure now adopted on land. As regards the discussion of ocean statistics, the decision is in every way admirable, viz., that the observations and results be published in such a manner that every foreign institute may be able to incorporate them with its own observations and results; that, to this end, the number of observations, as well as the means deduced from them, be preserved for single degrees square, and that, whatever charts be published, the results for single degrees square be printed in a tabular form.

In the proposed English instructions for keeping the log, we regret to see it stated that for all except wind observations it is sufficient to observe at the four-hourly periods, viz. at 4, 8, 12, A.M. and P.M. A strong recommendation should have been made to make the 10 A.M. and P.M. observations, particularly with the view of arriving at a correct knowledge of the distribution over the ocean of the daily barometric fluctuation which is of so great importance in its connection with atmospheric physics. Since by the hours recommended, no systematic observation will be made from 8 to 12 A.M. and P.M., the two daily maxima of atmospheric pressure will remain wholly unobserved, even approximately.

The box for protecting the thermometers on board, figured at p. 53 of the Report, is of faulty construction—the louvres being single and too wide apart to afford the required protection from the disturbing influences which are so great on board ship. A double-louvred box of the pattern, for instance, of Stevenson's, now so extensively used on land, is indispensable. An arrangement of this sort is the more desirable when it is considered how important it often is in practical navigation to know with exactness the difference between the temperature of the air and that of the sea.

It is with much satisfaction that we notice at pp. 19 and 20, the resolutions passed with reference to the cooperation of the navies of different countries in the working out of the problems of ocean meteorology. Doubtless the time will soon come when the navy will occupy, in practical ocean meteorology, the place occupied in land meteorology by the Central Office in prosecuting instrumental and physical researches; and when it will seriously grapple with the difficult problems of making *real* wind, rain, and hygrometric observations at sea; make hourly observations for determining the constants of temperature, humidity, and pressure over the ocean; and make observations at outlying stations, and observations at 0h. 43m. Greenwich mean time, in connection with the United States Signal Office; as well as collect data on matters more immediately connected with physical geography, such as those with which the *Challenger* has enriched physical science. Towards the bringing about of these desired results, the resolutions of the Conference are well-timed.

OUR BOOK SHELF

Rambles in search of Shells. By J. E. Harting, F.L.S., F.Z.S. (London: John Van Voorst, 1875.)

SAYS the author of this small work, in his introduction: "It has often been a matter of surprise to us that the study of the land and freshwater shells has not more votaries, especially amongst the fair sex. The subject may be easily coupled with botany, being, as it were, nearly associated with it; for, whether we ramble on the downs, in the woodland, or in the marsh, in search of any particular plant, we seldom fail to find in close proximity to it some species or other of mollusca which claims its shelter or support." The large field of entertaining detail—comparatively little trodden, except by the erudite few—which is opened up by a study of shells and their inmates, cannot be better entered than by a perusal of the work before us. Mr. Harting has a happy way of placing the rudiments of a science in a light which goes far to remove the comparative uninterestingness of its bare facts. These latter he intersperses with references to easily appreciated and well-known collateral associations, which retain the attention of the reader, at the same time that nothing is taught but trustworthy and important principles. It is evident that, to the beginner, the classification adopted by systematists is comparatively unintelligible, and often only confusing. That based upon the localities and characteristic soils which the different species inhabit, being at first sight much the more simple, is the one adopted. Accordingly, we find chapters devoted to the shells found on the London Clay, others on chalk soils, &c.; the less common species, from whatever soil, being described in proximity to their better known and nearest allies. Several carefully-drawn coloured plates of the species described greatly facilitate the identification of each. A useful appendix also is a list of the local catalogues of the native land and freshwater mollusca, with the assistance of which the study, commenced in the work itself, can be

extended by the enthusiastic local collector. The number of species described as undoubtedly British is one hundred and twenty, including the slugs, which, "though generally regarded as shell-less, have the shell placed beneath the mantle."

A Manual of the Mollusca. By S. P. Woodward. Third Edition. (London: Lockwood and Co., 1875.)

IN noticing a third edition of the late Mr. S. P Woodward's well-known "Manual of the Mollusca," our object is only to indicate wherein it differs from its predecessors. The body of the work is unaltered; whilst the new editor, Mr. Ralph Tate, in order to bring the work up to the present state of our knowledge, has added an appendix, containing the description of those recent and fossil genera which, either from more recent discovery or oversight, are not to be found in it. This appendix, with its separate index, occupies eighty-five pages, and is illustrated with twenty-seven woodcuts, including drawings of *Clydonites costatus*, *Cochloceras fischeri* (Hauer), *Eucyclus goniatus* (Desl.), *Nucleospira ventricosa* (Hall), &c. Its separate existence we do not object to, on account of the expensive typography of a work of the kind; nevertheless, the outlay involved in an incorporation of the two indexes into a single whole would have been fully made up for by the extra facility of reference afforded, and the diminution in the chance of any additional remarks on previously described genus being overlooked. In the preface to the second edition, which is retained in that under notice, it is remarked that "the chapter on Tunicata has been omitted, since they are more nearly allied to the Polozoa than to the Mollusca proper, and since the Molluscoidan group would have made the work inconveniently bulky." Such being the case, we cannot help asking why the Brachiopoda are not also removed. Is it not because they have shells, whilst the Ascidians are deficient in indestructible parts; not, by the way, that Ascidians are Molluscoidan now-a-days. Additional remarks will be found on the nature of *Belemnites*; that *Crioceras* must merge into *Ancyloceras* is shown to be certain; the genera *Vermetus* and *Siliquaria* are placed in a family by themselves, at the same time that their differences from the mimetic *Serpulidæ* are explained. Several of the families are re-arranged, at the same time that the newly added genera are introduced. The work with the appendix is as accurate a representation of the state of conchology in 1871 as was the first edition on its publication. We put it thus because we can find no difference between this third edition and the second, which has latterly been been bound up with Mr. Tate's appendix in exactly the same form as it appears in the newly produced work.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*]

Oceanic Circulation

I HAVE just read Dr. Carpenter's letter in NATURE (vol. xii. p. 454) in reference to my paper on the *Challenger's* crucial test of the wind and gravitation theories of oceanic circulation, read before the British Association, and am somewhat astonished at the nature of the objections which he advances.

"The doctrine," says Dr. Carpenter, "to which he (Mr. Croll) applied his test, was not mine, but a creation of his own. For his whole argument was based on the assumption that the ocean is in a state of static equilibrium; whereas the theory I advocate is, that the ocean never is and never can be in a state of equilibrium, so long as one part of it is subjected to polar cold and another to equatorial heat, but that it is in a state of constant endeavour to recover the equilibrium which is as constantly being disturbed."

Those who were present at the meeting and heard my paper read, or who have since seen it in the September number of the *Philosophical Magazine*, will no doubt feel surprised that the following paragraph should have escaped Dr. Carpenter's notice:—

"It will not do as an objection to assert that according to the gravitation theory the ocean never attains to a condition of static equilibrium. This is perfectly true, as I have shown on a former occasion;* but then it is the equator that is kept below and the poles above the level of equilibrium; consequently the disturbance of equilibrium between the equatorial and polar columns would actually tend to make the difference of level between the equator and the Atlantic greater than $3\frac{1}{2}$ feet, and not less, as the objection would imply."

If Dr. Carpenter will refer to my examination of the mechanics of the gravitation theory in the *Philosophical Magazine* for October 1871, "Climate and Time," chaps. ix., x., alluded to in the above paragraph, he will find page after page devoted to prove that a constant disturbance both of *level* and of *static equilibrium* is a necessary condition to circulation by gravity. Physicists may differ from me in regard to whether or not the present difference of temperature between the ocean in equatorial and polar regions is sufficient to produce circulation, but I do not expect that anyone familiar with mechanics, *who has been at the trouble to read what I have written on the subject*, will do so materially in regard to the way in which difference of temperature is conceived to produce motion.

It is singular that Dr. Carpenter should not have observed that his objection strengthens my argument instead of weakening it. For if it be true that the equatorial column, though in a state of constant upward motion, never attains to the height required to balance the polar column, then it must follow as a necessary consequence that the rise from the equator to latitude 38° in North Atlantic must be greater than I have estimated it to be; and, therefore, so much the more impossible is it that there can be any surface flow from the equator to the pole due to gravity.

The next objection is as follows:—"The only objection raised by Mr. Croll which has even a show of validity is based on the supposed 'viscosity' of water, which he asserts to be sufficient to prevent the disturbance of thermal equilibrium from exerting the effect which the gravitation theory attributes to it."

What possible connection can "viscosity" have with the crucial test argument? Suppose water to be a perfect fluid and absolutely frictionless: this would not in any way enable it to *flow up-hill.*

The crucial test argument brings the question at issue, in so far as the North Atlantic is concerned, within very narrow limits. The point at issue is now simply this: *Does it follow, or does it not, from the temperature-soundings given in Dr. Carpenter's own section, that the North Atlantic at lat.* 38° *is above the level of the equator?* If he or anyone else will prove that it does not, I shall at once abandon the crucial test argument and acknowledge my mistake; but if they fail to do this, I submit that they ought at least in all fairness to admit that in so far as the North Atlantic is concerned, the gravitation theory is untenable.

The Atlantic column is lengthened by heat no less than eight feet above what it would otherwise be were the water of the uniform temperature of 32° F., whereas the equatorial column is lengthened only four feet six inches. The expansion of the Atlantic column below the level of the bottom of the equatorial not being, of course, taken into account. How then is it possible that the equatorial column can be above the level of the Atlantic column? And if not, let it be explained how a surface-flow from the equator pole-wards, resulting from gravity, is to be obtained.

Edinburgh, Sept. 29

Dehiscence of *Collomia grandiflora*

THE following account of some observations of mine on the dehiscence of *Collomia grandiflora* may possibly prove interesting to some of your botanical readers. I can find no allusion to the singular mode in which the capsules as well as the seeds of this plant become liberated. The fruit is a three-celled capsule, and is almost wholly included within the tube of the calyx. When quite ripe it is of a pale straw colour, and becomes cartilaginous and highly polished, as does also the internal surface of the calyx tube. The latter is ribbed with fifteen prominent lines disposed in threes, each set pertaining respectively to the five sepals, and extending into their free portions. These ridges may possibly help to give direction to the capsule during its exit. Dehiscence

* Phil. Mag., Oct. 1871; "Climate and Time;" chap. ix.

takes place loculicidally, and the three dark-brown seeds, one in each cell, are exposed to view. It is at this stage that the phenomenon in question may be observed. The pressure exerted by the smooth sides of the somewhat obconical capsule against the equally polished surface of the calyx-tube occasions the rupture of the capsule from the base of the calyx, and its more or less rapid expulsion into the air with its three seeds. The latter, which are at this time free within the cells of the capsule, are carried to greater distances on account of the smaller amount of resistance they offer to the air by reason of their shape and weight; the action, in fact, being not altogether unlike that of the discharge of a cartridge and its contents from a rifle. The suddenness of the explosion depends very much on the state of the atmosphere at the time. On a hot day I have observed several instances of spontaneous discharges, whilst a slight touch only was necessary for the explosion of the remaining capsules whose dehiscence had already commenced. Many of the seeds were observed adhering to the upper leaves and calyx-segments, which are thickly covered with glandular hairs of a remarkably viscid nature. Contact with these moist bodies very soon induces the outgrowth of those curious and beautiful spiral hairs for which the seeds of this and a few other plants are remarkable, and thus they become doubly secured by adhesion. I have noticed in some cases when seeds adhere to the flat surface of a viscid leaf, that this outgrowth assumes a definite outline extending all round the seed in the form of a flat membranous expansion, and these, on removal, recall forcibly the appearance of ordinary winged seeds, like those of *Lepigonum marginatum*, for instance. Can this attachment be of any use to the seeds or to the plant itself by feeding on the nitrogenous products of their decomposition? Although I have observed a few of these attached seeds undergoing partial decay, yet, from the nature of their hard horny perisperm, it is not reasonable to suppose that it can take place to any great extent, unless the viscid secretion from the glands is able to render this substance sufficiently soluble for the purpose. If, however, a certain proportion do become sacrificed for the good of the plant, we can understand the object not only of the delicate spiral hairs for ensuring firm attachment, but also that of the explosive process, by means of which a certain number of seeds are conveyed beyond the reach of the viscid surfaces, and falling to the ground, are available for the reproduction of the plant. *Saxifraga tridactylites* might be mentioned as another instance of a viscid plant with the habit of retaining the seeds on its glandular parts; the much larger quantity, however, produced by this latter plant in proportion to what can be required for reproductive purposes would seem to do away with the necessity for any sudden mode of expulsion. Like most plants with sticky glandular hairs, the viscid parts of this Collomia may be seen covered with small insects in various stages of decomposition.

It might be asked, "What advantage can it be for an annual plant to feed on its own seeds, the production of which is the completion and, in a certain sense, the object of its existence?" I would suggest, though with diffidence, the possibility of certain annuals being raised by such means to a higher state of existence as biennials or perennials, in which condition they might or might not require the continued assistance of glandular hairs or other such contrivances. This might explain the occurrence of hairs on certain parts of plants either constantly present or at particular times of their life; such, for instance, as those on the first leaves of the turnip plant, and many other examples could be given, in the case of which we might suppose that the possession of such hairs, or whatever they may represent, have ceased to be required.

There does seem to be some sort of general relation as to the degree of hairiness between annuals, biennials, and perennials, and which often becomes apparent during the development of many plants which in their adult condition are destitute of hairs. On this hypothesis it seems to me conceivable that many of our large glabrous-leaved trees may have originated from hairy or glandular annuals, dependent, perhaps, more or less on aërial nitrogenous food. In any case it is interesting to investigate the true purpose—for such there must be—of the elaborate machinery of traps and spring-guns as displayed in the life of this Collomia.

J. F. DUTHIE

Royal Agricultural College, Cirencester

P.S. Since the above was written I have observed the effect of placing a few of the empty expanded capsules in water. In a short time (about half an hour) their valves became completely contiguous, and they presented the same appearance as they did shortly before dehiscence, with the exception of a transparency due to their containing water instead of seeds. This sensitiveness to the action of moisture is clearly a provision for preventing the filamentous outgrowth from the surface of the seeds whilst in the capsule

Lunar Phenomena

I HAVE pleasure in forwarding a brief account of facts relating to two very remarkable protuberances which were observed on the moon's disc in the Gulf of Siam, by Mr. E. C. Davidson, Telegraphic Engineer, and myself.

H.S.M.'s guard-ship *Coronation* (Champon Bay), July 13 (civil time), in lat. 10° 27′ 40″ N. and long. 99° 15′ E., at midnight, the moon bore S.W. by W. magnetic, and its altitude was about 20°, when a prominent projection was seen with the naked eye on the moon's upper limb. The best glasses on board were soon brought to bear upon it, and the enclosed sketches * (with due regard to proportion) were carefully made on the spot.

The protuberance, in colour, was similar to that of the moon.

On July 14, at 8 P.M., the moon was observed perfectly clear, but without a vestige left of the protuberance of the previous night. At this hour, however, a small one was noticed in a different position of the limb.

This also had disappeared before the moon rose on the evening of the 15th inst., when it finally presented its usual unbroken appearance.

The Strength of the Lion and the Tiger

IN NATURE, vol. xii., p. 474, in a review of Dr. Fayrer's book on the tiger, doubts are thrown by the reviewer on the statement that the tiger is stronger than the lion. Dr. Fayrer's statement cannot be contradicted by any person well acquainted with both animals. In my book on "Animal Mechanics," published in 1873, I have proved, p. 392, that the strength of the lion in the fore limbs is only 69·9 per cent. of that of the tiger, and that the strength of his hind limbs is only 65·9 per cent. of that of the tiger.

I may add that five men can easily hold down a lion, while it requires nine men to control a tiger. Martial also states that the tigers always killed the lions in the amphitheatre. The lion is, in truth, a pretentious humbug, and owes his reputation to his imposing mane, and he will run away like a whipped cur, under circumstances in which the tiger will boldly attack and kill.

At p. 482 you state that Dr. Bolau, of Hamburg, is about to publish an account of the anatomy of a gorilla which nearly reached Hamburg alive, and was preserved in spirits. Your readers will be glad to learn that he has been anticipated by Prof. Macalister, of Trinity College, Dublin, who has already published a full account of a similar animal, which nearly reached Liverpool alive some years ago, and was dissected by myself and Dr. Macalister. A comparison of his muscles with those of man, chimpanzee, and hamadryas, will be found in my "Animal Mechanics," p. 404 *et seq.*

A Snake in Ireland

THE enclosed letter to the editor of the Irish *Daily Express* may excite speculation as to how the snake got where it was found. The fact is worthy of record, at any rate, that a snake has been caught in Ireland. What would St. Patrick say?

"Sir,—My gardener this morning killed a large snake in the garden here, measuring five feet long by three inches in circumference. It has a black back, with light yellow belly; I do not know what species it belongs to, but have preserved it in spirits. Is it not very rare to find such in Ireland?—Your obedient servant, "FRANCIS WM. GREENE.

"Kilranalagh, Baltinglass, Co. Wicklow, Sept. 11."

I have not seen it, but my correspondent Lady M. has it in her possession, and remarks that its head is very small and its nose pointed; it is quite five feet long, black, and the colour of

* The sketches are not clear enough to be reproduced.

ashes underneath. It appears by a letter from Mr. Greene, "that a gentleman brought two Indian snakes to Ballinrodan, both of which escaped six or seven years ago; one of them was found half eaten by a pig shortly afterwards, and this might be the other, though how it lived through the winters I do not know."

It would be interesting to ascertain whence the snake came and how it found its way to the proscribed island.

London, Sept. 28 J. FAYRER

Origin of the Numerals

IN the novel "David Elginbrod," by George Macdonald, p. 45, is a suggestion of the origin of the forms of the numerals in daily use, very similar to that indicated by Mr. Donnisthorpe in last week's NATURE, p. 476. The disposition of the lines in some of the figures is very ingenious. G. W. WEBSTER

Chester, Oct. 4

IF your correspondent will refer to Leslie's "Philosophy of Arithmetic," p. 103 *et seq.*, he will find that very much is known respecting the origin of the numerals. By referring to p. 107, same work, he will find that the numerals he gave are wonderfully like the Sanskrit.

Newcastle-upon-Tyne, Oct. 4 WM. LYALL

Scalping

MR. CHARLES C. ABBOTT, in NATURE, vol. xii. p. 369, wishes to learn what other men, if any, besides the North American Indians, have the practice of scalping among them. The question is answered in Southall's "Recent Origin of Man," chap. ii. p. 40. "In this connection we may mention that the custom of *scalping* is not peculiar to the American Indians. Herodotus mentions that it was one of the most characteristic practices of the ancient Scythians. But this is not all: it is stated that the practice prevails at this day among the wild tribes of the frontier in the north-eastern district of Bengal. The *Friend of India*, commenting on this statement, adds: 'The Naga tribes use the scalping-knife with a ferocity that is only equalled by the American Indians, and the scalps are carefully preserved as evidences of their prowess and vengeance over their enemies. On the death of a chief, all the scalps taken by him during his warlike career are burned with his remains.'" G. PEYTON

OUR ASTRONOMICAL COLUMN

THE DOUBLE STAR Σ 2120.—As mentioned last week, M. Flammarion advocates the binary character of this star, identifying it, as Sir John Herschel had already done, with H. III. 89. Sir W. Herschel's observation runs thus:—

"III. 89. Ad 63^{am} Herculis. In linea per δ et ε ducta.

1782 Nov. 26. Double. About 4 degrees from δ towards ε Herculis, near the 63rd. Very unequal. L. r.; S. r. Distance 11″ 53‴. Position 47° 48′ n. following."

There is a contradiction here; a position "4 degrees from δ towards ε Herculis," which pretty well agrees with that of Σ 2120, would not be near 63 Herculis, which is little more than 1° s.p. δ.

The formula given in NATURE, vol. xii. p. 147, assigns for the position of the small star at Sir W. Herschel's date—

	Angle ...	36° 39′ ...	Distance	10″·72
The observation has	,, ...	42 12 ...	,,	11 ·18

It is by the difference between these positions, which however it may be remarked is not larger than we occasionally meet with on comparing Sir W. Herschel's measures with recent ones, in cases of stars which there is reason to suppose merely optically double, that the binary nature of the object is considered to be proved by M. Flammarion, as it had been by Sir John Herschel in the paper upon his father's measures, which appears in vol. 35 of the "Memoirs of the Royal Astronomical Society." Until that single observation is supported by curvature in the path of the small star subsequent to its nearest approach to the primary, which if this be really a binary system must probably become sensible within a few years from the present time, the suspicion of rectilinear motion of the small star as the cause of the change of position, representing as it fairly does the measures between 1829 and 1873, is not one perhaps that can be legitimately abandoned. The apparent fixity or nearly so of the principal component to which reference was made in our former remarks, is supported by Dr. Engelmann's comparison of the place deduced from meridian observations at Leipsic in 1867, with Struve's position in "Positiones Mediæ," for which the mean date is 1836·1; for secular proper motion he found $\Delta\alpha = +0s{\cdot}192$, $\Delta\delta = +2''{\cdot}40$—very insignificant quantities, and showing that if proper motion, as we have surmised, enters into the question, it is mainly the smaller star that is affected by it. M. Flammarion, relying as stated upon Sir W. Herschel's measure of 1782, concludes: "C'est donc un système orbital très-incliné, et c'est peut-etre celui dont l'aspect ressemble le plus aux systêmes de perspective." We leave it for the measures that may be made during the next few years to decide between these opinions.

THE NEBULA IN THE PLEIADES.—In No. 5 of "Publicazioni del Reale Osservatorio di Brera in Milano," Herr Tempel has laid down the stars in the Pleiades, from the "Durchmusterung," and traced the outline of the nebula near Merope as it appeared to him with a magnifying power of twenty-four on a telescope of four inches aperture. The outline is shown to be elliptical, one extremity of the longer axis, the northern one, at Merope, and the inclination of this axis to the circle of declination about 18°, so that as referred to Merope, the angle of position of the longer axis is 198°; the greatest and least diameters of the ellipse are roughly 35′ and 20′.

M. Wolf, of the Observatory of Paris, observing with the telescope of $0^{m}{\cdot}31$ aperture in March 1874, perceived two nuclei, one almost concentric with Merope, the other and brighter of the two at a distance of about seven seconds, on the same parallel, following. From the month of November 1874 to the end of February 1875 the nebula could not be seen notwithstanding the very favourable atmospheric conditions, and at the same time M. Stéphan was unable to detect it with the telescope of $0^{m}{\cdot}80$. M. Wolf concludes that the nebula is certainly variable, and that its period is pretty short.

Herr Tempel remarks that generally the nebula has been much more readily seen with small telescopes than with large ones, and doubt has been expressed as to any real variability of light; yet it is not easy to understand, except upon this supposition, why the nebula should be visible at certain times in a particular telescope and invisible at others, the circumstances of sky appearing to be about the same in all cases.

This nebula was first remarked by Herr Tempel, at Venice, on the 23rd of October, 1859.

THE SATELLITES OF URANUS AND NEPTUNE.—An elaborate and highly interesting investigation of the elements of these satellites from observations with the 26-inch equatorial of the United States Naval Observatory, Washington, and of the masses of the primaries thereby indicated, has been received from Prof. Newcomb during the past week; it forms an appendix to the Washington Observations for 1873. The most probable value of the mass of Uranus derived from these observations is $\frac{1}{22600}$, with a probable error of 100 in the denominator of the fraction. For Neptune the value of the mass by satellite-observations is $\frac{1}{19380}$; the mass deduced by Prof. Newcomb from the perturbations of Uranus

having been $\frac{1}{19700}$: the value resulting from the satellite-observations is preferred. A further account of this important memoir by the eminent American astronomer is reserved for next week.

THE MINOR PLANETS.—M. Leverrier's *Bulletin International* of Sept. 30 mentions the observation of a small planet, on Sept. 21st, by M. Perrotin at Toulouse, 13th mag., which may possibly be new, though at present there is a chance of its identity with No. 77, which is in the same quarter of the sky and has not been observed since 1868, or with No. 137, of which no elements have yet appeared. Its place at 8 P.M. was in R.A. 23h. 16m. 8s., and N.P.D. 95° 12′.

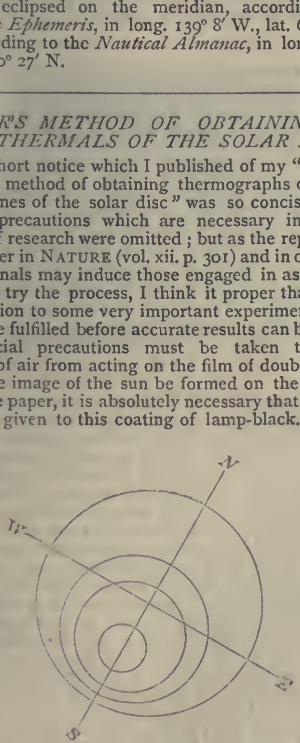
THE TOTAL SOLAR ECLIPSE OF 1878, JULY 29.—The *American Ephemeris* for 1878 is published. The elements of the total eclipse of the sun on July 29, derived from the Lunar Tables of Prof. Peirce, which are adopted for the calculations in that work, are almost identical with those of the *Nautical Almanac*, founded upon the Tables of Hansen, Denver. Colorado appears to be one of the principal places within the limits of the shadow, though some distance from the central line. The sun will be centrally eclipsed on the meridian, according to the *American Ephemeris*, in long. 139° 8′ W., lat. 60° 32′ N.; and according to the *Nautical Almanac*, in long. 139° 10′ W., lat. 60° 27′ N.

MAYER'S METHOD OF OBTAINING THE ISOTHERMALS OF THE SOLAR DISC

THE short notice which I published of my "Discovery of a method of obtaining thermographs of the isothermal lines of the solar disc" was so concisely written that the precautions which are necessary in this new method of research were omitted; but as the republication of my paper in NATURE (vol. xii. p. 301) and in other European journals may induce those engaged in astronomical physics to try the process, I think it proper that I should call attention to some very important experimental conditions to be fulfilled before accurate results can be reached.

1. Special precautions must be taken to prevent currents of air from acting on the film of double iodide.

2. If the image of the sun be formed on the blackened side of the paper, it is absolutely necessary that uniformity should be given to this coating of lamp-black. So difficult is this to achieve that I have generally formed the sun's image directly on the film of iodide. Slight irregularities in this film do not appear to affect the form of the isothermals; but the latter follow irregularities in the smoked surface.



3. The most important, and indeed absolutely essential, condition in these experiments is that the image of the sun shall be formed on a truly *horizontal surface*; for the centre of gravity of any isothermal formed on an *inclined* surface is always *above* the centre of the sun's image and in a vertical plane passing through this centre. Hence all isothermals thus formed are very excentric when referred to the sun's centre. They are also elliptical. The accompanying figure gives isothermals obtained on an inclined surface. *N S* is the solar axis. On obtaining these same isothermals on a horizontal surface they were, as near as could be seen, circular and concentric with the sun's image.

Of the influence of an inclined surface in displacing the isothermals there can be no doubt, and the same action has effected all of the results which have been obtained in the employment of thermopiles in connection with the sun's image received on screens attached to equatorial telescopes. This displacement would mislead an observer, and would cause him to be of the opinion that there existed a decided difference of temperature between the north and south solar poles, and between the portions of the periphery of the sun's image near the poles and near the solar equator. Do not these facts reached by me explain the difference in the results obtained by Secchi and Langley?

The above effects of inclined surfaces appear to be caused by a film of hot air which flows up over these surfaces, and especially on the lower surface of the screen. If the sun's image is received on a film of iodide enclosed between plates of glass or of mica, the excentricity of the isothermals is hardly apparent at first; but after some time it appears, produced by the action of the ascending film on the surface of the glass.

The proper method of research is to use a simple Fahrenheit's heliostat with a good plane mirror, and to throw the solar rays in the direction of the polar axis of the instrument. These rays traverse lenses of from 12 to 30 feet focus, and just before they have converged to form the solar image they are reflected perpendicularly, by another plane mirror, on to the horizontal surface of the iodide.

ALFRED M. MAYER

FAYE ON THE LAWS OF STORMS *

Examination of the Theory of Aspiration.—After a somewhat detailed account of opinions held regarding waterspouts in the prehistoric and Roman epochs, and from the sixteenth century downwards, all agreeing in this, that the water of the sea is sucked up to the clouds by these meteors (Fig. 6), M. Faye inquires, How then could it be doubted that waterspouts, and consequently tornadoes, typhoons, &c. are simply phenomena of aspiration?† Such has been in reality, since the time of Franklin, the point of departure for meteorologists; and hence the prevailing notions regarding hurricanes, that they are centripetal and formed by horizontal currents of air flowing from all quarters towards the centre of aspiration.

Clearly in this case the conclusions have not been drawn with the caution which science demands. To accept, with the eyes shut, the most astounding assertions without examination or verification; to believe, for example, that a waterspout could suck up the water of the sea to a height of 2,000 feet when the most powerful pump could not raise it to the height of forty feet; to admit that insubstantial vapours could form a tube whose sides are capable of resisting the whirling masses of water supposed to ascend through it; to assert that deluges of sea-water are engulphed in the clouds where the clouds cannot retain simple drops of rain, is not in accord with the usage of science, and indeed can only be explained by the dominating power of an old preju-

* Continued from p. 459.

† It not being considered as disputed that a tornado is nothing but a large waterspout, a typhoon only a large tornado, and that there is no essential difference between a cyclone and a typhoon, M. Faye proceeds to test the theory of centripetal aspiration as regards waterspouts and tornadoes, and conceives that the conclusions thus arrived at will have equal weight when applied to the theory of cyclones.

dice, which is constantly receiving new life and vigour by the persistent testimony of observers already prepossessed in its favour. There is another reason equally good which accounts for this mode of explaining phenomena. Of all physical inquiries, the most difficult are those which belong to the order of mechanics, which as little admit of sentiment in dealing with them as pure mathematics. In those fields of inquiry where pure mechanics can no longer guide us, the crudest hypotheses take root and grow: witness the wild dreams of the astronomers of the seventeenth century. Now the department of mechanics to which falls the exposition of the gyratory movements of liquids and gases, and on which depend exactly the atmospheric phenomena we speak of, does not yet exist, except as a first and most imperfect draft.

Taken thus at unawares, as it were, and compelled to rely on evidence altogether illusory and suggesting unhesitatingly the idea of aspiration on a vast scale, modern meteorology strives at least to free itself from conflicting impossibilities. Thus, instead of making the waterspout suck up water in its ordinary form, it is assumed that this water is first blown into spray by the conflict of the winds at the base of the waterspout, and then whirled aloft in this form. A curious experiment was even made in 1852 at Washington, for the purpose of showing that this is the case. The following account of it is taken from the "Fourth Meteorological Report to the Senate of the United States," by Prof. Espy:—

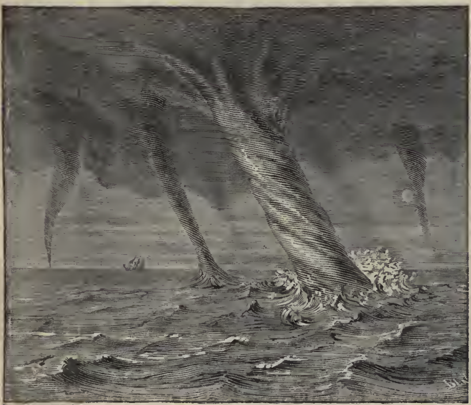


FIG. 6.

'The effect produced by the ascent of a column of air in a narrow space may be thus shown:—If we produce a simple rarefaction of two or three inches of mercury in the upper part of a vertical tube a few feet in length and five inches in diameter, by putting it in connection with the central opening of a machine in full blast, the air will rush into the tube by the lower orifice with a speed proportional to the square root of the diminution of pressure, or about 240 feet per second for an inch of mercury. Then, if a basin filled with water is placed under the opening of the tube and the surface of the water be brought to about $2\frac{1}{2}$ inches from the end of the tube, the water in the basin will be quickly sucked up and ascend the tube, and produce in miniature what takes place in a waterspout. If the tube is glass and of the same dimensions, the water will be seen rising in spray in the form of an inverted cone. This experiment was made in a foundry at Washington in the spring of 1852, in the presence of Prof. Henry and several distinguished members of Congress."

It is singular that none of those present at this experiment remarked the difference there is between a tube of metal or of glass and an almost ideal tube whose bounding surface is only thin insubstantial vapour. The experiment is, however, a proof of the resoluteness with which, in this age even, a belief in the powerful upward suction of waterspouts is entertained.

In order that an ascending current may take place in the atmosphere for some seconds, it is essential that a mass of a lower stratum of air be heated a little more than the air surrounding it. It thus becomes lighter than the layers above it, and consequently rises. In ascending, however, it expands and cools, and soon all further ascent is arrested at a height where the pressure and temperature equal the pressure and temperature of the ascending mass. It is, moreover, replaced from below by air of a lower temperature from all sides. Up to this point there is little, if any, resemblance to a waterspout; there is, however, already the beginning of a movement of ascension, and by means of some new additional hypotheses the phenomenon is completed by giving to it the essential characteristics of a real waterspout.

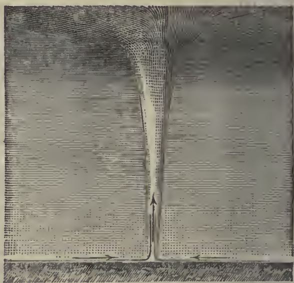

FIG. 7.

Moist air ascends, it is affirmed, more quickly and to a greater height than dry air. Prof. Espy maintains even that it will rise till the limits of the atmosphere be reached in this way:—Moist air in ascending expands and becomes colder; a portion of its aqueous vapour is condensed into mist, and the heat set free in the act of condensation maintains the mass of ascending air constantly at a higher temperature than the stratum of air through which it is ascending. Some physicists consider that these views, thus pushed to exaggeration, are erroneous, but the belief is pretty general, that "the heat due to the condensation" of aqueous vapour is sufficient to raise an ascending column of moist air to a much greater height than an equal column of dry air. Be that as it may, the result would be that when the layers of air resting on the ground are heated by the noonday sun and by radiation, and above all by contact with the ground itself, the equilibrium of the air is disturbed; we should see constantly appearing everywhere a stratum of mist obscuring the rays of the sun. It is useless to point out that this does not represent what takes place. We accept it, however, and proceed.

If we advert to the phenomena of mirage, we find there combined, according to the writers whose theory we are expounding, all the conditions which favour the production of a permanent local indraught of air, and consequently the essential conditions of the waterspout. When the air is perfectly calm and the soil highly heated, the lowest strata of the air are highly heated and thus become specifically lighter than the strata resting over them. But

as this excess of temperature is felt at the same time over a wide area, the lower stratum of air rises bodily, so to speak, over the whole region. Now there is no reason why the air should begin to ascend at one place rather than another in the region where the air is perfectly calm; there will be then between the lowest aërial stratum and the one immediately above it a sort of equilibrium, but an equilibrium so essentially unstable that the slightest accident, such as the striking of a light or the flight of a bird, instantly destroys it. As soon as the charm is broken at some point the lower air will there ascend, and as it is charged with moisture it will continue to rise in an ascending column to the higher regions of the atmosphere. In rising, this air will leave a vacuum below it, towards which will rush the air of a lower stratum. This will in turn follow the first in its ascent, and it is seen that gradually the air of this highly heated lower stratum will flow from all sides with an accelerating speed *towards the pathway opened by the first ascending puff of wind.* As this propagation of the horizontal movement extends wider and wider over the heated stratum, the air which arrives at the place where ascending currents have set in will be of the temperature required to keep up the indraught. Further, the *vis viva* of the air currents about the narrow space where the equilibrium was first disturbed will acquire a force capable of producing, a short distance from the point towards which they all converge, very considerable mechanical effects. Then, if the whirlwind advances on the sea, its surface, lashed on all hands by the converging winds, is thrown into a state of ebullition; the spray is drawn up in an ascending column and whirled aloft, however slight may be the spiral form assumed by the horizontal converging currents. The air which rises so violently in the waterspout will be thrust higher and higher, as we have just seen, by the force constantly called into play by the condensation of the vapour into cloud and rain; at length it reaches the high regions of the atmosphere, where it expands and swells into a dense cloud of enormous dimensions. This, then, is the theory of aspiration.

Before a physicist reasons in this way he ought to be well assured beforehand that the facts are as he supposes; in other words, that waterspouts suck up by a vast upright tube the air and the water of the lower strata. Otherwise he would not fail to remark that if the equilibrium, eminently unstable, which he assumes to be established, comes to be destroyed at any point, it would be quickly destroyed over the whole extent of the lower stratum, the different parts of which would then rise freely, each in its place successively, over the small space required for the re-establishment of the equilibrium of the atmosphere. If, in support of any other theory, a similar mechanical combination were proposed to him, he would reject it without hesitation, and say—in order that such phenomena can take place, in order that the lower air should flow horizontally towards a particular orifice and then rise vertically through this orifice, it would require to be forced to do so by some sort of indefinite but solid boarding placed over the lower stratum of air and pressing on it with all the weight of the atmosphere. If a hole be made in the boarding, the air will pass through it; but even in this case, its ascensional force determined by the slight difference in density between the layers on each side of the boarding will not be great, and the column of air issuing through the orifice will rise to no great height. In no conceivable case can it ever exhibit the terrible and destructive force of waterspouts and whirlwinds, or indeed any distant approach to it, under even the most favourable conditions. Lastly, let it be granted that the facts really are as they are supposed to be, and that the lower stratum of air is on every side in a state of motion towards an orifice of a limited size, where there is no material object to divert it from a horizontal to a vertical course, as in Fig. 7; it is plain that aërial currents could not change their course so abruptly in order to stream through this imaginary orifice; they would instantly enlarge and soon altogether efface from the sky the narrow tube of this meteor to which the

Fig. 8

advocate of aspiration clings because it is the *sine quâ non* of his cherished hypothesis.

But we shall pass over all these impossibilities which prejudice so readily forgets, and consider the consequences which result from this theory—not those which might be drawn to show its utter worthlessness, but those which its own partisans have deduced. It is so easy, from what has been said, to produce a waterspout at will, and everything connected with it—large dense clouds aloft with thunder and torrents of rain—that the idea could not but strike some one. Accordingly, it occurred to several persons in America, where the theory of aspiration has been received as favourably as in France, and the artificial production of a waterspout and a thunderstorm in the United States is gravely related in a letter from Mr. G. Mackay, which letter is published in the "Fourth Meteorological Report to the Senate" (Washington, 1857.) It would be a waste of time to make any further reference to an illusion which puts into man's hands the power of originating waterspouts, tornadoes, and typhoons, simply because it makes the phenomena depend on a state of unstable equilibrium in those layers of the atmosphere which immediately surround us.

Refutation of this Theory.—Let aspiration be established by natural or artificial means at one point in the midst of an absolute calm prevailing in the lower stratum of the atmosphere: there is no reason in such a case why the

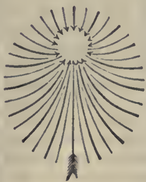

Fig. 9.

Fig. 10.

centre of aspiration should be displaced, because all is symmetrical and tranquil round this point. Hence it follows :—(1) Waterspouts, tornadoes, typhoons, and cyclones should be stationary. At most the column of

ascending air, when it has reached the elevated regions of the clouds, could not be diverted above by upper currents so as to assume the form represented in Fig. 8; for these upper currents could no more displace the focus of aspiration than they could move a locomotive by deflecting the column of smoke which issues from it. (2) The mechanical effects will be very limited, because the aspiring force being measured by a few millimetres of mercury, were the end of the suction-tube to be plunged into a river or the sea, the water would be raised there a few centimetres. Moreover, at the instant when the extremity of the tube reaches the ground or the water, the air ceases to flow into it and fails any longer to keep the ascending column together, and thus all mechanical action ought to disappear at this moment. Further, it is evident that if the phenomenon has its origin in a perfectly calm stratum of air where not a breath of air is felt, the element of mechanical work, that is to say the force or the motion, fails altogether, or becomes reduced to a feeble ascensional tendency in any stratum of air that may have acquired over the place an abnormal excess of a few degrees of temperature.

Compare now with the facts, these two conclusions drawn from the theory. It would be difficult to find a disagreement more complete. Everyone is aware of the ravages produced by hurricanes, typhoons, tornadoes, and even simple waterspouts and whirlwinds—ravages which imply an enormous development of mechanical force. Then, everyone knows that the peculiarity of all cyclones is to possess a movement of translation, often very rapid, which the theory of centripetal aspiration denies to them. Of all waterspouts hitherto observed, only one instance of a stationary one has been recorded; and even the stationary character in this exceptional case may have been not real but only apparent. As regards tornadoes, all those that traversed the United States since 1811 were propagated onwards with a speed varying from four or five to twenty metres a second. The well-known waterspout of Monville, in France, swept over a league in less than four minutes, or at a rate of about twenty metres per second. At such rates typhoons and cyclones, without exception, also advance; their movement of translation is usually increased as they proceed into higher latitudes, and varies from three to eighteen nautical miles an hour, or from two to ten metres per second.

It has been said by the advocates of the theory of aspiration as applied to hurricanes, that if the converging currents are stronger on one side than on the other, the centre of aspiration, that is the base of the waterspout, will be displaced in the direction indicated by the stronger currents, as shown in Fig. 9. But why this difference of speed, especially over the sea, where there are no inequalities of surface over which the different winds blow? The velocity with which air free to move rushes into a suction-tube is determined by the amount of the suction force; if the movement be impeded on one side of the orifice, the air will enter by the other with a determined velocity, but not with a velocity tripled or quadrupled. Moreover, in order that an excess of velocity of twenty metres per second on one side of the centripetally flowing currents could communicate a like velocity to the onward march of the waterspout, it would be necessary that a wind of the force of a terrible tempest blew in that direction exceeding by a velocity of twenty metres per second the contrary wind. This is scarcely compatible with the absolute calm which ordinarily prevails round waterspouts, tornadoes, and even typhoons.

Fig. 10 represents the appearance of a waterspout whose base is represented as driven forward by a supposed excess of velocity of the inflowing horizontal currents, whilst the top of the ascending column is retarded by the resistance of the air. Now the real figure is that represented in Fig. 11, and it agrees neither with Fig. 9 nor with Fig. 10.

It will be seen on reflection that under all these attempts at explanation there lies a settled conviction which Pliny has aptly expressed in these words: "Quum spissatus humor rigens ipse se sustinet,"—the idea, in fact, which was naïvely reproduced in the experiment at the foundry at Washington, in which it was tacitly assumed that the column of a waterspout or tornado is composed of some rigid material, and that it may be displaced bodily by a force acting on its lower part. In truth, the force which could so act is not to be found. The explanation suggested by Prof. Mohn, that the movement of translation of storms is determined by a difference in the average pressure in the front as compared with the rear of the storm, caused by the condensation of vapour which takes place in front, is insufficient, because we see waterspouts and tornadoes marching onwards, from which not a single drop of rain falls.

No navigator has ever shown that there is in a cyclone the least indication of a decided movement of ascension to which the essential cause of the phenomenon is attributed. Everyone speaks about ascending currents, but no one has seen them, or seems even to have had the idea of verifying their existence in the case of their assumed hurricanes of aspiration. The whole thing is taken for granted, and preconceived notions, whose origin

Fig. 11.

we have traced, have complete control over their thoughts. As regards waterspouts, no manner of doubt is entertained, for the water is seen whirled up their columns skywards. If this were really the case, waterspouts and tornadoes might draw up even to the sky the thousands of trees which they uproot, and a little afterwards furnish the spectacle of a whole forest tumbling from the clouds, it being evident that thousands of trees may be transported as easily to the clouds as thousands of tons of sea-water. Eye-witnesses are not wanting to prove that branches of trees have ascended beyond the clouds, they having been seen lying at some distance on the ground, covered with hoar-frost in the middle of summer.

What remains then of the theory of hurricanes which is based on centripetal aspiration? It starts from a prejudice, sacrifices at the outset the simplest notions of mechanics, and does not take the trouble to represent a single characteristic trait of the phenomenon. Is it then on this theory we are to rely for the rectification and completion of the laws of storms? Shall we borrow from it, in order to correct the diagrams of Reid and Piddington which are perhaps in some cases too absolutely circular, the hypothesis of centripetal currents suggested by it. Especially shall we sacrifice to it the practical rules of navigation followed during the past thirty years? Unhappily there is some cause for fear, for sailors themselves have long since been prepared by the tales and narrations of the forecastle, for these ideas of aspiration affirmed regarding tornadoes, typhoons, and cyclones. If then they are told that in a particular case one of the

laws of storms has suffered an exception, that the wind has on one occasion not blown perpendicularly to the direction of the centre, they will be tempted to cast aside the rules which have hitherto guided them. This would only be to sacrifice reality to an empty illusion, and science to error.

It is for this reason that we have insisted at some length on a prejudice which might result in consequences so deplorable. But half of our task is still before us. We have yet to point out the true theory of these phenomena, and to show how the sailing rules hitherto adopted are justified by it. In this way will these rules, thus cleared from empiricism, be invested with the authority which they at present stand in need of.

(*To be continued.*)

NOTES

THE following are some of the principal works in the various departments of science and in travel which are announced for publication during the present season. Messrs. Longman and Co. have the following in preparation:—"The Moon and the Condition and Configurations of its Surface," by Edmund Neison, F.R.A.S., illustrated with maps and plates. "An Epitome of the Geology of England and Wales," by Horace B. Woodward, F.G.S., Geologist on the Geological Survey of England and Wales; and a new volume of the "Text-Books of Science," "Telegraphy," by W. H. Preece, C.E., and J. Sivewright, M.A. "Shooting and Climbing in the Tyrol," with an account of the manners and customs of the Tyrolese, by W. A. B. Grohmann, with numerous illustrations from sketches by the author. "The Frosty Caucasus, an account of a walk through part of the Range and of an ascent of Elburz in the summer of 1874, by F. C. Grove, with map, and illustrations engraved on wood by E. Whymper, from photographs taken during the journey. "The Indian Alps and how we crossed them," being a narrative of two years' residence in the Eastern Himalayas, and two months' tour into the interior towards Kinchinjunga and Mount Everest, by a Lady Pioneer. This work will contain a large number of wood engravings and twelve full-page chromolithographs. "A Journey of a Thousand Miles through Egypt and Nubia to the Second Cataract of the Nile," being a personal narrative of four-and-a-half months' life in a Dahabeeyah on the Nile; with some account of the discovery and excavation of a rock-cut chamber or Speos at Aboo-Simbel; descriptions of the river, the ruins, and the desert, the people met, the places visited, the ways and manners of the natives, &c., by Amelia Edwards, author of "Untrodden Peaks and Unfrequented Valleys," &c. The work will also contain ground plans, facsimiles of inscriptions, a map of the Nile from Alexandria to Dongola, and about seventy illustrations engraved on wood from finished drawings executed on the spot by the author.—Messrs. Sampson Low and Co. have nearly ready for publication Mr. John Forrest's "Explorations in Australia." The work will include three different journeys, namely: (1) Expedition in search of Dr. Leichardt and his party; (2) A journey from Perth to Adelaide, around the Great Australian Bight; (3) From Champion Bay across the desert to the Telegraph and to Adelaide. The book will contain illustrations from the author's sketches. Messrs. Longman have also in the press the following:—A work by Dr. Arthur Leared, on "Morocco and the Moors," being an account of travels, with a general description of the country and its people, with illustrations. A new volume on Assyria, by Mr. George Smith, entitled "Assyrian Discoveries," containing the Chaldean accounts of the Creation, the temptation and fall of man, the Deluge, the Tower of Babel and Confusion of Tongues, Nimrod, &c. This book will be profusely illustrated. A translation of Herr Edouard Mohr's "Nach den Victoriafällen des Zambesi" (reviewed in NATURE, vol xii. p. 231), containing an account of the South African Diamond Fields, &c., is also promised; it will be accompanied by numerous full-page and other woodcut illustrations, several chromolithographs, and a map.—Messrs. Daldy, Isbister, and Co. have in the press a "Geology for Students and General Readers," embodying the most recent theories and discoveries, by A. H. Green, Professor of Geology and Mining in the Yorkshire College of Science. It will be divided into two parts, the first containing the elements of Physical Geology; and the second, the elements of Stratigraphical Geology. Each part will contain upwards of 100 illustrations by the author.—Messrs. Macmillan and Co. have in preparation for the ensuing season, "A Course of Practical Instruction in Elementary Biology," by Prof. Huxley, F.R.S., and H. N. Martin, B.A. "The Modern Telescope," by J. Norman Lockyer, F.R.S.; lectures delivered at the Royal Institution, with additions by G. M. Seabroke, F.R.A.S. This work will be copiously illustrated, and will be uniform with the author's "Solar Physics." Also a work on "Stethometry: Examination of the Chest by a new and more exact method;" with some of its results in physiology and practical medicine, by A. Ransome, M.D. The two following books of travel will also be published in the autumn by Messrs. Macmillan and Co.:—"The Two Expeditions to Western Yunnan, commanded by Major Sladen and Col. Horace Browne," by Dr. Anderson, Director of the Indian Museum, Calcutta, and Professor of Comparative Anatomy in the Medical College, Calcutta, with numerous maps and illustrations. "The Zoology and Geology of Persia," by W. T. Blanford, with narratives of travel by Majors Lovett, St. John, and Evan Smith, and an introduction by Sir Frederick Goldsmid. This work will contain coloured plates and maps, and will be issued in two octavo volumes.—Among Messrs. Smith, Elder, and Co.'s announcements of forthcoming books we notice the following which may be of interest to our readers:—"Science Byways," by Richard A. Procter; and "Notes on the Climate of the Earth, Past and Present," by Capt. R. A. Sergeaunt, Royal Engineers. This last work will be illustrated with diagrams.

THE Yorkshire College of Science at Leeds, which was informally opened a year ago, was formally "inaugurated" yesterday by the Duke of Devonshire and other eminent men. There was a luncheon in the Great Northern Hotel, and a public meeting in the evening, addressed by the Right Hon. Lyon Playfair and others. The first session of this College, it is said, was as successful as could be expected. We have already stated that we cannot regard this institution on its present basis as satisfactory. Except for students whose education up to a certain point has been complete, the curriculum of a science faculty by itself, however complete, may easily do more good than harm. What we want are not separate science colleges, but first-rate secondary schools in which science should find its proper place. When these secondary schools exist, then the students who have passed through them may benefit from a technical school in which no literature is taught—but not till then.

THE inaugural sitting of the International Geodesical Congress took place on the 20th September at the Ministry of Foreign Affairs, Paris, under the presidency of General Hanez, the delegate for Spain. No delegate was present for Great Britain or for the United States; the German Empire was represented by General de Bayer, the Russian Empire by General de Broch, the Austrian Empire by Dr. Oppolzer; Italy, Belgium, Roumania, Switzerland, and the several German States were also represented. M. Charles Jourdain, member of the French Institute, and general secretary of the Minister of Public Instruction, delivered a speech in the name of M. Wallon, who is travelling in the provinces. It was replied to by General Hanez and by Ge-

neral de Bayer. M. Faye spoke in the name of the French section, which had invited a number of eminent men of science to take part in the proceedings. A number of reports of the Permanent Section having been read, the assembly adjourned to the following day. On the following evening a number of the delegates visited the Observatory of Paris. It is stated that the longitude of Palermo and Lisbon will be determined electrically with the instruments which have been used for determining the longitudes of Vienna and Algiers.

A PAIR of Sea Lions are shortly expected at the Brighton Aquarium, from the coast of California. They most probably are specimens of Steller's Sea Lion (*Otaria stelleri*), or of Gillies-pie's Sea Lion (*O. japonica*), judging from the locality whence they were obtained. It must be remembered that the name Sea Lion corresponds with the genus scientifically known as *Otaria*, and that there are several species, two of which—*O. jubata* and *O. pusilla*, both from the Falkland Islands—are represented in the collection of the Zoological Society in Regent's Park. Further information with reference to these interesting animals, from some species of which the so-called sealskin of commerce is obtained, will be found in our abstracts of two lectures delivered in the Zoological Gardens by Mr. J. W. Clarke during the early summer of this year (NATURE, vol. xi. p. 514, and vol. xii. p. 8).

THE organisation of the French meteorological regions is progressing satisfactorily. The example was set by Montpellier for the southern Mediterranean region. The northern Mediterranean region has now been centralised at Marseilles, and will very shortly commence operations. A special Meteorological Congress will be held in Poitiers for the western and south-western regions. The date is not quite determined, but a day in the end of October will probably be chosen."

A NEW Physical Observatory is to be erected at Pawlowsk, in connection with the Imperial Russian Physical Observatory at St. Petersburg.

MR. W. B. HEMSLEY has been appointed librarian to the Lindley Library, at the rooms of the Royal Horticultural Society, South Kensington, in the place of Prof. Thiselton Dyer.

THE Astronomical School established at Montsouris under the authority of the French Bureau des Longitudes was opened on Monday morning at eight o'clock by Capt. Mouchez, the director, and Admiral Paris. The pupils are six in number, all of them being lieutenants in the national navy. The period of study is six months. Every two months two pupils will leave and be replaced by two other naval lieutenants. A number of sailors will be attached to the establishment. The students will be taught the practice of celestial photography, spectroscopy, meridian observations, &c.

WE noticed the establishment of a School of Anthropology as being in preparation in Paris some months ago. We are in a position now to give the complete list of professors and the subjects for the course of lectures :—Broca, anatomical anthropology ; Dally, ethnological anthropology ; De Mortillet, prehistoric anthropology ; Hovelaeque, linguistic anthropology ; Topinard, general anthropology ; Bertillon, statistical and geographical anthropology. MM. Broca, Dally, and Bertillon are connected with the press, and leading members of the Paris Anthropological Society ; M. de Mortillet is the Conservator of the Prehistoric Museum at St. Germains.

A MERIDIAN-ROOM, intended for the observations of the French Bureau des Longitudes, was opened last Saturday by M. Dumesnil. The Bureau is now an independent establishment, having an office for meetings of members and computers in a pavilion belonging to the National Institute.

IT is proposed to hold an Electrical Exhibition in Paris in 1877. It will be held in the Palais de l'Industrie, the object being to illustrate all the applications of electricity to the arts, to industry, and to domestic purposes. This project, which was initiated by Count Hallez d'Arros, has been received with general favour both by the scientific and industrial worlds, and the necessary funds have been already guaranteed. An organising committee is being formed, and the provisional offices of the Exhibition have been established at 86, Rue de la Victoire.

THERE has been recently published in Russia a work by MM. Mendeléef and Kirpetschoff, on the Compressibility of Gases. The authors have been led to several results which ought to attract the attention of physicists ; they tend, in fact, to prove that Mariotte's Law does not hold good at low pressures, and that some of the results of Regnault's experiments do not agree with those obtained in other conditions.

THE Swedish Arctic Exhibition arrived at Hammerfest on Sept. 26, in perfect health and condition. They have brought back a rich naturalist collection and several important hydrographic reports. The mouth of the Jenisei river was reached on the 15th of August, and Professors Nordenskjöld, Sundstroem, and Stuxberg took leave of the expedition four days afterwards. They will return to Sweden *viâ* Siberia.

THE following pretty optical experiment is sent us by Prof. F. E. Nipher. Observe a white cloud through a plate of red glass with one eye, and through green glass with the other eye. After some moments transfer both eyes to the red glass, opening and closing each eye alternately. The strengthening of the red colour in the eye, fatigued by its complementary green, is very striking. The explanation of the phenomenon is of course well known, and many modifications of the experiment will readily suggest themselves.

IT is known to many experimenters that pulverised magnetic oxide of iron is to be preferred to iron filings in making magnetic curves. It is easily pulverised to any desired fineness. We do not know why filings are so universally recommended by writers on this subject.

THE Botanical Society of France has been recognised as an establishment of public utility by a presidential decree of Aug. 26. French botany has recently sustained a great loss in the death (at the age of seventy-two years) of M. Boreau, director of the Botanic Garden of Angers. M. Boreau was the author of a "Flora of Central France and of the Basin of the Loire," a work which has reached its third edition. Many papers by him have appeared in the *Memoirs* of the Société Académique de Maine-et-Loire.

AT the International Medical Congress at Brussels, Prof. Marey gave before a large and interested audience a simple, clear, and very complete account of the principal advances in physiology which are due to the introduction of the graphic method into its means of investigation. The application of the methods of mechanics and physics, he believes, has shown what vast horizons are open to the researches of the physiologist, by proving that now we may calculate exactly infinitely small quantities in space and time.

THE August part, just published, of the *Bulletin* of the French Geographical Society contains a very curious and interesting paper by M. E. Cortambert, on "the geographical distribution of celebrated persons in France, or the density of the intellectual forces in various parts of France." It is intended to accompany a map in which, by various tints of colour, it is attempted to indicate the proportion of notable men which have been born in the various departments of the country. M. Cortambert goes

rapidly over the various regions and departments, indicates the relative proportion of notable men belonging to each, and the particular intellectual product in which each has been most fertile. As might be expected, the north, particularly the basin of the Seine, which includes Paris, the great centre of population, is the richest. Seine-et-Oise, l'Aisne, Seine-Inférieure, Calvados, Champagne, are also marked by a deep tint. In the east, Alsace and Lorraine—which in this respect may yet be considered French—Burgundy, especially the Côte d'Or, Doubs, Lyonnais, and French-speaking Switzerland, all stand out prominent. In the south, Isère, Bouches-du-Rhône, Hérault, Haute-Garonne, Gironde, are the most remarkable. The west, as a whole, is but slightly tinted, notable exceptions being Ille-et-Villaine, Charente-Inférieure, and to some extent Maine-et-Loire and Finistère. In general, however, Brittany, whose inhabitants have many other noble qualities, does not show any great eminence from an intellectual point of view. This M. Cortambert is inclined to attribute to the fact that the Bretons are still to a large extent Celtic; and it is noteworthy that the centre of France, where also the same element is still strong, is also comparatively poor in eminent intellectual products. With regard to the particular kind of intellectual product for which each district is noted, M. Cortambert finds that the north is specially fertile in poets, claiming such names as Malherbe, Corneille, Racine, Molière, Boileau, La Fontaine, Voltaire, Beranger, De Musset; while in science it has produced such names as La Place, Élie de Beaumont, Delambre, Ducange; also not a few men eminent as painters, warriors, musicians, historians, and a large proportion of geographers. From the east come many men who have a world-wide fame in the natural, physical, and medical sciences—Buffon, Cuvier, Daubenton, Berthollet, André Ampère, Jussieu, Bichat, Récamier, Saussure, Bonnet, De Candolle, Agassiz, and others; in other departments also, specially in literature and art, this region has been fertile in great names. The south stands out prominent in the region of orators, but has also produced such men as Fermat, Legendre, Arago, Borda, Montesquieu, Montaigne, Tournefort, and Adanson. Brave sailors and celebrated voyagers are the special product of the west. In Brittany and the Centre, philosophy seems to dominate; to the latter belong Pascal and Descartes, and the daring humourist Rabelais. Altogether M. Cortambert's researches in this direction are of special interest, and will be of real value if he connects the results above indicated, as he states he intends to, with the nature of the physical and ethnographical characteristics of the various regions which he has surveyed.

We read in the Lille papers that the Catholic University of that town has been granted the use of Saint Eugenie Hospital, under certain restrictions.

The *Geological Magazine* states that Dr. W. Waagen has been appointed to the post of Palæontologist to the Indian Survey rendered vacant by the death of Dr. Stoliczka.

Scientific work will soon be resumed in Paris with activity, the Geographical, Biological, Anthropological, and other societies recommencing work within a few days. The Institute is the only French scientific institution which takes no holiday, even for any religious solemnity or national festivity. The regular weekly meetings were only interrupted *once* during the Commune, when civil war was raging in Paris. M. Élie de Beaumont, who was the perpetual secretary, tried to reach the Institute in order to open the sitting, but he was prevented by insurgents refusing to allow him to cross the barricades.

We have now the final fasciculi of a work, the publication of which has extended over the last five years, the "Nomenclator Botanicus," by Dr. L. Pfeiffer, of Cassel. In two volumes, amounting to over 3,500 pages, are here enumerated all the names and synonyms which have been applied to classes, orders, tribes, families, divisions, genera, and sub-genera of plants, from the time of Linnæus or earlier to the end of the year 1858, with reference to the place of publication. The work will be indispensable to anyone compiling a monograph of a genus or order. It is intended shortly to continue the work down to the most recent times.

The intended publication is announced, by subscription, of a "Flora of Clackmannan," by Messrs. James R. and T. Drummond. Subscribers' names are to be sent to Messrs. Maclachlan and Stewart, Edinburgh.

The Report of the Curators of the Botanical Exchange Club (Dr. J. T. Boswell and Mr. J. F. Duthie) for the last two years has just been published. It gives the new localities for scarce plants discovered during that time, and describes in great detail the observations which have been made on new forms or varieties of British plants.

The *Photographic News*, in speaking of "Photography and the Illustrated Press," gives some examples of the extent to which the latter is now dependent on the photographic art. The *New York Daily Graphic*, besides often executing its pictures from photographs, employs a photo-mechanical process in the production of some of its work. At the office of the *Moniteur Universel*, which is one of the most extensive printing and publishing establishments in France, arrangements are being made for large photo-printing works, as well as for producing coloured pictures by M. Leon Vidal's photo-chromic process. In this country photography is used to aid the artist in sketching to a great extent. One of these days, no doubt, the *News* believes, we shall have our papers illustrated by photographs *pur et simple*, but even now photography has far more to do with the execution of the illustrations in our journals than most people may be aware of.

"We were witness," says the *Photographic News*, "the other day of a very pretty application of light made by a gardener. Everybody knows that the ripening and colouring of fruit are due for the most part to light and heat, and that the roses upon an apple are influenced by the manner in which the sun strikes it. On looking at some fine wall-fruit in a Kentish garden, the proprietor called our attention to the manner in which he allowed his peaches to be partially covered by a leaf or two, in places—namely, where he wished them to remain green—and thus heighten by contrast the purple bloom on other portions of the fruit. There were many examples of a leaf being very sharply photographed upon the fruit, and the grower, by exercising a little care during the ripening season, thus enhanced the beauty of his fruit, and also their value, as in the case of a peach it is not only its flavour, but its appearance, which governs the price at Covent Garden."

A correspondent writes as follows to the *Derry Sentinel*:—"On Sunday evening last, while going into the country, I observed at Churchill, Glendermott, a bird which at first sight I could not easily class among any known species. On coming closer, however, I found that it was a white swallow. There was no perceptible difference between it and the common swallow, with the exception of its plumage being of the purest white. Other swallows were flying about at the same time, but this *rara avis* shunned their company, and did not seem anxious to join them, as it flitted about by its solitary self, and kept at a respectful distance from the others. As I have never heard of a white swallow having been seen about this part of the country before, I consider it to be a very strange visitor."

Prof. E. Morren, of Brussels, has been making some experiments with insectivorous plants, with the result that he combats the view that they possess the power of absorbing and assimi-

lating animal matter, as stated by many observers in this and other countries. He says that so far as *Pinguicula longifolia* and *Drosera rotundifolia* are concerned, at least, he believes that the glutinous excretions of their leaves simply hasten decomposition, which is moreover attended by the usual concomitant phenomena. In very early stages he found monads, bacteria, the mycelium of various fungi, and other conditions of putrefaction. So far as the action of the mucus on the entrapped insects and on coagulated albumen is concerned, he affirms that it is similar to that of pure water, sugar-water, and the honey-secretions taken from the flowers of *Aechmea nudiflora*. Nevertheless he admits having seen all the admirable contrivances for catching and retaining insects.

MR. G. M. DAWSON, F.G.S., has just issued a report to the Canadian Government, on the geology and resources of the region in the forty-ninth parallel, between the Lake of the Woods, S.E. of Lake Winnipeg, and the Rocky Mountains; in other words, of the western portion of the boundary of British America. Much of the country traversed had been previously quite unknown, geographically as well as geologically, which fact adds greatly to the importance of the report, the bulk of which is devoted to the account of the Cretaceous and Tertiary strata of the plains between the Rocky Mountains, as they are constituted at the boundary, and the Lake of the Woods. The Survey of the United States Government to the south of the above-mentioned region, when taken in conjunction with that under notice, forms a vast addition to geologic knowledge. Among the most important results arrived at is the discovery of beds which seem to gap over the apparently considerable interval between the Cretaceous and lower Tertiary periods.

THE following interesting statistics on the libraries of Europe are taken from M. Block's recently published "Statistique de la France comparée avec les divers pays de l'Europe":—Paris has six great libraries belonging to the State and open to the public. Outside Paris there are in France 338 libraries which possess more than 3½ million volumes; of this number 41 are open in the evening. Great Britain possesses 1,771,493 volumes, or six vols. to each 100 persons of the population (this must surely refer solely to the British Museum library). Italy has 11·7 volumes per 100 inhabitants. In France there are 4,389,000 volumes, or 11·7 per 100 persons; in Austria, 2,488,000 vols. or 6·9 per 100; in Russia, 852,000 vols., or 1·3 per 100; in Belgium, 509,100 vols., or 10·4 per 100. Of all countries, France possesses the greatest number of volumes, and Paris alone has one-third of them in its libraries. Since 1865 students' libraries have been formed over nearly the whole of France. Since that year these libraries have increased from 4,833, containing 180,854 volumes, to (in 1870–1) 13,638, containing 1,158,742 volumes.

THE additions to the Zoological Society's Gardens during the past week include four Tigers (*Felis tigris*) from India, presented by H.E. the Governor-General of India; an Ocelot (*Felis pardalis*) from South America, presented by Mr. H. Kirtley; a Golden Agouti (*Dasyprocta aguti*) from South America, presented by Mr. Henry T. Balfour; a Cuvier's Toucan (*Ramphastos cuvieri*) from Upper Amazons, presented by Mr. A. Blumenthal; a Chilian Sea Eagle (*Geranoaëtus aguia*) from Paraguay, presented by Mr. E. Nelson; two Red and Yellow Macaws (*Ara chloroptera*) from South America, presented by the Misses Rix; three Tigers (*Felis tigris*), a Leopard (*Felis pardus*), a Caracal (*Felis caracal*), two Musanga Paradoxures (*Paradoxurus musanga*) from India, a Black Lemur (*Lemur macaco*) from Madagascar, a Crab-eating Opossum (*Didelphys cancrivora*) from Central America, two Mexican Deer (*Cervus mexicanus*), deposited; a Great-billed Parrakeet (*Tanygnathus megalorhynchus*) from Gilolo, received in exchange; an American Darter (*Plotus anhinga*) from South America, purchased.

*SOME LECTURE NOTES ON METEORITES**

II.

WE may next turn our attention to the nature of the substances which fall on these occasions, and in the first place it may be briefly stated that they are of three kinds: first, masses of iron, alloyed with nickel, termed aërosiderites, or briefly siderites; secondly, stony meteorites (aërolites), which consist of silicates somewhat analogous to terrestrial rocks, but having nickeliferous iron disseminated in small granules throughout them: and finally, there is a sort of meteorite which is intermediate between these iron and stone masses, consisting of a sponge-like mass of the iron, containing in its hollows stony matter similar to that of the aërolites. These are what are termed siderolites (or meso-siderites). These different kinds of meteorites—namely, siderites, siderolites, and aërolites—then, comprehend all the forms of matter, as at present known, which fall to the earth from the regions external to its atmosphere.

Of these different kinds of meteorites, national as well as private collections have been formed in most countries in Europe. The most celebrated and historical collection of them is that at Vienna, formed by the gradual and generally contemporary acquisition of specimens of the meteorites as they have fallen or been found from time to time, from the early years of this century, and descriptions of them have been given by very eminent Viennese mineralogists. Then we have in the British Museum a not less complete collection, numbering now about 294 different meteorites. Next to these in completeness is the collection at Berlin, founded on that formed by Chladni.

The importance of the study of such collections of meteorites becomes evident, if we consider a remark of Humboldt's, in the latter part of his "Cosmos," to the effect that there are only two avenues to our knowledge of the universe outside of us, one being light, by the agency of which the motions of the heavenly bodies are revealed to us, while the other consists in the masses of matter that come to our earth from that outer universe; and that these are the only means by which we are able to take any cognisance of what is going on in the boundless regions of space.

Since Humboldt's time, indeed, light has become a totally different instrument in our hands to what it was. No longer are the heavens for us without speech or language, for light is indeed the language of the universe, though man has only yesterday begun to interpret the voices whereby one star calleth to another star.

Our interpreter is the prism, that most subtle and sensitive implement for probing the character of the most distant matter provided only it be luminous. In Humboldt's time light merely enabled us to record and calculate the mute motions of the orbs around us. Now not only are we able so to tell their motions, but we may feel new truths "trembling along that far-reaching line" which connects our eye with a star, and take cognisance of the physical conditions and chemical composition of the matter in active change upon the surface of that star. And this altogether new source of knowledge throws an entirely new interest around the question of the origin or sources of meteoric matter. Let us then next inquire of the meteorites themselves what they have to tell us in elucidation of these questions.

The first aspect of a meteorite is that of a fragment. One cannot look at it without saying so. But as to the question whether it came as a fragment into our atmosphere, or whether it became a fragment after it had entered it, we can at least say that its present fragmentary form is mainly due to the action of that atmosphere itself. Still, it is eminently probable, from other grounds, that meteorites encounter our earth, and probably our system, in the guise of fragments, or rather of angular and unshaped masses—chips, as it were, thrown off in the great workshop; matter flung out into space, not yet used up in the making of the worlds. It will be well first to consider what an examination of their physical characters and general internal structure will reveal to us. For the incrustation and pitted surface of aërolites already described an explanation was sought on the hypothesis of external fusion arising from the sudden development of enormous heat on the surface of a mass internally brittle and contracted, owing to its very low temperature. And among the more purely mechanical characteristics, we must not pass over the general want of compactness in meteorites. Thus, though a meteorite generally seems very compact, if it be suspended in chloride of mercury to dissolve the iron without affecting, or with only slight effect on, the other minerals in it, you

* Continued from p. 487.

will dissolve meteoric iron out of it; but the remainder of the mass will, after this treatment, in most cases, crumble into a granular powder, showing that the cohesion of the mass is not like that of an ordinary terrestrial rock. Some aërolites, again, will even crumble in the fingers without previous treatment.

The rocks to which they bear the nearest resemblance, in respect of their mechanical structure, among the products of our volcanoes, are some volcanic bombs, and, as regards several of the aërolites, certain kinds of volcanic tufa.

Now, in examining these bodies more closely, the first thing that calls for attention is that they are composed entirely, or almost entirely, of crystalline substances; and that matter thus coming from regions beyond our world crystallises in the same way, and is obedient to the same law, as matter which crystallises on the globe.

Sections of meteorites cut thin and ground down to transparent slices, when examined by means of polarised light, are seen to be crystallised throughout; the crystalline character of the substances being evidenced by the interference tints which colour the different crystals of which the sections are made up. Another characteristic of many meteorites, in which they differ from ordinary terrestrial rocks, is what has been termed by Gustav Rose their chondritic structure. The minerals in these are found to be more or less aggregated in little spherules, which are distributed in different degrees of abundance in different meteorites through the ground-mass of the stone.

Sections of chondritic meteorites show them to consist in some cases almost entirely of spherules. Such is the case with the Parnallee aërolite, of which the most varied groups of spherules may be seen assembled in a single section. Some of these spherules are encased, as it were, in minute shells of metallic (nickeliferous) iron, or of such iron mingled with a kind of pyrites peculiar to meteorites, an iron sulphide termed troilite, constituted by an equivalent of sulphur combined with one equivalent of iron. Minute granules of troilite and iron, without any definite form, are so seen to be disseminated among the grains of the interspherular ground-mass of the meteorite.

A closer inspection of the spherules further reveals in many cases the presence of *intro*spherular iron. In some spherules the meteoric silicates may be seen, radiating from a point, but while the spherule is enclosed in a mixed outer mass of silicates, iron and troilite in little black specks are seen scattered all through it, presenting the appearance of having been spurted, as it were, from a point, the larger particles to the greater distance: and these specks consist in part of nickeliferous iron, while some are meteoric pyrites (troilite).

In connection with the subject of these spherules, which form so characteristic a feature of many stony meteorites, it should be mentioned that occasionally some of the spherules are seen to be broken in half and the halves separated from each other to some small distance, a fact of considerable significance, though not easy of interpretation in connection with the history of the meteorite and the more or less violent crises it must have passed through at successive periods in that history.

Evidence of another kind of historical succession in the events and influences through which a meteorite may have passed is afforded by the not rare peculiarity of a sort of vein, like a mineral vein, running through the meteorite. In fact, just as in a mine one may meet with a fissure that, once dividing the "country," but subsequently filled by rocky matter, cuts across the course of a mineral vein which itself was originally formed in a similar way; and just as such a cross fissure thus intersecting with the original metalliferous vein often gives us evidence of a *heave*, i.e. that one side of the new fissure has slid upwards or downwards along the other, so an exactly similar thing is met with in meteorites, and is admirably seen in the microscopic sections of them.

Such a fissure will sometimes divide several spherules lying on its track, the two sides of the fissure having slid, the one along the other. The corresponding halves of the spherules are in such cases separated to some distance along the fissure, and this is itself filled with the vein of meteoric iron or troilite, in some cases with a black fused substance, like the crust of a meteorite.

In passing next to the consideration of the chemistry of meteorites, one of the first inquiries that suggests itself is whether and to what extent the elementary composition of these cosmical rock-fragments accords with that of our own world, or with the revelations which the prism has afforded us regarding the constitution of the matter in energetic action on the surface of our sun, or of those far distant suns, the stars; or, again, in those still uninterpreted assemblages of luminous matter that we call the nebulæ. Now, the elements that have been already recognised by analysis as existing in meteorites form a list that comprises one-third of all the elements known to our chemistry; and these, the more abundant elements on our world. They are—

Hydrogen	*Chromium*	Arsenic
Lithium	*Manganese*	Vanadium ?
Sodium	*Iron*	Phosphorus
Potassium	*Nickel*	Sulphur
Magnesium	*Cobalt*	Oxygen
Calcium	*Copper*	Silicon
Aluminium	Tin	Carbon
Titanium	Antimony	Chlorine

Now, of these elements, those in italics have also been found by the spectroscope to be constituents of the solar surface, together with zinc, strontium, and cadmium, which metals have not yet been met with in meteorites.

The number of elements recognised as existing in activity on the solar orb will undoubtedly be largely increased with the progress of the combined study of the solar spectrum and of the conditions under which the several lines belonging to the different elements are developed. It is by study of this kind that Mr. Lockyer has detected potassium in the sun. The fact that at the present time all the elements detected in the sun excepting three are met with in meteorites, while on the other hand the meteorites contain five metals not as yet found in the sun, at the same time that the six metalloids found in them are so strangely all apparently absent from the surface of our great luminary, might seem to place difficulties in the way of our recognising a general unity of elementary composition in the matter that composes the various orbs and wandering masses that pervade our universe.

But it is clear, on the other hand, that it is too early as yet to look on these results as establishing even probable exceptions to such a unity.

That carbon, sulphur, potassium, and phosphorus, elements so frequently met with in meteorites and on our globe, should, with nitrogen, be absent or have escaped detection among the elements involved in the active operations on the surface of the sun, is certainly not a little surprising. Nor is the failure of the prism to detect the lines due to oxygen and silicon among those presented by the solar photosphere to be accounted for by assuming the persistency of particular silicates in resisting decomposition or vaporisation even in a solar temperature, for Von Rath has shown that silicates such as augite and leucite are actually deposited by a process of sublimation even at the comparatively low temperatures of our volcanoes. Yet it is difficult to believe that the last-mentioned elements can be absent from the great central body of our system, whether we reason from analogy, from their great importance in the composition of our earth, or from the more than probability that these elements must have been contributed to a large amount to the material of the sun by meteoric matter falling into his surface.

Mr. Lockyer has indeed grasped this difficulty with a bold hand, and has not hesitated to declare as a probable explanation of the results obtained from the spectra of the reversing layer and chromosphere of the sun, that the elements exist there not in a molecular but in an atomic condition; and he further assumes that the metalloids exist in a more simple elementary condition than that in which we know them; their terrestrial existence being assumed to be that of compounds which have yet to be resolved into their constituents by our chemistry, though under the fierce chemistry of the sun it is only as thus resolved that they exist on his surface. It is startling for the chemist to be thus called upon to believe that enormous temperatures are endowed with a dissociating power, capable of not merely severing the bonds of ordinary chemical combination, but further of forcing into a condition of ultimate atomic disintegration composite molecules where these are the form under which the chemist has learnt to recognise the ordinary condition of even the isolated elements. Certainly the concordance of the heights to which the different gaseous elements rise in the reversing layer with the weights of the atoms of those elements as represented by their equivalents in the older chemistry, would lend something more than a justification to the even bolder hypothesis that recognises in the metalloids (such as silicon, sulphur, and oxygen, as they exist in our world) compounds of other and to our chemistry unknown elements, were we able to assert that the gaseous molecules of the metals in question, other than hydrogen, potassium, and sodium, must necessarily, like those of these elements, be double. It would be, in any case, a

splendid result of solar physics to establish the nature of the gaseous molecules of so many elements that have as yet defied the experimental methods of our terrestrial laboratories. The banded character of the spectra of so many of these metalloids has lent a really important argument to Mr. Lockyer in his bold speculation as to their compound nature, in consequence of its parallelism with the case of compound gases, and his hypothesis has the merit of giving thus an explanation of the apparent absence of elements that every argument would lead us to look for, founded on a principle as ingenious as it is bold in its application.

The recognition by Mr. Huggins in the spectra of the stars of the lines belonging to hydrogen, sodium, magnesium, calcium, and iron, and of carbon compounds in comets and nebulæ, tends strongly to confirm the probability of a general identity in the chemical nature of the matter which pervades our universe; and further shows that the results of these investigations present no obstacle to our drawing any conclusion to which the logic of facts might otherwise guide us as to meteorolitic matter having been in its origin foreign to the solar system. Observations by v. Konkoly of the magnesium, sodium, and possibly also iron lines in the August meteoric swarm, like those by Alexander Herschel of the sodium line in those same St. Lawrence meteors, are of value as extending the coincidence in the elementary constitution of the sun, the stars, and meteorites, to those minuter forms of meteoric matter which, by their dispersion in the atmosphere, have hitherto been unattainable for the purposes of investigation.

In passing from the merely elementary components of meteorites to the chemical forms—that is to say, to the minerals in which these elements are grouped in them, we find ourselves in the presence of aggregates of crystallised minerals that at once remind us of our terrestrial rocks. At a first aspect they might easily be taken for rocks formed under conditions not very different from those of our globe. A closer inspection, however, brings out distinctive characters in these that evidence a very different set of conditions as having prevailed in the formation of the meteoric and the terrestrial rocks. Without going into minute mineralogical variations, and needlessly multiplying names, we may tabulate in a very short list the constituent minerals of the different sorts of meteorites. Several of these minerals are nearly identical in composition and crystallographic character with corresponding minerals met with in terrestrial rocks; others again are unknown, while some of them could hardly exist permanently as terrestrial minerals; and two present the composition of minerals familiar to us in our own rocks, but crystallographically distinct from these as belonging to different types of symmetry or "systems" from theirs.

In the Elementary Condition.

Iron with Nickel, traces of Cobalt and Copper, in some and probably in all cases with Hydrogen, Carbonic oxide, or other gases occluded in the metal.

Carbon (graphitic and plumbaginous).

Sulphur.

Compounds.

Ferrous Sulphide (*Troilite*)	FeS
Magnetic Pyrites	Fe_7S_8
Magnesium Sulphide ?	MgS
Calcium Sulphide (*Oldhamite*)	$Ca(Mg)S$
A Titanium—Calcium Sulphide (*Osbornite*)	?
Magnetite	Fe_3O_4
Chromite	$(FeCr)_3O_4$
Silica (orthorhombic as *Asmanite*)	SiO_2
,, (hexagonal as Quartz) ? } Tin Oxide	SnO_2
Silicates, viz. :—	
Olivine varieties	$\left(Mg_{\frac{n}{m}}Fe_{\frac{m-n}{m}}\right)_2SiO_4$
Enstatite	$MgSiO_3$
Bronzite varieties	$\left(Mg_{\frac{n}{m}}Fe_{\frac{m-n}{m}}\right)SiO_3$
Augite varieties	$\left(Mg_{\frac{n}{m}}Ca_{\frac{m-n}{m}}\right)SiO_3$
,, varieties containing corresponding ferrous silicate.	
Anorthite	$CaAl_2SiO_8$
Labradorite ?	
,, in tesseral forms (Tschermak's Maskelynite).	
Schreibersite varieties (phosphides of iron and nickel).	
Hydrocarbons (not yet sufficiently investigated).	

The names printed in italics are thus new to our mineralogy. The mineral to which I originally gave the name of Oldhamite is in all probability a mixture of two minerals—a Calcium Sulphide (which would be the pure Oldhamite) and a Magnesium Sulphide; and it is probable that they are not uncommon, though sparsely scattered, ingredients in freshly fallen meteorites, which, however, the action of a damp atmosphere rapidly decomposes into calcium sulphate or carbonate, and free sulphur, all which minerals occur in minute quantities occasionally in meteorites after they have been exposed to the weather.

Until the year 1867 the mineralogical department at the British Museum was without a laboratory, and chemical analyses could not be performed. I accordingly had recourse in 1861 to microscopic investigation as my only means of attacking the mineralogical problems presented by meteoric rocks. By the use of polarised light, of which the position of the plane of polarisation was accurately determined, it was possible, by the aid of an eyepiece goniometer and also of a revolving stage, to determine with some precision the directions of the principal sections in any of the minute sections of crystals which a fragment of a meteorite worked down to a thin transparent slice might present. Where such crystal sections happened to be approximately parallel to a zone plane, and the traces of the faces belonging to the zone could be seen with sufficient sharpness, or where cleavage planes occurred parallel or at recognisable inclinations to faces of the zone, important decisions could be arrived at by aid of polarised light. And this method is now becoming one of great importance to petrologists.

It was thus that I was enabled to anticipate with much confidence the orthorhombic character of one and the clinorhombic character of another ingredient (the enstatite and augite) in the Busti meteorite, and determine the cubic character of the oldhamite in that meteorite in 1862; and to be the first to announce the more than probability of enstatite (including of course, as the term then did, bronzite) being an important ingredient in meteorites; in the case of the Nellore meteorite in June 1863 and of that of Kaee in August 1864; a view confirmed afterwards (in November 1864) by Dr. Lawrence Smith on his repeating his analysis of the meteorite of Bishopville. Of the meteorites of Busti and of Manegaum, before they were cut, only minute fragments were at my disposal; and though in naming and first describing oldhamite in 1862, I had spoken of it as having all the appearance of being a "calcium galena," a small amount of probably sulphur and gypsum that separated in the watch-glass in which I made a qualitative investigation of it constrained me to say that I believed it to contain an excess of sulphur beyond that in the neutral sulphide.

Of the Manegaum meteorite also I employed only a minute fragment for investigation, and I attributed the bronzite of that meteorite to olivine, the section of the crystal examined not being really paralled to a zone-plane, and was confirmed in this error by finding the powdered bronzite not to be insoluble in acids. The addition of a laboratory to the department in 1867 enabled the long-desired analysis of the minerals I had separated to be made; and Dr. W. Flight being at my request appointed chemical assistant, I was able, with the help of his analytical skill, to complete the account of the minerals the presence of which in the meteorites in question had been determined so many years before.

The separated sulphur in the oldhamite proved, when a sufficient amount was taken for investigation, to be due to a superficial decomposition of the mineral, while bronzite was shown to be distinctly soluble in acid. The methods I adopted for the investigation of meteorites have since been employed by other observers, as well in the mode of using the directions of the principal sections of crystal-sections in the microscopic examination of terrestrial rocks as in the mode of attacking a meteorite by separating and isolating by toilsome microscopic selection its ingredient minerals; the plan by which the silicates in the Breitenbach siderolite and also those in fresh amounts from the Busti aërolite had been separated with a view to analysis in 1864 and 1865. Viktor von Lang, to whose assistance and to whose friendship I owe two or three of the most valued years of my life, while he was my colleague, measured, and some time afterwards published the account of the crystals of bronzite in the Breitenbach meteorite; the first occasion on which the crystallography of that mineral had been made out, only the system and approximate prism angle of the terrestrial bronzite and enstatite being previously known through the optical researches of Des Cloizeaux.

The form of asmanite, the orthorhombic variety of silica, occur-

ring in the same meteorite, offered a difficult problem which I had taken in hand. One little crystal, however, carrying a portion of a zone with four consecutive faces, picked out in 1867, furnished the final key to its crystallography.

N. S. MASKELYNE

(*To be continued.*)

INSTINCT AND ACQUISITION.*

SO great was the influence of that school of psychology which maintained that we and all other animals had to acquire in the course of our individual lives all the knowledge and skill necessary for our preservation, that many of the very greatest authorities in science refused to believe in those instructive performances of young animals about which the less learned multitude have never had any doubt. For example, Helmholtz, than whom there is not, perhaps, any higher scientific authority, says: "The young chicken very soon pecks at grains of corn, but it pecked while it was still in the shell, and when it hears the hen peck, it pecks again, at first seemingly at random. Then, when it has by chance hit upon a grain, it may, no doubt, learn to notice the field of vision which is at the moment presented to it."

At the meeting of this Association in 1872, I gave a pretty full account of the behaviour of the chicken after its escape from the shell. The facts observed were conclusive against the individual-experience psychology. And they have, as far as I am aware, been received by scientific men without question. I would now add that not only does the chick not require to learn to peck at, to seize, and to swallow small specks of food, but that it is not a fact, as asserted, and generally supposed, that it pecks while still in the shell. The actual mode of self-delivery is just the reverse of pecking. Instead of striking forward and downward (a movement impossible on the part of a bird packed in a shell with its head under its wing), it breaks its way out by vigorously jerking its head upward, while it turns round within the shell, which is cut in two—chipped right round in a perfect circle some distance from the great end.

Though the instincts of animals appear and disappear in such seasonable correspondence with their own wants and the wants of their offspring as to be a standing subject of wonder, they have by no means the fixed and unalterable character by which some would distinguish them from the higher faculties of the human race. They vary in the individuals as does their physical structure. Animals can learn what they did not know by instinct and forget the instinctive knowledge which they never learned, while their instincts will often accommodate themselves to considerable changes in the order of external events. Everybody knows it to be a common practice to hatch ducks' eggs under the common hen, though in such cases the hen has to sit a week longer than on her own eggs. I tried an experiment to ascertain how far the time of sitting could be interfered with in the opposite direction. Two hens became broody on the same day, and I set them on dummies. On the third day I put two chicks a day old to one of the hens. She pecked at them once or twice; seemed rather fidgety, then took to them, called them to her and entered on all the cares of a mother. The other hen was similarly tried, but with a very different result. She pecked at the chickens viciously, and both that day and the next stubbornly refused to have anything to do with them.

The pig is an animal that has its wits about it quite as soon after birth as the chicken. I therefore selected it as a subject of observation. The following are some of my observations:—That vigorous young pigs get up and search for the teat at once, or within one minute after their entrance into the world. That if removed several feet from their mother, when aged only a few minutes, they soon find their way back to her, guided apparently by the grunting she makes in answer to their squeaking. In the case I observed the old sow rose in less than an hour and a half after pigging, and went out to eat; the pigs ran about, tried to eat various matters, followed their mother out, and sucked while she stood eating. One pig I put in a bag the moment it was born and kept it in the dark until it was seven hours old, when I placed it outside the sty, a distance of ten feet from where the sow lay concealed inside the house. The pig soon recognised the low grunting of its mother, went along outside the sty struggling to get under or over the lower bar. At the end of five minutes it succeeded in forcing itself through under the bar at one of the few places where that was possible. No sooner in than it went without a pause into the pig-house to its mother, and was at once like the others in its behaviour. Two little pigs I blindfolded at their birth. One of them I placed with its mother at once: it soon found the teat and began to suck. Six hours later I placed the other a little distance from the sow; it reached her in half a minute, after going about rather vaguely; in half a minute more it found the teat. Next day I found that one of the two left with the mother, blindfolded, had got the blinders off; the other was quite blind, walked about freely, knocking against things. In the afternoon I uncovered its eyes, and it went round and round as if it had had sight, and had suddenly lost it. In ten minutes it was scarcely distinguishable from one that had had sight all along. When placed on a chair it knew the height to require considering, went down on its knees and leapt down. When its eyes had been unveiled twenty minutes I placed it and another twenty feet from the sty. The two reached the mother in five minutes and at the same moment.

Different kinds of creatures, then, bring with them a good deal of cleverness, and a very useful acquaintance with the established order of nature. At the same time all of them later in their lives do a great many things of which they are quite incapable at birth. That these are all matters of pure acquisition appears to me an unwarranted assumption. The human infant cannot masticate; it can move its limbs, but cannot walk, or direct its hands so as to grasp an object held up before it. The kitten just born cannot catch mice. The newly hatched swallow or tomtit can neither walk, nor fly, nor feed itself. They are as helpless as the human infant. Is it as the result of painful learning that the child subsequently seizes an apple and eats it? that the cat lies in wait for the mouse? that the bird finds its proper food and wings its way through the air? We think not. With the development of the physical parts, comes, according to our view, the power to use them, in the ways that have preserved the race through past ages. This is in harmony with all we know. Not so the contrary view. So old is the feud between the cat and the dog, that the kitten knows its enemy even before it is able to see him, and when its fear can in no way serve it. One day last month, after fondling my dog, I put my hand into a basket containing four blind kittens, three days old. The smell my hand had carried with it set them puffing and spitting in a most comical fashion.

That the later developments to which I have referred are not acquisitions can be in some instances demonstrated. Birds do not *learn* to fly. Two years ago I shut up five unfledged swallows in a small box not much larger than the nest from which they were taken. The little box, which had a wire front, was hung on the wall near the nest, and the young swallows were fed by their parents through the wires. In this confinement, where they could not even extend their wings, they were kept until after they were fully fledged. Lord and Lady Amberley liberated the birds and communicated their observations to me, I being in another part of the country at the time. On going to set the prisoners free, one was found dead—they were all alive on the previous day. The remaining four were allowed to escape one at a time. Two of these were perceptibly wavering and unsteady in their flight. One of them, after a flight of about ninety yards, disappeared among some trees; the other, which flew more steadily, made a sweeping circuit in the air, after the manner of its kind, and alighted, or attempted to alight, on a branchless stump of a beech; at least it was no more seen. No. 3 (which was seen on the wing for about half a minute) flew near the ground, first round Wellingtonia, over to the other side of the kitchen-garden, past the bee-house, back to the lawn, round again, and into a beech-tree. No. 4 flew well near the ground, over a hedge twelve feet high to the kitchen-garden through an opening into the beeches, and was last seen close to the ground. The swallows never flew against anything, nor was there, in their avoiding objects, any appreciable difference between them and the old birds. No. 3 swept round the Wellingtonia, and No. 4 rose over the hedge just as we see the old swallows doing every hour of the day. I have this summer verified these observations. Of two swallows I had similarly confined, one, on being set free, flew a yard or two too close to the ground, rose in the direction of a beech-tree, which it gracefully avoided; it was seen for a considerable time sweeping round the beeches and performing magnificent evolutions in the air high above them. The other, which was observed to beat the air with its wings more than usual, was soon lost to sight behind some trees. Titmice, tomtits, and wrens I have made the subjects of a similar experiment and with similar results.

Again, every boy who has brought up nestlings with the hand

* Read at the Bristol meeting of the British Association.

must have observed that while for a time they but hold up their heads and open their mouths to be fed, they by-and-by begin quite spontaneously to snap at the food. Here the development may be observed as it proceeds. In the case of the swallow I am inclined to think that they catch insects in the air perfectly well immediately on leaving the nest.

With regard, now, to man, is there any reason to suppose that, unlike all other creatures, his mental constitution has to be in the case of each individual built up from the foundation out of the primitive elements of consciousness? Reason seems to me to be all the other way. The infant is helpless at birth for the same reason that the kitten or swallow is helpless—because of its physical immaturity; and I know of nothing to justify the contrary opinion, as held by some of our distinguished psychologists. Why believe that the sparrow can pick up crumbs by instinct, but that man must learn to interpret his visual sensations and to chew his food? Dr. Carpenter, in his "Mental Physiology," has attempted to answer this argument in the only way in which it could be answered. He has produced facts which appear to him to prove "that the acquirement of the power of visually guiding the muscular movements is experimental in the case of the human infant." More than forty years ago Dr. Carpenter took part in an operation performed on a boy three years old for congenital cataract. The operation was successful. In a few days both pupils were almost clear; but though the boy "clearly recognised the *direction* of a candle or other bright object, he was unable as an infant to apprehend its *distance;* so that when told to lay hold of a watch he groped at it just as a young child lying in its cradle." He gradually began to use his eyes; first in places with which he was not familiar, but it was several months before he trusted to them for guidance as other children of his age would do. No one will doubt the accuracy of any of these statements; but I cannot agree with Dr. Carpenter that he had in the case of the boy anything "exactly parallel" to my experiment of hooding chickens at birth and giving them their sight at the end of one or two days. This boy was couched when three years old. Probably sight would have been at first rather puzzling to my chickens, had they not received it until they were six months old. Dr. Carpenter seems to have forgotten for the moment that instincts as well as acquisitions decay through desuetude, and that this is especially true when the faculties in question have never once been started into action and are of the kind which develop through exercise. Another and vital difference between Dr. Carpenter's experiment and mine is this, that when at the end of two days I gave my chickens sight, I did not do so by poking out or lacerating the crystalline lenses of their eyes with a needle.

The presumption, then, that the progress of the infant is but the unfolding of inherited powers remains as strong as ever. With wings there comes to the bird the power to use them; and why should we believe that because the human infant is born without teeth, it should, when they do make their appearance, have to discover their use by a series of happy accidents?

One word as to the origin of instincts. In common with other evolutionists, I have argued that instinct in the present generation may be regarded as the product of the accumulated experiences of past generations. More peculiar to myself, and giving a special meaning to the word experience, is the view that the question of the origin of the most mysterious instincts is not more difficult than, or different from, but is the same with the problem of the origin of the physical structure of the creatures. For, however they may have come by their bodily organisation, it, in my opinion, carries with it a corresponding mental nature.

In opposition to this view it has been urged that we have only to consider almost any well-marked instinct to see that it could never have been a product of evolution. We, it is said most frequently, cannot conceive the experiences that might by inheritance have become the instincts; and we *can* see very clearly that many instincts are so essential to the preservation of the creatures that without them they could never have lived to acquire them. The answer is easy. Granting our utter inability to go back in imagination through the infinite multitude of forms, with their diversified mental characteristics, that stand between the greyhound and the speck of living jelly to which, according to the theory of evolution, it is related by an unbroken line of descent. Granting that we are, if possible, still less able to picture in imagination the process of change from any one form to another. What then? Not surely that the theory of evolution is false! For the same argument will prove that no man present can possibly be the son of his father. Our ignorance is very great, but it is not a very great argument.

The other objection, that the creatures could never have lived to acquire their more important instincts, rests on a careless misunderstanding of the theory of evolution. It assumes in the drollest possible way that evolutionists must believe that in the course of the evolution of the existing races there must have from time to time appeared whole generations of creatures that could not start on life from the want of instincts that they had not got. There can be no need to say more than that these unfortunate creatures are assumed to have been singularly unlike their parents. The answer is, that it is not the doctrine of evolution that the bodies are evolved first by one set of causes and the minds are put in afterwards by another. This notion is but the still lingering shadow of the individual-experience psychology. As evolutionists, whether we take the more common view and regard the actions of animals as prompted by their feelings and guided by their thoughts, or believe, as I do, that animals and men are conscious automata, in either case we are under no necessity of assuming in explanation of the origin of the most mysterious instincts anything beyond the operation of those laws that we see operating around us, but concerning which we have yet to learn more, perhaps, than we have learned.

THURSDAY, OCTOBER 14, 1875

THE INAUGURATION OF THE YORKSHIRE COLLEGE OF SCIENCE

THE formal opening of the College of Science at Leeds by the Duke of Devonshire, which we briefly announced last week, is an event of no mean importance to the county, and of no small interest to the rest of the community, inasmuch as we must regard it as another indication of the great educational movement which has already been experienced by Manchester, Newcastle, Birmingham, and Bristol, and is beginning to be felt more or less strongly in every industrial centre throughout the country. This movement, as Mr. Forster tells us, is not merely to give education to the captains of industry; it is to increase the culture of every individual working man and working woman in the land, and to give them not elementary education alone, but skilled knowledge to enable them to earn their living as efficiently as possible by affording them the key to the stores of knowledge.

It really appears that at last, in this county utterly devoid of any organisation for anything but the lowest education, there are persons who are gradually realising the fact, the statement of which has been dinned into our ears by the best informed minds for more than a quarter of a century, that the industrial supremacy of this country depends on other factors than natural resources, mental vigour, industry, and perseverance. The illustrious Liebig more than a generation ago, and in the very town which witnessed the ceremony of last week, warned us how impossible it was for England permanently to preserve this supremacy unless she bestowed more attention on the sciences which formed the basis of her chief industries. Nothing could be happier than the coincidence that Dr. Playfair, who then interpreted this memorable saying of the great German philosopher, should be present to see the Yorkshire people establishing an educational organisation, which is in no small degree the outcome of the counsel given to them so long ago. Truly the bread cast upon the waters has returned to Leeds after many days. And now let the promoters of the Yorkshire College take heed to the words of counsel given by the many eminent men whom they invited to take part in the opening ceremony. If the county is as earnest in furthering its welfare as we believe it to be, the institution ought not to remain long on its present limited basis: we hope and trust that the opinion of its President, Lord Frederick Cavendish, that to restrict the College to natural science would make it "a one-legged, one-sided concern," is shared by the rest of the Council. We do not want a Yorkshire College of Science, but a Yorkshire College in which science will be found in its proper place. It must be remembered that the whole duty of these local colleges is not limited to the instruction in the particular sciences which more directly relate to the manufacturing industries of the districts in which they are placed; they must be made to act as *nuclei* for higher culture by the establishment of chairs of Art and Literature. As Dr. Playfair told the people of Leeds, "a College of Science, such as we are inaugurating to-day, is admirable in itself, but it is not complete. Perhaps it even focusses the light too strongly on a particular spot, and for this reason it intensifies the darkness around. Its directors are too enlightened men not to see this, and I am sure they will aid in the co-ordination of your other educational resources." We are aware that the establishment of an institution on so broad a basis as we have indicated is a work of time and patience, but that it can be accomplished, and in the face of great disadvantages, is evident from the example of Owens College. There are doubtless special difficulties in the case of the Yorkshire College; no John Owens has yet come to its aid with a munificent endowment, nor has it the advantage of being connected with an established institution in the manner that the Newcastle College is affiliated to Durham, or the proposed Bristol College to Oxford.

Yorkshiremen are proverbially a hard-headed race, with a keen eye to immediate practical benefits, but they must have patience, not forgetting that institutions similar to their own College have had their day of small things, and that it has needed much money and much time before their advantages have been fully realised. We have just one more word of advice and caution. The wealthy manufacturers who, roused by the fear of foreign competition and the cry for technical education, aid the struggling institution with their money, may be too apt to demand the establishment of technical classes as the condition of their support; and in consequence of the outside pressure thus exerted on the government of the College, it may be driven to regard such classes as the main feature of the work of the professors and lecturers.

We would counsel the College authorities to weigh well the words of the gentleman whose advice they specially asked. Dr. Playfair warned them against giving the College too much of a technical character, at least in its infancy. "The object of education, even in a technical school, is not to teach men how to use spinning jennies or steam-hammers, but it is to give a cultured intelligence which may be applied to work in life, whatever that may be. Teach science well to the scholars, and they will make the applications for themselves. Good food becomes assimilated to its several purposes by digestion. Epictetus used to say that though you feed sheep on grass, it is not grass but wool which grows upon their backs. So if this College teach science as a branch of human culture, it will reappear as broad cloth, worsted, puddled iron, or locomotives, according to the digestive capacities of the Leeds manufacturers who consume it."

BURTON'S "ULTIMA THULE."

Ultima Thule; or, a Summer in Iceland. By Richard F. Burton. With Historical Introduction, Maps, and Illustrations. Two vols. (Edinburgh and London: W. P. Nimmo, 1875.)

OF the 780 pages which make up these two handsome volumes, only one half is occupied with an account of Capt. Burton's doings in Iceland during the summer, June to September 1872, which he spent there. No one, of course, can conceive Capt. Burton having any temptation to the production of a mere big book, and we have no

doubt that his object has been to enlighten the British public as to the real condition of Iceland and its interesting people. Indeed he hints as much in his preface; "the main object of the book," he says, "has been to advocate the development of the island."

Capt. Burton's method of accomplishing his object will, certainly be effective with those who take a real interest in Iceland, and who are willing to take the trouble to master the contents of his two volumes. The Introduction, covering 260 pages, consists of a condensed mass of facts compiled from many sources, relating to Iceland in all its aspects, and he who studies them thoroughly will be well rewarded for his pains; besides the mere pleasure of adding to his knowledge, he will possess an excellent vantage-ground from which to watch the progress of the island and any future attempts that may be made to increase our knowledge of it. Iceland is gradually becoming a popular tourist-ground, and when good hotels are built and the means of travel are improved and organised, no doubt it will be included in the programme of the omnipresent Cook. Intending travellers, as well as all who desire to see the most trustworthy information about Iceland put in an accessible form, ought to feel grateful to Capt. Burton. He has indeed acted in a very unselfish manner in thus compiling what is really a valuable monograph on Iceland, instead of concentrating the attention of the public exclusively on himself and his own experiences in the country. So great an explorer as Capt. Burton has long ago proved himself to be would have been perfectly justified in so doing, and therefore the voluntary service he has rendered to Iceland and the British public is all the more enhanced.

There has been a great deal more written about Iceland than most people are aware of; in his Introduction, Mr. Burton gives a list of no less than fifty works, mostly English narratives of travel, which have been written during the present century, not to mention all that has been written in previous centuries. The author has not, however, confined himself in collecting his facts and theories to what has been published, but has drawn largely on the liberality of willing friends who have made special studies of various points connected with the country, its history, and its people. The result is, we believe, a handier and more complete account of Iceland than will be found in any other single work.

The first section of the Introduction treats "Of Thule," and consists of a formidably learned discussion as to the applications which the classical term has had in various writers and at various times, from Pytheas of Marseilles downwards. Of course the important point in such a discussion is to ascertain what Pytheas meant by the term; and although it seems to us that the few details concerning "Thule" which have been preserved apply more appropriately to Iceland than to any other country which has been proposed, we are inclined to doubt with St. Martin ("Histoire de Géographe," p. 104) whether Pytheas ever saw the country, and to think it more probable that he got his accounts from the inhabitants of North Britain. This, however, is not the place to discuss such a question, even had we space. Capt. Burton, who seems to take delight in advocating improbable theories, makes much more than we think the evidence justifies of the few ecclesiastical remains which the first Norsemen found on the island, and of the traditions concerning the Irish ecclesiastics who at one time found their way to the coasts. These latter no doubt found their way to Iceland at first by accident; afterwards very probably they may have resorted to it in considerable numbers because there they could live in retirement "far from all men's knowing." But, apart from these Irish priests, Mr. Burton is inclined to believe that Iceland may have had a considerable prehistoric population, the remains of which he does not despair of seeing brought to light. At present there is no evidence whatever on which to base such a belief, and had any such population ever existed in the island, we may be almost certain that some indications of its existence would have been met with during the thousand years that the Norse have possessed it. The Bull of Gregory IV., dated about 835 A.D., in which Iceland and Greenland seem to be mentioned, cannot but be regarded with the gravest suspicion, and we have a strong impression that quite recently conclusive proof has been found that the names of these two countries are interpolations.

Capt. Burton concludes this section by referring to the various etymologies that have been proposed for the term "Thule;" we dare say most readers will be struck with the hopelessness of ever finding an origin for the word, and with the utterly improbable theories which the most learned men allow themselves to advance. Here we may remark that one of the notable points of the work before us is etymology; Capt. Burton seldom, we might with confidence say never, introduces a Norse word—and his pages bristle with them—without giving its etymology. This is a most commendable feature, though its value is much diminished by the want of a sufficient index, the three pages at the end of the work being quite inadequate to a book so rich in facts of all kinds. We think it would have added to the value of the work and the comfort of the reader, if a special etymological index had been given. Capt. Burton's flights into comparative etymology are sometimes of the most daring kind. And the reckless way in which he resorts to Semitic and even Turanian languages for congeners to Aryan roots and even Teutonic words, will rather astonish sober students of the science of language.

Besides a sketch of the history of Iceland, the author furnishes in the Introduction valuable details concerning the following matters:—Physical Geography, including Geology, Hydrography, Climate, Chronometry, &c.; Political Geography, Anthropology, Education and Professions, Zoological Notes (including notes on the Flora, Agriculture, Fishing, Industry, &c.), Taxation, and a *Catalogue-raisonné* of Modern Travels in Iceland, besides instructions as to what preparations an intending traveller ought to make. Under these various heads there are many points we should like to notice did space permit; under all of them the reader will find a vast amount of useful information, which it must have taken Captain Burton no little trouble to collect and condense. In speaking of the climate, Capt. Burton doubts much if the Gulf Stream has anything to do with its comparative mildness, and especially the commonly accepted theory that a branch of the great "river in the ocean" bifurcates

off the south-west corner, one arm proceeding northward and the other along the south coast, both reuniting in the North Atlantic between Iceland and Norway. We have certainly much yet to learn about the causes which contribute to form the climate of a country, but without the action of some such influence as would be derived from the Gulf Stream, it seems to us difficult to account for the comparatively mild climate of Iceland as contrasted with the decidedly Arctic climate of countries in the same latitude. But this is a dangerous question to enter upon; what is wanted at present is not so much discussion as facts.

Capt. Burton tells us in his preface that he "went to Iceland feeling by instinct that many travellers had prodigiously exaggerated their descriptions, possibly because they had seldom left home." Stay-at-home people will therefore be grateful that so experienced a traveller and so trained an observer as Capt. Burton has gone over the old ground and told them in a plain, matter-of-fact, yet exceedingly graphic way, what is actually to be seen. In his account of his tour the usual "stupendous" writing will not be found, and many indeed may be inclined to think that the narrative has too much of the "nil admirari" spirit about it. This is not our opinion: Capt. Burton shows frequently throughout the work that he is quite prepared to admire all that is admirable in the country and its people, and concerning the latter especially, it was quite time that we should have a sober and trustworthy account. Travellers hitherto have been too much inclined to look upon the Icelander under quite an auroral glow, as a descendant of the "Hardy Norseman" with his traditional tawny beard, fair hair, brawny build, splendid fighting qualities, with an infusion of rude gentleness. The Icelander is no doubt a descendant of the dauntless men who contributed their share in the building up of the English people, but there seems little reason to doubt that he is a degenerate one. If we can believe Capt. Burton, as well as the reports of some other recent travellers, the chief virtue of the Icelander is laziness, which keeps him as well from doing harm as positive good. Even that gentleness of manner and primitive simplicity of social intercourse which early travellers tell us characterised the people, seem to be rapidly leaving them. But this is inevitable, and from a practical and humane point of view not to be regretted; it is the first stage in the breaking up of their long lethargy, and to doing away with a condition of society which is really an anachronism. There does not seem to be native energy sufficient to the development of the resources of the country, and it is well that foreign attention and foreign capital should be drawn to it, [especially with an eye to the no doubt extensive sulphur resources; we believe such intercourse would benefit the Icelanders by bringing them, with all their dormant good qualities, into the active life of the present.

It is unnecessary to follow Capt. Burton in what was to a great extent a tour, though an unusually critical one, over previously trodden ground, rather than a journey of exploration. He begins at the end with pretty full notes of a visit to Orkney and Shetland, which he paid on his return from Iceland. Concerning the prehistoric and other antiquities of these islands he has of course something to say, and we commend his criticisms to the antiquarian. In Iceland he stayed some time at Reykjavik before setting out to explore the island, and concerning the capital, its institutions and people, as well as what is to be seen in the neighbourhood, he has much to say, finding a little to praise and a great deal to blame. The Icelander can obtain a very fair education in his own country, with even a smattering of science, and it seems to us that it would not take much to convert the High School of Reykjavik into a really good high-class school. Much has been expected to result from the new constitution granted to Iceland last year; we have no doubt that this, combined with other new influences, will have a good effect upon what we cannot but regard after all as a healthy scion of a good stock. After spending some days at the capital Capt. Burton set out on a trip to the north in the *Jón Sigurðsson* steamship. The principal features of the west and north-west coast are described with considerable minuteness, and many interesting details given concerning the various places at which the steamer stopped—Stykkishólm, Flatey, Eyri or Isafjörd, Borðeyri, and Grafarós, the termination of the trip. At every stopping-place Capt. Burton used the short time at his disposal most industriously in making himself acquainted with whatever was noteworthy. Some space is devoted to the Snæfellsjökull (4,577 Danish feet) and its associations, and to the striking features which characterise the bold north-west peninsula.

On his return from the northern trip, Capt. Burton made the popular round from Reykjavik by the Krisuvik sulphur springs, Hekla, the Geysirs, Thingvellir, back to the starting-point. Here his observations are especially minute, and his descriptions somewhat photographic, as it is in reference to this region that previously travellers have been specially exaggerative. Capt. Burton has of course seen too much of some of the most "stupendous" scenery in the world to be much impressed with any of the features to be seen in this often travelled round. It is evident, however, that he desired to observe without bias, and to record impartially what he saw; and if at times he seems too depreciatory, there is ample excuse for his measured statements in the irritation naturally caused by the ecstatic descriptions of previous travellers. With regard to the sulphur deposits at Krisuvik and in the My-vatn district, ample information will be found in the work; Mr. Vincent's paper read at the Society of Arts is reproduced, and a considerable appendix is devoted to the subject, consisting of papers by various authorities who have given attention to the subject. Capt. Burton himself seems to think that much more can be made out of the My-vatn district than out of that of Krisuvik.

Hekla, Capt. Burton speaks of as a humbug, and its ascent mere child's play. "The Hekla of reality is a commonplace heap, half the height of Hermon, and a mere pigmy compared with the Andine peaks, rising detached from the plains. . . . A pair of white patches represent the 'eternal snows.' . . . We [there were two young ladies with him] had nerved ourselves to 'break neck or limbs, be maimed or boiled alive,' but we looked in vain for the 'concealed abysses,' for the 'crevasses to be crossed,' and for places where 'a slip would be to roll to destruction.' We did not sight the 'lava-wall, a capital protection against giddiness.' The snow was anything but slippery." In short, for those who have never seen

a volcano, Hekla may be a wonder, but as compared with other volcanoes it is a mere smoking cinder-heap. Whatever may be the value of Capt. Burton's conclusions, his minute comparative study of this notable feature of Icelandic scenery deserves attention. The Geysirs also he inspected with considerable minuteness, and concludes that in their present condition they are "like Hekla, gross humbugs; and if their decline continues so rapidly, in a few years there will be nothing save a vulgar solfatara, 440 by 150 yards in extent." In this connection a pretty full account is given of the various attempts which have been made to account for the action of Geysirs. The whole of this portion of the narrative we deem of special value.

Capt. Burton's final trip was to eastern Iceland. He sailed from Reykjavik to Berufjörð on the east coast. Thence he proceeded with a small cavalcade on ponies north-west by devious ways to the My-vatn, the lake in the neighbourhood of which sulphur is so plentiful. The lake itself and the neighbouring district he describes in considerable detail, and notes carefully the prominent features to be met with in the route from Berufjörð. On his return he attempted to climb the steep pyramidal mountain of Herðubreið (5,447 feet), a few miles south of My-vatn, but after a strenuous effort failed to reach the summit. He also paid a visit to Snæfell and the northern boundary of the great glacier Vatnajökull, which for the first time has been recently crossed by the indomitable Mr. Watts. Capt. Burton speaks of the glacier with considerable enthusiasm, and gives a minute and striking picture of all he was able to observe; and now that Mr. Watts has shown the way, we may hope ere long to have its main features observed and described in detail. While in this region the traveller was in the vicinity of the mysterious central desert of Iceland, the Ódáða Hraun, which the ignorant natives still people with fierce robbers.

Capt. Burton thus nearly accomplished the circuit of the island, and it is impossible in the space at our disposal to give any adequate idea of even his personal narrative. His lively pictures, sketched with the hand of a master, of Icelandic character and of social life among all classes, are specially attractive. Nothing worthy of note escapes his observation, and both the scientific and the "general" reader will find the work to abound in interest and instruction. As a corrective to the usual indiscriminating narrative of Icelandic travel, it is invaluable. As we said at the beginning, the work as a whole will give a better idea of the country from all points of view than any other single work hitherto published.

One of the most marked features in Capt. Burton's style is its digressiveness and excessive allusiveness; in the present work he carries it often to a perplexing extent, and unless the reader be as well-informed as the traveller himself, he is apt to get bewildered. This feature enforces the most careful reading, and we therefore, perhaps, ought not to consider it a fault.

The lithographic and other illustrations which adorn the work are creditably done and add to its value. The general map is very good and useful, but would have been more so had it been on a larger scale. The special map of the My-vatn and Vatnajökull district is excellent. The publisher deserves the word of praise which the author awards him in the preface.

DUPONT AND DE LA GRYE'S "INDIGENOUS AND FOREIGN WOODS"

Les Bois indigènes et étrangers: Physiologie, Culture, Production, Qualités, Industrie, Commerce. Par Adolphe E. Dupont et Bouquet de la Grye. (Paris: Rothschild. London: Asher and Co., and Williams and Norgate.)

THE science of forest conservation, as is well known, is much more carefully attended to in France and Germany than it is in England or even in India, where, indeed, much has been done of late years in the conservation of the valuable timber trees in which the forests of our Eastern Empire abound.

Though it cannot be denied that Scotland turns out some clever foresters, it is in Continental Europe that forestry is taught under a complete system, practical lessons and lectures being conducted in the forests themselves amongst the very objects which it is the aim of the student to become closely acquainted with. The forest, to the young forester, is in every respect what the hospital is to the medical student. In it he sees the various forms of disease or of injury resulting from mismanagement, and by comparison of the effects of judicious and scientific treatment the means of success or failure are practically demonstrated. It is from these facts that the curriculum of training young officers for the Indian forest service, which now obtains, includes a given time of study in France or Germany. In consideration of this established and systematic course of instruction, it is not surprising that there should issue from the Continental press from time to time some valuable works on forest produce, either with regard to the cultivation of the trees or the utilisation and application of their timber.

The work before us is one which we should not expect to be produced in England, except, perhaps, as a translation. It is a bulky book of 552 pages, and is of a very comprehensive nature, including the consideration of all matters connected with trees from the very beginning of life to the commercial aspects of the timber trade. Being the joint production of a naval architect and a conservator of forests, each author has done much towards making the book valuable to all interested in the growth and production of timber.

The first chapter is devoted to the physiology of plants, and occupies 128 pages; rather too much, it must be confessed, when it is borne in mind that a good deal of the ground has been gone over before in most manuals of botany: the latter part of the chapter, however, is interesting, as showing the effects of climate, altitude, rains, &c. Chapter II. treats of cultivation in its various phases, and its effects upon the quality of the woods in a commercial point of view. Passing over the chapter on forest statistics, in which some interesting comparisons are given on the extent of forests in France, Germany, Russia, Sweden, Norway, &c., and passing also that on the working of the forests, in which, however, is a notice on the production of charcoal—essentially a French industry—we come to Chapter V., on the quality and defects of wood. This subject is treated of very fully in its various bearings; and with regard to the drying or desiccating process, which is a very important matter, as upon it rests nearly the whole question of commercial value, we have some facts, many of which, though not

absolutely new, are worth recording, and should be well known to forest officers. Thus we are told (page 278) the proportion of water contained in wood varies according to the season. Schubler and Neuffler found in the fir (*Abies*) 53 per cent. in January and 61 in April; in the ash (*Fraxinus*), 29 per cent. in January and 39 in April. These facts prove that trees contain more water at the time of the ascent of the sap than in winter. Besides, it has been found that small branches contain more free water than large ones, and that these last contain more than the trunk, which results agree with the knowledge we possess of the porous nature of the different parts. The presence of the bark retards desiccation considerably.

Uhr having had some trees felled in June, after the ascent of the sap, and then having had them placed in the shade, found that those from which the bark had been removed had lost 34·53 per cent. of water in July, 38·77 in August, 39·34 in September, 32·62 in October; whilst those with the bark untouched had only lost during the same periods 0·41, 0·84, 0·92, 0·98. Thus it will be seen that the desiccation of barked wood proceeds much more rapidly. It is only stripped trunks of small size and soft wood that dry up with the rapidity above mentioned.

The numerous woodcuts dispersed throughout the book, and more especially those showing the defects of wood, are accurate representations of the subjects intended to be illustrated. A large portion of the book is devoted to the consideration of felling and cutting up timber, and of machinery used in its manipulation. J. R. J.

OUR BOOK SHELF

Zur lehre der Parallel-projection und der Flächen. Von Prof. Dr. Wilhelm Matzka. (Prag, 1874.)
Grundzüge einer Theorie der cubischen Involutionen. Von Dr. Emil Weyr. (Prag, 1874.)

THESE two reprints from the "Abhandlungen der k. böhm. Gesellschaft der Wissenschaften" are purely mathematical, as may be gathered from their titles. The author of the first treatise states that the *orthogonal* projection of broken lines on given axes, whether in a plane or in space, has been discussed in scientific works on theoretical and practical mathematics, but the *oblique* projection has not obtained so great prominence. The subject is gone into very thoroughly by Dr. Matzka, as may be inferred from the fact of its discussion occupying 70 quarto pages.

The work by Dr. Weyr needs only to be mentioned in these columns, as his exhaustive treatment of any subject he takes in hand, especially of a geometrical character, is well known—"Nihil tetigit, quod non ornavit." The treatise occupies 54 quarto pages.

Practical Hints on the Selection and Use of the Microscope. By John Phin. (The Industrial Publication Company, New York.)

THE contents of the small volume before us fully justify the wording of its title. On the other side of the Atlantic the system of puffing worthless optical instruments seems to be on a much greater scale than in this country. "To the young student whose means are limited, and to the country practitioner whose ability to supply himself with instruments often falls far short of his desires, the offer of a serviceable microscope for a couple of dollars is a great temptation, and when the instrument in question is endorsed by a long list of clergymen, lawyers, and even editors, this temptation becomes irresistible." To show what these worthless microscopes really are, and what ought to be expected of the most ordinary one, are the main objects the author has in view in the earlier pages of the work. Further on he explains the manner of using the instrument, and the method of mounting specimens for examination. Accurate formulæ are given for the preparation of a large number of preservative solutions, amongst which we do not find any sufficiently novel to deserve special mention. It is in the practical nature of its remarks, and not in their novelty, that the value of Mr. Phin's short book rests, and to the tyro it will be found to give information of real value. Beside Mr. R. B. Tolles, J. Grunow, J. Zentmayer, and W. Wales are mentioned as manufacturers of good objectives in the United States; and Mr. McAllister's stands are particularly praised.

The Sleep of Flowers

IN your "Notes" (vol. xii. p. 484) you mention a recent paper by M. Royer on this little-understood class of phenomena. We are acquainted with the objects of most of the spontaneous and periodical movements of plants, but of the physiological means by which these same movements are effected we know little or nothing. But it is important to remember that phenomena like in effect may be diverse in cause. The folding up of petals may have nothing physiologically in common with that of foliage-leaves. In fact, these phenomena may be divided into several classes. Thus movements due to irritation or concussion must be considered apart from those due to spontaneity, and the movements which form part of the series of processes of growth, such as the first unfolding of leaves and flowers, from those which occur in mature organs, though movements belonging to any two of these classes may be exhibited by the same plant, as in Oxalis and Mimosa. *Cereus grandiflorus* opens between 7 and 8 P.M., *Mirabilis jalapa* between 5 and 7 P.M. There is every probability that these times are those at which the insects which fertilise these two species also come forth, and that the same object exists in the case of other species which open and close their flowers more than once, "waking" and "sleeping;" but in the case of Cereus and Mirabilis the movement is one of growth only, though, no doubt, affected by external influences, such as the variation of heat and light. We have, however, cases of true "sleep" in *Ipomœa nil* and *Calystegia sepium*, which open between 3 and 4 A.M.; *Tragopogon*, the ligulate florets of which behave like petals, and which, opening at the same time, closes again before noon; *Anagallis arvensis*, opening at 8 A.M. and closing when the sky is overcast; the Mesembryanthaceæ, which open generally about 12—*Mesembryanthemum noctiflorum*, which opens between 7 and 8 P.M., being an exception; and *Victoria regia*, which opens for the first time about 6 P.M., closes in a few hours, opens again at 6 A.M., and closes finally and sinks in the afternoon; and in many other cases. Besides the causes mentioned in your note, the movements have been attributed to actinism. That they are not hygrometric is clear from the fact stated by Sachs, on the authority of unpublished experiments by Pfeffer ("Text-book of Botany," p. 798), that they take place under water. These same experiments show them to be due to variations in the temperature, and when the temperature is constant, to variations in the intensity of light, and also to be accompanied, at least in some cases, with an increase of the length of the inner side of the phyllæ of the perianth when opening. Light certainly seems to have more to do with the movements of the "poor man's weather-glass" than heat, though perhaps atmospheric pressure might equally well be argued to be their cause. We must remember that as osmotic action is constantly going on at the root-hairs and in the growing parts of living plants, so a constant molecular diffusion of gases is going on through cell-walls, besides the passage of gases through stomata. "The movements of diffusion," as Sachs says (p. 614), "tend to bring about conditions of equilibrium which depend on the co-efficients of absorption of the gas by

a particular cell-fluid, on the molecular condition of the cell-wall, &c., on temperature, and on the pressure of the air. But these conditions are continually varying, and the equilibrium continually disturbed." That a turgescence such as M. Royer describes occurs in many cases is well known, Space does not allow a detailed description of the physiological mechanism, but nearly all we yet know may be found in Sachs, who, however, attributes the phenomena directly solely to the passage of water and the elasticity of the cell-walls. Indirectly the cause may very possibly be heat acting as M. Royer supposes. It would be interesting to learn the effect of pollination on these plants, especially whether after it had taken place *Victoria regia* would re-open. G. S. BOULGER.

Dehiscence of the Capsules of *Collomia*

IN Mr. Duthie's very interesting account (vol. xii. p. 494) of the mode of dehiscence of the capsules of this plant, he suggests that the purpose of the projection of the seeds on to the viscid hairs of the plant itself may possibly be found in its enabling the plant to live on its own seeds. Surely this is a superfluous and needlessly improbable hypothesis. The violent discharge of the seeds is undoubtedly one of the modes adopted by nature for their dispersion to plots of ground where the mineral constituents of the soil which they mainly require have not been entirely used up by the parent plant. Their interception by the parent plant is no doubt accidental. The purpose served by the viscid hairs of this and other plants still remains to be discovered if we follow the clue afforded by Mr. Darwin's observations on insectivorous plants. The violent expulsion of the seeds from the ripe capsule is a much more common phenomenon than that which we have exhibited in *Collomia*, together with a few other plants, as *Acanthus*, *Ruellia*, *Eschscholtzia*, and *Geranium*, where the whole fruit is thrown off together. Mr. Duthie will find a good description of the phenomenon in Hildebrand's "Die Schleuderfrüchte und ihr im anatomischen Bau begründeten Mechanismus," in Pringsheim's "Jahrbuch" for 1873–74. The author draws an interesting comparison between the structure of *Collomia*, with its single seed in each division, and its apparatus for projecting these to a distance, and that of the allied genus *Gilia*, with its numerous seeds in each division, which possess no such mechanism, but which, being much lighter, are consequently more easily dispersed by the wind.

ALFRED W. BENNETT

Oceanic Circulation

MR. CROLL's statement (vol. xii. p. 494), that the North Atlantic in lat. 38° is above the level of the equator, is based partly on the *Challenger* soundings and partly on Muncke's determinations of the thermal expansion of sea-water, which, however, *were not made on sea-water at all*, but on a saline solution prepared for him by Leopold Gmelin, according to data furnished by the incomplete analyses of Vogel and Bouillon La Grange. As Mr. Croll's statement depends on such very minute differences of volume, I am led to ask him to compare the rate of expansion of *real* sea-water, as determined by Prof. Hubbard, with Muncke's table; he will notice a discrepancy sufficiently wide to make it a matter of interest to ascertain how far the employment of the American observations may serve to substantiate or modify his conclusion.

Yorkshire College of Science, Oct. 11 G. E. THORPE

High Waves with a North-west Wind

YOUR correspondent Capt. Kiddle has again called attention (vol. xi. p. 386) to the greater height of waves raised by a north-west wind, over those raised by a S.W. wind. I have observed the fact twice in the mid-Atlantic, but also very often on the west coast of Scotland, from which it is evident the phenomenon can be due to no particular combination of currents.

An examination of synoptic charts, for the dates of many cases, has convinced me that the phenomenon is due to the nature of the circulation of the air in a cyclone.

In the south-east portion of a cyclone, where S.W. winds are found, the wind seems to blow along and almost off the surface of the sea; while in the south-west portion, where N.W. winds are found, the wind seems to bear down on the sea, and "harrow" it into streaks of foam.

A perfectly analogous phenomenon appears in dust whirls, where to the right front of the centre the dust is closely packed, and tends to rise off the ground; while behind the centre the dust is "raked" into streaks by the more downward direction of the blast.

The portion of the Atlantic about 45° N. latitude, and between 40° and 50° W. longitude, where Capt. Kiddle has observed such high waves, has long been known as the "Roaring Forties." An examination of synoptic charts of the North Atlantic, for every day of the year 1865, shows that the bad weather in those parts is generally due to one of two conditions of the distribution of atmospheric pressure.

In the commoner case, the great area of high barometric pressure, which constantly covers the North Tropical Atlantic, stretches northwards to the east of Newfoundland like a wedge, on the east side of which cyclones are formed which go in an E. or N.E. direction.

In the rarer but more violent case, the great Atlantic area of high pressure rises into two heads or humps, one about Madeira, the other about Bermuda, stretching up to Newfoundland. Cyclones coming from Labrador work round this hump to the S.E., and die out in mid-Atlantic. In either case gradients for N.W. winds, often very steep, are formed between the fortieth and fiftieth parallels of longitude. RALPH ABERCROMBY

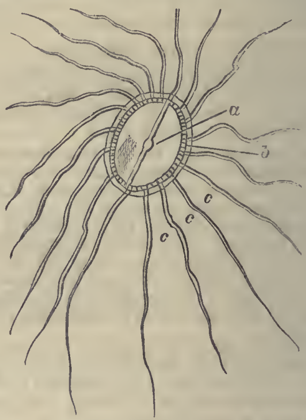
Diatoms

I HAVE reason to think that I have made a discovery which may change the ideas of naturalists as to the nature of some *Diatoms*.

In collecting *Diatomaceæ* I have found a species of *Navicula* (?) which is invested with a gelatinous envelope, and from the edges of the frustule project a number of long processes or arms of the same soft nature. These vary much in number, in some specimens being eight or ten, and in others as many as twenty-five or even more. They are longer than the frustule, and radiate from it with much regularity. The Diatoms when detected (upon a floating *fucus* common in the sea hereabout) were dead, and I was unable to detect any movements.



a, the frustule: *b*, the gelatinous envelope projecting beyond the margin; *c c c*, the processes, or pseudopodia.

I have examined so many individuals of this *Diatom* that I think it hardly likely that I have been deceived, as they are by no means very minute.

Dr. Carpenter, in the fifth edition of his admirable work on the microscope, speaks of some observations by Mr. Stevenson on the genus *Coscinodiscus*, which hint at the possibility of some Diatoms having appendages projected through apertures of the frustule. The highest power of my microscope is one of Messrs. R. and J. Becks, $\frac{1}{8}$th, a very fine glass.

I propose to forward as soon as possible the sticks, dry and in balsam, as well as the "gathering" in spirits, to a competent diatomist, who will confirm my observations if correct, and I send this to NATURE to secure priority in case I have really made a discovery. W. W. WOOD

Manila, July 20

Tails of Rats and Mice

It is, I believe, pretty generally supposed that rats and mice use their tails for feeding purposes in cases where the food to be eaten is contained in vessels too narrow to admit the entire body of the animal. I am not aware, however, that the truth of this supposition has ever been actually tested by any trustworthy person, and so think that the following simple experiments are worth publishing.

Having obtained a couple of tall-shaped preserve bottles with rather short and narrow necks, I filled them to within three inches of the top with red currant jelly which had only half stiffened. I covered the bottles with bladder in the ordinary way, and then stood them in a place frequented by rats. Next morning the bladder covering each of the bottles had a small hole gnawed through it, and the level of the jelly was reduced in both bottles to the same extent. Now, as this extent corresponded to about the length of a rat's tail if inserted at the hole in the bladder, and as this hole was not much more than just large enough to admit the root of this organ, I do not see that any further evidence is required to prove the manner in which the rats obtained the jelly, viz., by repeatedly introducing their tails into the viscid matter, and as repeatedly licking them clean.

However, to put the question quite beyond doubt, I refilled the bottles to the extent of half an inch above the jelly level left by the rats, and having placed a circle of moist paper upon each of the jelly surfaces, covered the bottles with bladder as before. I now left the bottles in a place where there were no rats or mice, until a good crop of mould had grown upon one of the moistened pieces of paper. The bottle containing this crop of mould I then transferred to the place where the rats were numerous. Next morning the bladder had again been eaten through at one edge, and upon the mould there were numerous and distinct tracings of the rats' tails, resembling marks made with the top of a penholder. These tracings were evidently caused by the animals sweeping their tails about in the fruitless endeavour to find a hole in the circle of paper which covered the jelly.

NEWCOMB ON THE URANIAN AND NEPTUNIAN SYSTEMS.

When the 26-inch equatorial, with an object-glass "nearly perfect in figure," was mounted at the United States Naval Observatory, Washington, it was resolved that its great powers should be first devoted to systematic observations of the satellites of the exterior planets, with the view not only to the better determination of the elements of their orbits, but, more especially, of the masses of their primaries; previous attempts in this direction, from the great difficulties attending observations, having led to very discordant values. Accordingly all the minor arrangements of the instrument were completed with this particular object in view, and no other regular work of dissimilar character was attempted while the satellite-observations were in progress.

In the memoir (Washington Observations, 1873, Appendix I.) to which allusion was made in this column last week, Professor Newcomb describes generally his method of observation; and with respect to his measures of the inner satellites of Uranus, which he thinks may fairly be regarded as the most difficult well-known objects in the heavens, he expresses surprise at the degree of precision with which he was able to bisect them with the faintly-illuminated wire of the micrometer, an examination of the individual measures having shown that they were not more discordant than those of the outer satellites.

In discussing the observations of the satellites of Uranus, extending from January 1874 to May 1875, circular elements are assumed for the formation of equations of condition, and by the usual methods elliptical orbits are obtained for each satellite; but it results that there is but slight evidence of any real excentricity of the orbits, and none whatever of any mutual inclination. Circular elements derived similarly are retained, and Tables for the ready prediction of the positions of the satellites which are most essential for their certain observation are founded upon them, and appended to Prof. Newcomb's memoir. The most probable mean plane of the orbits is found to have the following elements:—

Ascending node on earth's equator ...	$165°·10 + 1°·43\ (t-1850)$
Inclination	$75°·14 - 0·14\ (t-1850)$

Or, as referred to the ecliptic,

Ascending node	$165°·48 + 1°·40\ (t-1850)$
Inclination	$97·85 - 0·013\ (t-1850)$

(The motion of the satellites of Uranus is direct upon the equator, but retrograde when referred to the ecliptic.)

Other elements are:—

	Mean Longitude	Radius of orbit.	Period of Revolution. Days.
Ariel	21°·83	13″·78	2·52038
Umbriel	136°·52	19″·20	4·14418
Titania	229°·93	31″·48	8·70590
Oberon	154°·83	42″·10	13·46327

Mean noon at Washington, 1871, December 31, is taken for the epoch of mean longitude, which is reckoned from the point where the orbit intersects the plane parallel to the earth's equator and passing through the centre of the planet. The arc values of radii of orbits are for the distance [1·28310]. If we assume the mean solar parallax, 8″·875, and adopt Clarke's equatorial semi-diameter of the earth, we find from these values the following distances of the satellites from Uranus, expressed in English miles.

Ariel ...	118,100	Titania ...	269,800
Umbriel ...	164,550	Oberon ...	360,800

It may be mentioned that Sir W. Herschel's observations between the years 1787 and 1798 are brought to bear upon the determination of the periods of Oberon and Titania.

For reasons which are given, Prof. Newcomb thinks it "extremely improbable that the masses of the satellites exceed $\frac{1}{15000}$ of that of the planet," in which case the Uranocentric perturbations due to mutual action will be "incapable of detection with any instrumental means yet known." He mentions that, seen with the 26-inch telescope, the brighter satellites, Titania and Oberon, shine with about the brilliancy of a fourth magnitude star to a single unassisted eye.

We must not omit to state that the discovery of the inner satellites, Ariel and Umbriel, is distinctly assigned by Prof. Newcomb to Mr. Lassell; indeed, there appears every reason for believing that these excessively minute objects have not yet been recognised with any instruments except the Washington refractor and the reflectors which Mr. Lassell has constructed: the discovery of these satellites may be dated from the definitive announcement made by Mr. Lassell to the Royal Astronomical Society in November 1851. Prof. Newcomb remarks that "where any difficulty whatever is found in seeing the outer satellites," he would not hesitate to pronounce it impossible to see the inner ones, and thus it is not likely that the Bothkamp and other observations can have referred to the latter.

Though no systematic search was made for additiona satellites, Prof. Newcomb believes "he may say with considerable certainty that no satellite within 2′ of the planet and outside of Oberon, having one-third the brilliancy of the latter, and therefore that none of Sir William Herschel's supposed outer satellites can have any real existence."

In the Washington refractor the planet has always presented a sea-green colour, no variations of tint being ever noticed. Markings upon the disc were not especially looked for, but if any had been visible they would hardly have escaped remark.

The observations of the satellite of Neptune are treated in a very similar manner to those of the satellites of Uranus. No certain amount of ellipticity is exhibited,

and circular elements are accordingly used in the formation of tables for the prediction of the positions of the satellite. For the epoch 1873, December 31, Washington mean noon, the mean longitude of the satellite, reckoned from the intersection of the orbit with the plane parallel to the earth's equator, and passing through the centre of the planet, was 98°·96; the node on equator, 183°·03, and the inclination, 121°·7. The radius of the orbit at the mean distance of Neptune [1·47814] is found to be 16″·275, or 218,550 miles. The mean motion assumed at the commencement of the discussion was that founded upon the observations of Mr. Lassell (Hind, "Monthly Notices," vol. xv.), and does not appear to admit of any sensible correction. Prof. Newcomb thinks the motion of mean longitude is correct within 2° or 3° a century. The period of revolution of the satellite is 5·8769 days.

No trace of a second satellite of Neptune has ever been seen, though it has been looked for carefully on several occasions.

The conclusion to which Prof. Newcomb's investigations have led, "that the orbits of all the satellites of the two outer planets are less excentric than those of the planets of our system, and that, so far as observations have yet shown, they may be perfect circles," will appear a remarkable one.

We take this opportunity of presenting the elements of the orbits of Uranus and Neptune adopted in the Tables of Prof. Newcomb, as perhaps an acceptable addition to the preceding outline of his researches on the satellites of these planets. The values of the major axes here given are not those which would result from the mean motion with correction for the mass, but in the case of Uranus include a constant term in the perturbations of the radius vector, and in that of Neptune, constants introduced by the action of the planets, and effect of secular variation of the longitude of the epoch :—

	URANUS.	NEPTUNE.
Mean longitude, 1850 Jan. 0·0 G.M.T.	28° 25′ 17″·1	335° 5′ 38″·9
Longitude of perihelion	168 15 6·7	43 17 30·3
Ascending node	73 14 8·0	130 7 31·9
Inclination	0 46 20·5	1 47 0·6
Excentricity	0·0469236	0·0084962
Mean motion in the Julian year	15425″·75	7864″·935
Semi-axis major	19·19130	30·07055
Period in days	30686·63	60186·64

CASSOWARIES

LIKE the minor planets, Cassowaries are of late years continually increasing in number. A short time ago there was but one "Cassowary" recognised by naturalists, which was vaguely stated to inhabit "the Moluccas." Even Mr. Wallace's extensive researches in the Indian Archipelago only resulted in ascertaining the exact island to which the original *Casuarius galeatus* is restricted, without making us acquainted with other species. But recent expeditions into the less known parts of the Papuan sub-region have led to a much more extended knowledge of the subject, and we have now arrived at the conclusion that the genus *Casuarius* embraces a numerous group of species, each of which has special distinctive characters and a peculiar geographical distribution. Six of these forms of Cassowary are at the present time represented by specimens living in the Gardens of the Zoological Society of London, where they have attracted much attention. It is with the hope of obtaining further exact information concerning these fine birds from travellers in the countries which they inhabit that I have drawn up the following short summary of the present state of our knowledge of the different species.

The Cassowaries may be divided into three sections, as shown in the subjoined table :—

Table of Species of the Genus Casuarius.

a. Casside lateraliter compressa; appendicula cervicis aut duplici aut divisa.

1. *C. galeatus*, ex ins. Ceram.
2. *C. beccarii*, ex ins. Aroensi Wokan.
3. *C. australis*, ex Australia bor.
4. *C. bicarunculatus*, ex ins. Aroensibus.

b. Casside transversim compressa; appendicula cervicis unica.

5. *C. uniappendiculatus*, ex Papua.

c. Casside transversim compressa; appendicula cervicis nulla.

6. *C. papuanus*, ex Papua boreali.
7. *C. westermanni*, ex ins. Papuana Jobie (?).
8. *C. picticollis*, ex Papua meridionali.
9. *C. bennetti*, ex Nov. Britann.

The first of these sections contains the large species allied to the original *C. galeatus*. These have on their heads an elevated casque, laterally compressed and terminating in a ridge in the same line as the culmen of the bill. They have also a large fleshy caruncle on the front of the neck, ending in two distinct flaps. A single species, which stands somewhat alone and forms a second section, is also of large size, but has the casque transversely compressed and ending in a ridge at a right angle to the culmen. It has but one medial throat-wattle, whence it has been named *uniappendiculatus*. The third section embraces the smaller species allied to Bennett's Cassowary, or the Mooruk. These have the casque transversely compressed as in the one-wattled species, but have no wattle on the throat—only a bare, brightly coloured space. They are further distinguishable by the extraordinary form of the claw of the inner toe, which attains a remarkable length and is used as a weapon of attack. Of these three sections, the following nine species are now known with more or less certainty :—

1. THE COMMON CASSOWARY (*G. galeatus*), of which there is now no doubt that the island of Ceram is the true habitat. Of this species we have now one example, not yet adult, in the Zoological Society's Gardens.

2. BECCARI'S CASSOWARY (*C. beccarii*).—This form is closely allied to *C. galeatus*, but is easily distinguishable from it by having only one medial throat-wattle, which is slightly divided at the extremity. It has a large elevated casque like the Australian Cassowary, and remarkably large strong legs. The species was originally described by me from a specimen in the Museo Civico at Genoa, which was brought by Beccari from the Aroe Islands; but the living individual now in the Zoological Gardens (if it is really of the same species) was obtained in the south of New Guinea by H.M.S. *Basilisk*.

3. THE AUSTRALIAN CASSOWARY (*C. australis*).—Of this Cassowary, remarkable in the adult for its large size and highly elevated casque, we have now two specimens living in the Gardens. It is a native of Northern Queensland and the peninsula of Cape York.

4. THE TWO-WATTLED CASSOWARY (*C. bicarunculatus*).—This species, which is easily known, even in the young condition, by having the wattles separated and placed far apart on the sides of the neck, was first described from two examples, formerly living in the Zoological Gardens, but now dead. There are several stuffed specimens of it in the Leyden Museum, which were undoubtedly obtained in the Aroe Islands.

5. THE ONE-WATTLED CASSOWARY (*C. uniappendiculatus*).—The single small wattle which ornaments the middle of the neck at once distinguishes this fine species, of which we have now in the Gardens a young specimen brought by H.M.S. *Basilisk* from the coast on the north of New Guinea, opposite Salawatty. There is a good figure of this Cassowary in the supplement to Gould's "Birds of Australia."

6. THE PAPUAN CASSOWARY (*C. papuanus*).—This name has been given to two specimens in the Leyden Museum, obtained near Dorey, in New Guinea, by Rosen-

berg. Prof. Schlegel at first identified them with the Mooruk, but afterwards admitted their distinctness. My belief is that they are probably the same as the next species (*C. westermanni*), although the colours of the neck, as restored in the stuffed specimens, do not quite agree.

7. WESTERMAN'S CASSOWARY (*C. westermanni*).—This species I established on a bird still living in the Zoological Gardens, which we received from Mr. Westerman in 1871. At first I referred this bird to *C. kaupi*, of Rosenberg, until that naturalist showed that the pretended species which he had so named was nothing more than the young of *C. uniappendiculatus*. I then changed our bird's name to *C. westermanni*. I have recently seen two other living specimens of this bird in the Zoological Gardens at Rotterdam. It has been suggested that its true home is the island of Jobie, in the Bay of Geelvink, where Dr. Meyer ascertained the existence of a Cassowary, but was not able to procure specimens.

8. THE PAINTED-NECKED CASSOWARY (*C. picticollis*).—This species was likewise established by me on a specimen now living in the Zoological Gardens, which was obtained by the officers of H.M.S. *Basilisk* at Discovery Bay, on the east coast of New Guinea. It greatly resembles the Mooruk, but differs in its brilliantly-coloured neck, of which I have given a drawing in the P. Z. S. for the present year (1875, Part I.)

9. THE MOORUK, OR BENNETT'S CASSOWARY (*C. bennetti*).—In 1857 Mr. Gould described this Cassowary from a drawing sent to him by Dr. George Bennett, of Sydney, and soon afterwards a living pair were sent to us by our excellent friend, after whom the species had been named. These birds bred in the Gardens in 1864, but we have now unfortunately lost them. Bennett's Cassowary is an inhabitant of New Britain, to the east of New Guinea, and is easily distinguishable from its congeners by its blue throat and back of the neck.

Omitting for the moment the doubtful *C. papuanus*, it will be thus seen that we have tolerably certain indications of the districts in which the other eight Cassowaries are found. It would be very desirable, however, to get further information concerning them, and also to ascertain what is the Cassowary of Jobie, and whether the other islands adjacent to New Britain possess, as is probable, indigenous species of this group.

P. L. SCLATER

ANOTHER MONSTER REFRACTOR

THE experiment rendered possible, now some ten years ago, by Mr. Newall, and made with such triumphant success by Mr. Cooke, is again bearing fruit. Another monster telescope, indeed the largest yet attempted, is now in course of construction at Mr. Grubb's new works, near Dublin. This instrument has been ordered by the Imperial and Royal Austro-Hungarian Government for the new Observatory now in course of erection at Vienna. The object-glass will have an aperture of over 26 inches, probably about 27 inches, according as the discs of glass, which are being manufactured in the rough, by M. Feil, of Paris, may turn out on finishing. The focal length is to be about 32 feet. The general form of mounting will be modified to suit the special requirements of such a monster instrument. The great base casting (weighing some seven to eight tons) will form a chamber (about 12 feet long, 4 feet 6 inches wide, and 8 feet high) for the clock, which will be massive in proportion to the other parts. The axes will all have their friction relieved by anti-friction apparatus. The tube will be entirely of steel, and all the various motions of the instrument, as well as the reading of the different circles, will be available to the observer from the eye-end of the telescope.

A circular chamber of 45 feet diameter has been provided in Mr. Grubb's new workshops, to be covered for the present by a corrugated iron roof 50 feet high. In this the telescope is to be set up, and over this will be meanwhile erected an enormous steel dome, revolving on the system of rollers designed some years since by Mr. Thomas Grubb, and adopted at Dunsink Observatory, near Dublin, and at Lord Lindsay's Observatory. All of this dome and revolving machinery is afterwards to be removed to Vienna. Thus, by taking down the stationary iron roof, when the steel dome is erected over it, the equatorial will be placed in perfect working order, under its own roof in Dublin, for trial. It is proposed to attempt to illuminate the verniers and circles by Geissler's tubes. If M. Feil can, as he hopes, perfect the pair of discs required within twelve months, Mr. Grubb expects to have the whole instrument complete by the autumn of 1878, in which year, we may remark, it is not impossible that the British Association may be invited to Dublin. Should Lord Rosse's reflector be in order and the Vienna telescope complete, Section A will certainly muster in great force.

THE DIFFERENCE OF THERMAL ENERGY TRANSMITTED TO THE EARTH BY RADIATION FROM DIFFERENT PARTS OF THE SOLAR SURFACE

PÈRE SECCHI, in the second edition of "Le Soleil," published at Paris 1875, again calls attention to the result of his early investigations of the force of radiation emanating from different regions of the sun's surface, reiterating without modification his former opinions regarding the absorption of the radiant heat by the solar atmosphere. It will be well to bear in mind that the plan adopted by the Italian physicist in his original researches, on which his present opinion is based, was that of projecting the sun's image on a screen, and then, by means of thermopiles, measuring the temperature at different points. The serious defects inseparable from this method of measuring the intensity of the radiant heat I need not point out, nor will it be necessary to urge that a correct determination of the energy transmitted calls for direct observation of the temperature produced by the rays projected towards the earth. Accordingly, on taking up that branch of my investigations of radiant heat which relates to the difference of intensity transmitted from different parts of the sun's surface, I adopted the method of *direct* observation. The progress was slow at the beginning, owing to the necessity of constructing an astronomical apparatus of unusual dimensions, but having devised means which rendered the employment of any desirable focal length practicable, the work has progressed rapidly. An instrument of 17·7 metres (58 feet) focal length, erected to conduct preliminary experiments, has proved so satisfactory that the construction of one of 30 metres focal length, which I supposed to be necessary, has been dispensed with. Considering that the apparent diameter of the sun at a distance of 17·7 metres from the observer's eye is 162·4 millimetres even when the earth is in aphelion, the efficacy of the instrument employed might have been anticipated. The nature of the device will be readily comprehended by the following explanation:—Suppose a telescopic tube 17·7 metres long, 1 metre in diameter, devoid of object-glass and lenses, and mounted equatorially, to be closed at both ends by metallic plates or diaphragms, at right angles to the telescopic axis. Suppose the diaphragm at the upper end to be perforated with two circular apertures 200 millimetres in diameter, situated one above the other in the vertical line, 360 millimetres from centre to centre; and suppose a third circular perforation whose area is one-fifth of the apparent area of the solar disc, viz. 72·6 millimetres diameter, to be made on either side of the vertical line. Suppose, lastly, that the diaphragm which closes the lower end of the tube be perforated with three small apertures 6 millimetres in diameter, whose centres correspond exactly with the centres of the three large perforations in the upper diaphragm. The tube being then directed towards the sun, and actinometers applied below the three small apertures in the lower diaphragm, it will be evident that two of these instruments will, after due exposure to a clear sun, indicate maximum solar intensity, say 35° C., while the actinometer applied in line with the perforation whose area is one-fifth of the apparent area of the solar disc, will indicate $\frac{35}{5} = 7°$ C., unless the central portion of the solar

disc radiates more powerfully towards the earth than the rest, in which case a higher intensity than 7° C. will be indicated by the actinometer referred to. It will be readily understood that the solar rays entering through the perforations at the upper end of the tube, converge at the lower end and pass through the small perforations, causing maximum indication of the focal actinometers as stated. Now, suppose that a circular plate, the area of which is exactly $\frac{4}{5}$ of the apparent area of the sun, viz. 145·2 millimetres diameter, be inserted concentrically in either of the two large perforations of the diaphragm at the top of the telescopic tube. The apparent diameter of the sun being as before stated 162·4 millimetres, it will be perceived that the inserted plate will only partially exclude the solar radiation, and that the rays from a zone 1′ 42″ wide will pass outside the said plate, converging in the form of a hollow cone at the lower end of the tube, and there enter the respective actinometer. The indication of the latter will then show the thermal energy transmitted by radiation from a zone whose mean width extends 49″ from the sun's border. It should be particularly observed that the three focal actinometers employed will be acted upon *simultaneously* by the converged rays, (1) from the entire area of the solar disc, (2) from a *central* region containing $\frac{1}{5}$ of the area, and (3) from a *zone* at the border containing also $\frac{1}{5}$ of the area of the solar disc. It is scarcely necessary to point out that an accurate comparison of the intensity of the radiant heat emanating from the central part and from the sun's border calls for *simultaneous* observation, in order to avoid the errors resulting from change of zenith distance and variation of atmospheric absorption during the investigation. The great advantage of obtaining also a simultaneous indication of the intensity transmitted by radiation

FIG. 1.

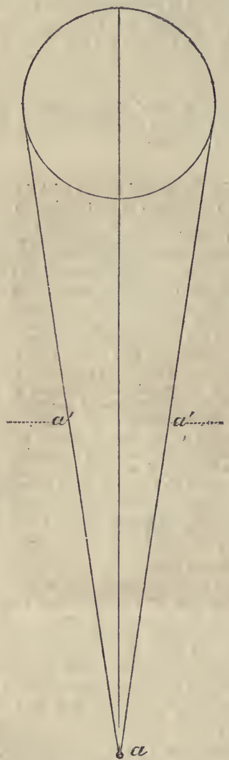

FIG. 2.

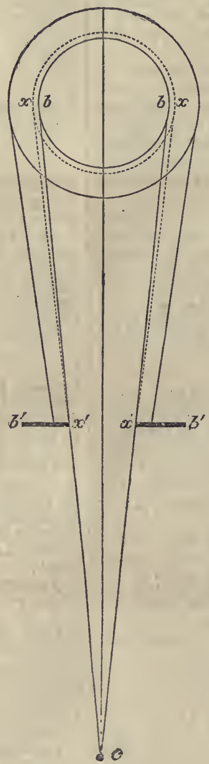

FIG. 3.

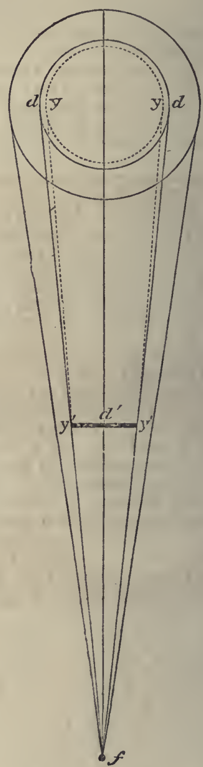


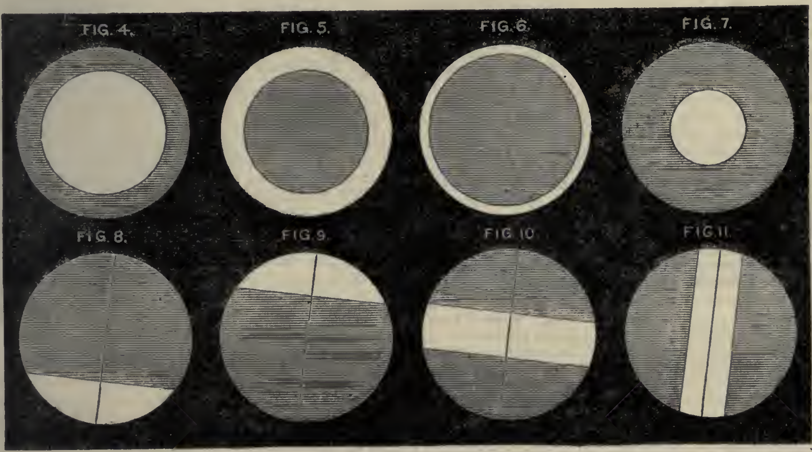
from the entire solar disc is self-evident, since this indication serves as an effectual check on the observed intensities emanating from the *centre* and from the *border*. The latter obviously must be less, while the former must be greater, for a given area, than the indication of the focal actinometer which receives the radiation of the entire solar disc.

The foregoing demonstration, based on hypothesis, having established the possibility of ascertaining by direct observation the temperature produced by the rays projected from certain parts of the solar surface, let us now examine the means actually employed. An observer on the 40th deg. latitude, stationed on the north side of a building 28 metres high pointing east and west, can just see the sun pass the meridian, during the summer solstice, if he occupies a position about 8 metres from such building. Now, if an opaque screen perforated by a circular opening 313 millimetres in diameter be placed on the top of the supposed building, the entire solar disc may be seen through the same, provided it faces the sun at right angles. But if the perforation in the said screen be 140 millimetres in diameter, only $\frac{1}{5}$ of the area of the solar disc will be seen. And if the screen be removed and a circular plate 280 millimetres in diameter put in its place, the observer, ranging himself in line with the plate and the sun's centre, can only see a narrow border 1′ 42″ of the solar disc. Obviously the screen placed on the top of the building might be perforated like the upper diaphragm of the supposed telescopic tube, and a plate resembling the lower diaphragm, secured by appropriate means near the ground, might be made to support the focal actinometers in such a manner that their axes pass through the centres of the perforations of the screen above the building. It is hardly necessary to state that the plate supporting the actinometers should be attached to some mechanism capable of imparting to it a parallactic move-

ment, during the observation, corresponding with the sun's declination and the earth's diurnal motion; and, that some adequate mechanism should be employed for regulating the position of the perforated screen and adjusting the focal distance in accordance with the change of the subtended angle consequent on the varying distance from the sun. It will be evident that since the first-named mechanism rests on the ground, while the latter is secured to a massive building, far greater steadiness will be attained by our simple and comparatively inexpensive device, than by employing a telescopic tube of the most perfect construction mounted equatorially.

With reference to the influence of diffraction, it should be stated that before determining the size of the screens intended to shut out certain parts of the solar disc during the investigation, the amount of inflection of the sun's rays was carefully ascertained. Two distinct methods were adopted: (1) measuring the additional amount of heat transmitted to the focal thermometers in consequence of the inflection of the rays; (2) increasing the *theoretical* size of the screens until the effect of inflection was overcome and the luminous rays completely excluded. Regarding the first-named method of ascertaining the diffraction, it is important to mention that the temperature transmitted to the focal actinometers by the inflected radiation which passes outside of the theoretically determined screens is not proportionate to the inflection ascertained by the process of enlargement referred to. This circumstance at first rendered the investigation somewhat complicated, but it soon became evident that the discrepancy is caused by the comparatively small inflection of the *invisible* heat rays. It will be seen presently that the radiant heat which passes outside of the screens in consequence of diffraction is considerably less than that which would be transmitted to the focal actinometers if the calorific rays were subjected to an amount of inflection corresponding with the enlargement of the screens beyond the theoretical dimensions necessary to exclude the luminous rays.

Let us first consider the method of ascertaining the inflection of the rays by measuring the additional amount of heat transmitted to the focal actinometers. Fig. 1, see illustration, represents the solar disc, *a* being the focal actinometer exposed to the converged rays, *d' a'* representing an imaginary plane situated 17·7 metres from *a*, at which distance the section of the pencil of converging rays will be 162·4 millimetres in diameter, provided the earth is near aphelion. Fig. 2 also represents the solar disc, and *c* the actinometer exposed to the converged rays; but a perforated screen *b' b'* is interposed, the perforation being of such a size that only the rays projected by the central half of the solar disc (indicated by the circle *b b*) pass through the same and reach the focal actinometer. The screen *b' b'* being situated 17·7 metres from *c* when the earth is in the position before referred to, the said perforation must be 114·83 millimetres in diameter, in order that the lines *b x' c* may be straight. Fig. 3 likewise represents the solar disc, its area being divided in two concentric halves by



the circle *d d*; but in place of a perforated screen, an opaque circular screen *d'* is introduced at the same distance from the focal actinometer as in Fig. 2; consequently the lines *d y' f* will be straight. Now, if the actinometers *a*, *c*, and *f* be exposed to the converged solar radiation *simultaneously and during an equal interval of time*, *c* and *f* receiving the heat from one half of the solar disc (the former from the central and the latter from the surrounding half), the temperatures of *c* and *f* added together should correspond exactly with the temperature transmitted from the entire solar disc to *a*. Observation, however, shows that the temperatures of *c* and *f* together is 0·091 greater than the temperature imparted to *a*. Hence an increase of temperature of nearly one-eleventh is produced by the inflection of the calorific rays, one-half being the result of the bending of the rays within the perforation of the screen *b'b'*, the other half resulting from the bending outside of the screen *d'*. The increment of temperature being thus known, the degree of inflection may be easily determined by drawing a circle *x x* round the circle *b b*, covering an additional area of $\frac{0·091}{2} = 0·0455$; and by inscribing a circle *y y* within *d d*, covering an area of 0·0455 less than the area of *d d*. It will be perceived on reflection that *x x' b* represents the angle of inflection of the calorific rays within the perforation of the screen *b' b'*, and that *d y' y* represents the angle of inflection outside of the screen *d'*. Demonstration shows that the former angle measures 14″·57, while the latter measures 14″·86, the mean being 14″·71. Having thus determined the inflection resulting from invisible radiation, let us now ascertain the inflection of the luminous rays. As before stated, the apparent diameter of the sun at a distance of 17·7 metres from a given point is 162·4 millimetres when the luminary is furthest from the earth. Now our investigation shows that a screen 167 millimetres in diameter hardly suffices to exclude the luminous rays; hence their inflection amounts to $\frac{167 - 162·4}{2} = 2·3$ millimetres at a distance of 17·7 metres. Their angle of inflection will therefore be 26″·81, against 14″·71 for the dark rays. We have thus incidentally established the fact that the inflection of the luminous and calorific rays differs nearly in the same proportion as the calorific energies of the visible and invisible portions of the solar spectrum.

Our space not admitting of a detailed account of the result of the investigation, the leading points only will be presented. The observations have all been made at noon, the duration of the exposure to the sun having been limited to seven minutes, during which period the actinometers are moved, by the parallactic mechanism, through a distance of about 55 centimetres, from west to east. The intensity of the radiant heat imparted to the actinometers has been recorded by the observers at the termination of the fourth, fifth, sixth, and seventh minute, the

exact moment for reading off being indicated by a chronograph. The relative intensities transmitted by radiation from the centre and from the border of the solar disc, first claim our attention. Fig. 6 represents the solar disc covered by a circular screen 145·25 millimetres in diameter, excluding the rays excepting from a narrow zone, the mean width of which is situated 49″ from the border of the photosphere. Fig. 7 shows a screen excluding the solar rays excepting from the central portion, *the area of which is precisely equal to the area of the narrow zone in* Fig. 6. The following table shows the intensities transmitted to the actinometers during an observation, August 25, 1875, the radiation from the solar disc being then excluded in the manner shown in Figs. 6 and 7 :—

Time.	Central portion. Cent.	Border. Cent.	Rate of difference.
4′	3°·28	2°·19	$\frac{2·19}{3·28} = 0·667$
5′	3°·56	2°·37	$\frac{2·37}{3·56} = 0·665$
6′	3°·73	2°·49	$\frac{2·49}{3·73} = 0·667$
7′	3°·88	2°·60	$\frac{2·60}{3·88} = 0·669$
			Mean = 0·667

It should be particularly observed that this table records the result of four distinct observations; nor should it be overlooked that although the intensities vary greatly for each observation in consequence of the continued exposure to the sun, yet the rates showing the difference of the intensity of the rays transmitted from the border, inserted in the last column, is practically the same for each observation, the discrepancy between the highest and the lowest rate being only 0·004.* Persons practically acquainted with the difficulty of ascertaining the intensity of solar radiation will be surprised at the exactness and consistency of the indications of our actinometers. This desirable exactness has been attained by surrounding the actinometers with water-jackets, which communicate with each other by connecting pipes, through which a steady stream of water is circulated. By this expedient the chambers containing the bulbs of the several thermometers are maintained with critical nicety at equal temperature, an inexorable condition when the object is to determine differential temperature with great exactness. Apart from this, the chambers which contain the bulbs of the thermometers are air-tight, the radiant heat being admitted through a small aperture at the top of the chamber, covered by a thin crystal.

Referring to the preceding table, it will be seen that the intensity transmitted by radiation from the sun's border, represented in Fig. 6, is 0·667 of the intensity transmitted from the central region represented in Fig. 7, the area of each being precisely alike. From the stated intensity must be deducted the heat imparted to the actinometer by the inflection of the calorific rays. The circumference of the perforation of the screen shown in Fig. 7 being exactly one-half of the circumference of the screen in Fig. 6, while the central region radiates more powerfully than the border, fully one-half of the inflected radiation from the border will be balanced by the inflected radiation emanating from the central region. Agreeable to the previous demonstration relating to Figs. 2 and 3, it will be seen that the unbalanced inflection amounts to 0·029; hence the radiation transmitted from the border zone will be $0·667 - 0·029 = 0·638$ of the intensity of radiation transmitted from the central region. We have thus shown by a reliable method that the intensity of the rays directed towards the earth from the border zone suffers a diminution of $1·000 - 0·638 = 0·362$ of the intensity of the radiation emanating from the central region. But the mean depth of the solar atmosphere of the border zone, in the direction of the earth, is 2·551 greater than the vertical depth, while the mean depth over the central region referred to is only 0·036 greater than the vertical depth of the solar atmosphere. Consequently, if we accept the assumption that the retardation is as the depth, the absorption by the solar atmosphere cannot exceed $\frac{0·362}{2·551 - 0·036} = 0·144$ of the radiant heat emanating from the photosphere.* It will be found, on referring to the revised edition of "Le Soleil," vol. i. p. 212, that Père Secchi makes the following statements regarding the absorptive power of the solar atmosphere. (1) "At the centre of the disc, that is to say perpendicularly to the surface of the photosphere, the absorption arrests about $\frac{5}{8}$ or more exactly $\frac{62}{100}$ of the total force." (2) "The total action of the absorbing envelope on the hemisphere visible from the sun is so great that it allows only $\frac{12}{100}$ of the total radiation to pass, the remainder, namely, $\frac{88}{100}$, being absorbed." It is unnecessary to criticise these figures presented by the Roman astronomer, as a cursory inspection of our table and diagrams is sufficient to show the fallacy of his computations. Apart from determining the absorptive power of the solar atmosphere, the most important problem which may be solved by accurately measuring the intensity of the radiation emanating from various parts of the disc, is that relating to the sun's emissive power in different directions. In order to decide this question, I have adopted the plan of measuring the energy of the radiant heat transmitted from zones crossing the solar disc at right angles, as shown in Figs. 10 and 11. Should it be found that our actinometers are equally affected by the radiation from these zones, each of which occupies an arc of 30 deg. containing one-third of the area of the disc, the inference will be irresistible that the sun emits heat of equal intensity in all directions. It should be borne in mind that, agreeable to our method, the radiations from these zones are observed simultaneously. The arrangement exhibited in Figs. 10 and 11 hardly needs explanation. Referring to Fig. 10, it will be seen that two segmental screens are employed excluding the radiant heat, excepting from the zone, which is parallel with the sun's equator. Similar screens are employed (see Fig. 11) for excluding the rays excepting from the zone parallel with the sun's polar axis. The curvatures of the segmental screens, it should be observed, have been struck to a radius of ninety millimetres, in order to cut off effectually the inflected radiation from the sun's border. Obviously diffraction has not called for any correction of our observations relating to this part of the investigation, since the inflected radiation from the equatorial zone exactly balances the inflected radiation from the polar zone. It only remains to be stated that repeated observations show that the radiant energies transmitted to the actinometers from the two zones are identical. The result of observations relating to the radiation emanating from the polar regions, represented in Figs. 8 and 9, together with other observations, will be discussed in future communications.

J. ERICSSON

* All my instruments for measuring radiant heat have been graduated to the Fahrenheit scale, which practically is more exact than the Centigrade, owing to its finer divisions. For the benefit of the Continental readers of NATURE, and in order to satisfy English and American advocates of the course Centigrade, the observed temperatures have been reduced to that cale before being entered in our tables.

* In the first edition of "Le Soleil," p. 264, the author assumes that the absorption of the calorific rays by the atmosphere "augments in proportion to the secant of the zenith distance;" in other words, as the depth of the atmosphere penetrated by the rays.

SOME LECTURE NOTES ON METEORITES †

III.

AMONG the mineral constituents of meteorites the unstable sulphides, it is hardly necessary to observe, could with difficulty be conceived as continuing permanently undecomposed, or as being even formed under the ordinary conditions of rock formation on our globe; and the same remark may be extended, though with some limitation, to the metallic iron that is so characteristic and ubiquitous a constituent of almost every, if, indeed, not (as maintained by Dr. Lawrence Smith) of every meteorite. On the other hand, it is to be remembered that the rocks that we are acquainted with on our globe are only those composing its outer crust; rocks which represent the results of the corrosive action of the atmospheric agencies, oxygen, carbonic acid, and water, and their counterpart the ocean, on whatever material the consolidated surface of our planet offered for their action. The endless cycle of mechanical and chemical disintegration, decomposition, and reconstruction would be limited to a shallow shell, and even the fresh matter forced out to the surface in volcanoes, through the contraction of the cooling globe, would consist in all likelihood only of the lower-lying layers of an already to a certain degree metamorphosed material. Whether the inner core of this planet is still in the meteoric condition—that is to say, still may contain such minerals as native iron, associated with nickel, not to say magnesium or calcium sulphides, is a question not to be lost sight of in explaining the high specific gravity of our globe as compared with that of the rocks that form its crust.

† Concluded from p. 507.

That the silicates contained in meteorites should be identical, or nearly so, with corresponding minerals in our globe seems only the natural consequence of the identity in the elements that constitute both. They are essentially magnesium silicates—namely, olivine the basic, and enstatite (or bronzite) the neutral silicate, the latter taking the form of augite to an amount corresponding to the calcium present, where this latter element is a constituent of the meteorite. Where, at the first production of the meteoric minerals by the union of their elements, the oxygen was in sufficient amount to allow of a portion of the iron present being in the state of an oxide, ferrous oxide is combined in the silicate, and the meteoric olivines are from this cause generally ferriferous, and the enstatite also assumes one of the varieties of that mineral which the mineralogist has termed bronzite. The silicic acid is rarely in excess of the amount requisite to form an enstatite or augite; usually the contrary condition is evidenced by the presence of some olivine. The case of the occurrence of free silica in the Breitenbach meteorite, at present exceptional, may, however, hereafter prove to be characteristic of a type, and its occurrence, not as quartz, nor even as tridymite (the crystallised silica discovered by von Rath), but in the form to which I gave the name asmanite, in crystals belonging to the orthorhombic system with the specific gravity of fused quartz, seems to point to conditions, probably involving an enormous temperature, as those under which such meteorites have been formed, and such as have not been realised in the production of any of the acid or super-siliceous silicates of our globe. The felspathic ingredients of meteorites are for the most part basic, chiefly consisting of anorthite, the most basic of terrestrial felspars, known as a crystallised mineral in volcanic rocks. Crystals of meteoric anorthite were measured by Viktor von Lang at the British Museum, with results quite concordant with those yielded by the crystals from the volcanoes of our planet. A felspar with a composition corresponding to that of labradorite, on the other hand, in the only meteorite in which its presence has been established beyond doubt, is proved by Tschermak to crystallise in the cubic system, instead of the anorthic system to which terrestrial labradorite belongs.

Attempts have been made to classify meteorites according to their mineralogical constitution. As a provisional method, such a classification has its uses; but while we find that the same meteorite may contain distinct portions which severally would authorise its being placed in different classes, such a classification must necessarily be very imperfect.

The best general divisions are those of Gustav Rose; and in the following table are classed the various groups of Aërolites, with a statement of the minerals that are met with in them:—

Aërolites.

CHONDRITIC	Olivine. Bronzite. Augite. Nickel-Iron. Troilite.
EUKRITIC...	Augite. Anorthite. Nickel-Iron.
CHLADNITIC	Bronzite or Enstatite. Augite (occasional). Nickel-Iron. Troilite Oldhamite (occasional). Osbornite. Chromite.
CHASSIGNITIC... ...	Olivine. Chromite.
CARBONACEOUS ...	Olivine. Enstatite. Nickel-Iron. Sulphur. Carbon. Troilite. Chromite. Hydrocarbons.

The great division of meteorites into iron masses or siderites, mixed masses or siderolites (the pallasites and mesosiderites of Rose), and aërolites or stony meteorites; and the sub-division of the latter into chondritic and non-chondritic varieties, seems to be a sufficiently logical division. And among the non-chondritic aërolites, those designated in Gustav Rose's classification as Eukrites form one well-marked group. They consist of anorthite mingled sometimes with augite in a crystallogranular admixture, with nickel-iron, troilite, magnetic pyrites, a little olivine, and small amounts of other minerals. The crystals of anorthite and the augite in the eukritic meteorite of Juvinas have afforded satisfactory goniometrical measurements, and been identified as regards their crystalline forms—the former, as before mentioned by V. von Lang, and the augite by Gustav Rose—with the corresponding terrestrial minerals; and it is the eukritic aërolites which most closely resemble some of our volcanic rocks.

The carbonaceous meteorites form another remarkable though not a distinct group. In these we meet with minerals which, if occurring in a terrestrial rock, would lead us to ascribe to that rock an igneous origin; they are the same minerals that occur in other meteorites (olivine, enstatite, &c.), but are associated with carbon and with a minute amount of a white or a yellowish crystallisable matter, soluble in ether and partly so in alcohol, and exhibiting the characters and the composition of one or more hydrocarbonous bodies with high melting points. Such an ingredient permeating a rock on our globe would assuredly be accepted as a product resulting indirectly from animal or vegetable existence. We must be cautious, however, in the extending of this generalisation to celestial hydrocarbons. It seems not at all improbable that this singular ingredient of these otherwise stony and fire-formed meteoric rocks may have been taken up by the mass subsequently to its formation; perhaps while passing through an atmosphere of these hydrocarbonous substances in the form of a vapour. The probability of this is enhanced by the smallness in the amount (about 0·25 per cent. only) of the white soluble bodies contained in the aërolite, and by the fact that the whole of it may be dissolved out from a mass of considerable size by the direct treatment of the solid aërolite by the boiling solvent, even without previous pulverisation; the substance, in short, mechanically fills the pores of the aërolite, but does not appear to be otherwise contained or entangled in the interior of the silicates or of the compacter aggregations of these within the meteorite.

The remaining divisions into which aërolites have been grouped are less distinctly marked, and their boundaries less fixed than those we have considered. In fact, a more comprehensive knowledge of all the varieties of meteorites and the modes in which their constituent minerals may be associated is needed for our forming a complete classification of them, and it is only necessary to make one observation in order to indicate the importance of our being able thus to arrange together these meteorites which are strictly comparable, and may be supposed to have had a common or at least a similar origin and history.

Such a classification is in fact a necessary preliminary to our ever successfully dealing with the problem of the periodically recurrent visitation to our earth of any particular class or group of meteorites. And it is here that the great collections of meteorites brought together in the National European Museums already are, and promise in a far higher degree in the future to be, so valuable. They offer the opportunities for the most complete comparison and the widest induction that our limited material admits of.

It may thus be possible hereafter by their aid to trace such a periodicity in the falls of meteorites of particular kinds as has been established in the cases of several meteor showers; or again the accumulation of observations recording the directions from which these bodies fall to the earth may enable us to connect those of a particular class with some definite direction that may indicate for these a common source in space. It may be feared, however, that owing to the species of refraction which their paths must undergo on entering the atmosphere, and the great difficulty, if not impossibility, of obtaining very accurate comparable parallactic observations of their paths, it will be impossible to rely on any calculated elements of their orbits before approaching our planet.

One of the difficulties confronting us in any endeavour to trace them to their sources, lies in the near similarity of composition of very large groups of them, such for instance as the entire group of the chondritic aërolites, or again that of the siderites, a similarity so close in each case as to render it difficult at first to suppose that the masses belonging to either of these groups originated under dissimilar conditions, or in widely sundered regions of space.

A difficulty of a similar kind further presents itself in the relative importance of nickel as an ingredient in the iron element of meteorites. One cannot indeed institute a comparison in this respect with the iron of our globe, which cannot be said to exist within the scope of our knowledge in the native state, while on

the other hand the silicates composing meteorites, and those constituting the mass of our terrestrial rocks, are alike almost devoid of nickel; and a process that would reduce the iron in such rocks (*e.g.* serpentine or lherzolite) as contain traces of this element would simultaneously reduce the nickel also to the metallic condition, as has been shown by Daubrée.

Among those who have sought to throw light on the part of our problem which deals with the chemical history of meteorites, M. Daubrée, the distinguished Director of the Ecole des Mines, stands forward. He has subjected both meteorites and certain terrestrial rocks in some respects mineralogically allied to them to fusion under special conditions. He has, further, reviewed in a valuable article in the *Comptes Rendus* of the French Academy, the two opposite chemical conditions under which aërolitic matter may be supposed to have assumed its present form; those namely, first, of the oxidation with a limited supply of oxygen of the elements composing a meteorite assumed as combined *inter se*; and secondly, a condition under which a basic ferruginous silicate may be supposed to be converted into a neutral silicate with the emancipation of free iron by the operation of reducing agents, such as hydrogen or carbon, acting on the ferrous silicate at a high temperature.

In this way an olivine, rich in diferrous silicate, would become a bronzite poor in ferrous silicate, or become an enstatite without any iron in it at all, the iron lost in either case by the olivine being separated as metallic iron; and M. Daubrée performed transformations of this kind.

Now, the remarkable discovery by the late Prof. Graham of hydrogen in the Lenarto iron, and that recently made by Wöhler of carbonic oxide in the iron of Ovifak (due, however, probably in this case to the action of magnetic iron-oxide on the carbon of the meteorite), and also by Prof. Mallet of the same gas in a meteoric iron from Virginia, lend some probability to the view of M. Daubrée.

Still the existence of great masses of siderolites like those of Pallas and from Atacama, rich in ferruginous olivine, and presenting, so far as the analyses may be trusted, no trace of enstatite, or even bronzite, offers a great obstacle to the view that the iron in these cases was the result of a reduction from olivine. So again the Breitenbach siderolite, notwithstanding its large ingredient of free silica (as asmanite) consists largely of a bronzite very rich in ferrous monosilicate. This bronzite, however, it is to be said, resists the reducing action of hydrogen at a considerable temperature.

The similarity, not to say the peculiarity, as well in their chemical nature as in their mechanical condition that I have alluded to as characterising so many meteorites would seem to impose some restrictions on our freedom in tracing the origin of these bodies to distant and dissevered regions of interstellar space. And, indeed, though a great unity and simplicity in condition and in material would seem to rule throughout the stellar universe, as viewed by our present means of knowledge, and so far would justify our treating lightly the sameness of the meteoric material that reaches us as a check on our reasonings; yet it is to be borne in mind that the prism has only begun to interpret for us the language of the stars, and that further research may introduce complexity, and narrow the limits of our problem. On the other hand, we can only reason legitimately from the standing-point of the present; and it is equally probable, nay, almost certain, that the stellar spectra, in which, for instance, the lines characterising nickel have not yet been found, will, on direct search for them, yield those lines, and then the arguments otherwise converging on the probability of meteorites coming to us from interstellar space will acquire an almost conclusive character; for the difficulties in the way of our confining their origin to our own solar system are almost insuperable. Their high proper velocity, often far greater than that of the earth in her orbit, the directions of their motion, sometimes direct, often retrograde, and continually at high angles to the ecliptic, are not consistent with their being portions of asteroidal matter sporadically dispersed, while they are still less so with any explanation of meteorites as resulting from lunar volcanoes or from any lost telluric satellite, or from satellitic matter that had escaped the centralising influence of gravitation.

Whether any of the meteorites are intercepted by our earth while passing nodes common to our orbit, and to long cometary orbits described by innumerable meteoric groups around the sun, is a question we cannot answer in the present condition of our knowledge.

But reasoning by analogy from the movements of the meteor-swarms that we are acquainted with, this is rendered highly probable by the identification beyond a question of the orbits of periodic meteor-swarms with those of known comets, and the statement of Leverrier that these meteor-swarms are probably vast cosmical clouds consisting of sparsely-spread particles; and that some of them entering our solar system from interstellar space have been drawn aside by planetary attraction, and have assumed a circum-solar orbit. When the curve is an ellipse, they of course remain in our system, and are seen now as comets, or also again in certain very rare instances, where their orbit intersects with our own, as star-showers, which recur annually, or at the long intervals separating their approach to their perihelia, according as they have or have not been long enough members of our system for the meteoric dust to have become more or less equally distributed along their orbit in a ring, or have still only the form of a prolonged cloud continually becoming more and more annular in the distribution of its ingredient particles.

Four cases of unquestionable accordance between comets and meteor showers are established in—

The Lyriad meteoric shower (April 20–21) and Comet I. of 1861 (Galle and Weiss).
The Perseids meteoric shower (August 10–11) and Comet III. of 1862 (Schiaparelli).
The Leonids meteoric shower (November 13–14) and Comet I. of 1866 (Oppolzer, Peters, and Schiaparelli).
The Andromedes meteoric shower (November 27–28) and Biela's Comet (Galle and Weiss).

If we imagine meteorites to have a similar history, but with the difference that the meteor-particles are assembled into larger masses or clusters of them, and that these consequently are separated from each other by far vaster distances than is the case with the even widely-spread units that compose a meteor-swarm, we may comprehend why the meteorite is such a rare visitant as compared with the meteors proper, of which thousands must pass into our atmosphere every hour. Indeed, when we consider what has been before alluded to, touching the comparatively loose condition of aggregation of so many meteorites, and when we remember that the fine dust and little particles of a meteoric cloud are separated by no such atmosphere, gaseous or vaporous, as prevents actual contact between surfaces on a terraqueous globe, we may perhaps go so far as to suppose that if groups of the individual particular units of a meteor cloud once should approach each other to a distance small enough to give their mutual gravitation a sensible influence, they might gradually collect into masses, and acquire a cohesion more or less compact according to the conditions imposed on such masses during their subsequent history. Such is possibly the case with the nuclei of the comets, which would thus possess the character of a cluster of meteorites, while the coma is composed of meteoritic particles of the character of ordinary meteors.

There is one respect in which the comparison of the smaller meteors with those of greater magnitude and with meteorites may seem to point to a difference of some importance in the character of the objects themselves. The velocities usually ascribed to the former class of bodies are in many cases very much higher than that belonging to the larger objects. Thus, a velocity of 140 miles per second has been ascribed to some of the smaller meteors. Mr. Hind, however, gives the perihelion velocity of the August swarm at 26 miles per second, which, added to the motion of the earth (as the meteors are retrograde), would give a velocity of about 40 miles at a point so near their perihelion as that in which our earth meets them. On the other hand, a velocity of from 13 to 40 miles per second is that usually ascribed to the larger meteoric masses, and to meteorites of which the actual fall has been witnessed.

Furthermore, we have to consider, on the one hand, the very great difficulty in determining the parallax of a body moving so rapidly in the absence of accurate instrumental means of observing it, and on the other hand, the fact that a large meteoric mass is sure to be observed best, and by daylight almost exclusively, during the more brilliant and imposing, and therefore the nearer and more slowly traversed, portion of its track. Thus the small particles represented by the ordinary meteor are kindled and extinguished almost instantaneously in the upper part of the atmosphere, while the meteoroid masses of larger volume are observed and reasoned upon almost entirely during the more imposing part of their course, namely, their passage through its lower and denser regions.

While, then, we are restrained by the facts, as they at present stand, from separating into different classes of cosmical phenomena the meteors and the meteoroid bodies known as fireballs and meteorites, and I must add the comets, so are we constrained

to recognise for all of these bodies—whether on encountering the earth they had become actually members of the solar family or not—an ultimately extra-solar origin; that, in fact, whether they, some or all of them, had become temporarily or permanently imprisoned, as it were, in the vortex of solar attraction, the probability is that they originally entered our system from the interstellar spaces beyond it. And it may further be said, that the tendency of scientific conviction is in the direction of recognising the collection towards and concentration in definite centres of the matter of the universe, as a cosmical law, rather than the opposite supposition of such centres being the sources whence matter is dispersed into space.

In the meteorites that fall on our earth (certainly in considerable numbers) we have to acknowledge the evidence of a vast and perpetual movement in space of matter otherwise unseen, about which we can only reason as part of a great feature in the universe, which we have every ground for not supposing to be confined within the limits of the solar system.

That this matter, whether intercepted or not by the planets and the sun, should to an ever-increasing amount become entangled in the web of solar and planetary attraction, and that the same operation should be collecting round other stars and in distant systems, such moving clouds of meteoric particles as have been treated by Schiaparelli, Leverrier, and other astronomers, whether as indivi luals or in clusters widely separated, of wandering stone or iron, is a necessary deduction from the view that we have assumed regarding the tendency of cosmical matter to collect towards centres.

But in order to trace the previous stages of the history of any meteorite, and in particular to determine the conditions under which its present constitution as a rock took its origin, we have only for our guide the actual record written on the meteoric mass itself; and it is in this direction that the mineralogist is now working.

But the process is necessarily a gradual one. We may indeed assert that the meteorites we know have, probably all of them, been originally formed under conditions from which the presence of water or of free oxygen to the amount requisite to oxidise entirely the elements present were excluded; for this is proved by the nature of the minerals constituting the meteorites, and by the way in which the metallic iron is distributed through them.

The progress of solar physics and the reflex light it is likely to shed on the condition of the primeval chaos of nebular matter, and the stages by which suns and planets were evolved, will no doubt help to explain the origin of meteorites; and possibly they in turn will be found to offer some not unimportant evidence on those cosmogenic questions which still belong to the more speculative region of Science.

N. S. MASKELYNE

A CITY OF HEALTH.*

IT is my object to put forward a theoretical outline of a community so circumstanced and so maintained by the exercise of its own free will, guided by scientific knowledge, that in it the perfection of sanitary results will be approached, if not actually realised, in the co-existence of the lowest possible general mortality with the highest possible individual longevity. I shall try to show a working community in which death, if I may apply so common and expressive a phrase on so solemn a subject—in which death is kept as nearly as possible in its proper or natural place in the scheme of life.

Before I proceed to this task, it is right I should ask of the past what hope there is of any such advancement of human progress. For as my Lord of Verulam quaintly teaches, "The past ever deserves that men should stand upon it for awhile to see which way they should go, but when they have made up their minds they should hesitate no longer, but proceed with cheerfulness." For a moment, then, we will stand on the past.

From this vantage-ground we gather the fact, that onward with the simple progress of true civilisation the value of life has increased. Ere yet the words "Sanitary Science" had been written; ere yet the heralds of that science, some of whom, in the persons of our illustrious colleagues Edwin Chadwick and William Farr, are with us in this place at this moment; ere yet these heralds had summoned the world to answer for its profligacy of life, the health and strength of mankind was undergoing improvement. One or two striking facts must be sufficient in the brief space at my disposal to demonstrate this truth. In England, from 1790 to 1810, Heberden calculated that the general mortality diminished one-fourth. In France, during the same period, the same favourable returns were made. The deaths in France, Berard calculated, were 1 in 30 in the year 1780, and during the eight years from 1817 to 1828, 1 in 40, or a fourth less. In 1780, out of 100 new-born infants in France, 50 died in the two first years; in the later period, extending from the time of the census that was taken in 1817 to 1827, only 38 of the same age died, an augmentation of infant life equal to 25 per cent. In 1780 as many as 55 per cent. died before reaching the age of ten years; in the later period 43, or about a fifth less. In 1780 only 21 persons per cent. attained the age of 50 years; in the later period 32, or eleven more, reached that term. In 1780 but 15 persons per cent. arrived at 60 years; in the later period 24 arrived at that age.

Side by side with these facts of the statist we detect other facts which show that in the progress of civilisation the actual organic strength and build of the man and woman increases. Just as in the highest developments of the fine arts the sculptor and painter place before us the finest imaginative types of strength, grace, and beauty, so the silent artist, civilisation, approaches nearer and nearer to perfection, and by evolution of form and mind develops what is practically a new order of physical and mental build. Peron—who first used, if he did not invent, the little instrument the dynamometer, or muscular strength measurer—subjected specimens of different stages of civilisation to the test of his gauge, and discovered that the strength of the limbs of the natives of Van Dieman's Land and New Holland was as 50 degrees of power, while that of the Frenchmen was 69, and of the Englishmen 71. The same order of facts are maintained in respect to the size of body. The stalwart Englishman of to-day can neither get into the armour nor be placed in the sarcophagus of those sons of men who were accounted the heroes of the infantile life of the human world.

We discover, moreover, from our view of the past, that the developments of tenacity of life and of vital power have been comparatively rapid in their course when they have once commenced. There is nothing discoverable to us that would lead to the conception of a human civilisation extending back over two hundred generations; and when in these generations we survey the actual effect of civilisation—so fragmentary, and overshadowed by persistent barbarism—in influencing disease and mortality, we are reduced to the observation of at most twelve generations, including our own, engaged indirectly or directly in the work of sanitary progress. During this comparatively brief period, the labour of which, until within a century, has had no systematic direction, the changes for good that have been effected are amongst the most startling of historical facts. Pestilences which decimated populations, and which, like the great plague of London, destroyed 7,165 people in a single week, have lost their virulence; gaol fever has disappeared, and our gaols, once each a plague-spot, have become, by a strange perversion of civilisation, the health spots of, at least, one kingdom. The term Black Death is heard no more; and ague, from which the London physician once made a fortune, is now a rare tax even on the skill of the hard-worked Union Medical Officer.

From the study of the past we are warranted, then, in assuming that civilisation, unaided by special scientific knowledge, reduces disease and lessens mortality, and that the hope of doing still more by systematic scientific art is fully justified.

I might hereupon proceed to my project straightway. I perceive, however, that it may be urged, that as mere civilising influences can of themselves effect so much, they might safely be left to themselves to complete, through the necessity of their demands, the whole sanitary code. If this were so, a formula for a city of health were practically useless. The city would come without the special call for it.

I think it probable the city would come in the manner described, but how long it would be coming is hard to say, for whatever great results have followed civilisation, the most that has occurred has been an unexpected, unexplained, and therefore uncertain arrest of the spread of the grand physical scourges of mankind. The phenomena have been suppressed, but the root of not one of them has been touched. Still in our midst are thousands of enfeebled human organisms which only are comparable with the savage. Still are left amongst us the bases of every disease that, up to the present hour, has afflicted humanity.

The existing calendar of diseases, studied in connection with the classical history of them, written for us by the longest unbroken line of authorities in the world of letters, shows, in un-

* An Address by Dr. B. W. Richardson, F.R.S., at the Brighton meeting of the Social Science Association. Revised by the author.

mistakable language, that the imposition of every known malady of man is coeval with every phase of his recorded life on the planet. No malady, once originated, has ever actually died out; many remain as potent as ever. That wasting fatal scourge, pulmonary consumption, is the same in character as when Cœlius Aurelianus gave it description; the cancer of to-day is the cancer known to Paulus Eginæta; the Black Death, though its name is gone, lingers in malignant typhus; the great plague of Athens is the modern great plague of England, scarlet fever; the dancing mania of the Middle Ages and convulsionary epidemic of Montmartre, subdued in its violence, is still to be seen in some American communities, and even at this hour in the New Forest of England; smallpox, when the blessed protection of vaccination is withdrawn, is the same virulent destroyer as it was when the Arabian Rhazes defined it; ague lurks yet in our own island, and, albeit the physician is not enriched by it, is in no symptom changed from the ague that Celsus knew so well; cholera, in its modern representation, is a more terrible malady than its ancient type, in so far as we have knowledge of it from ancient learning; and even that fearful scourge the great plague of Constantinople, the plague of hallucination and convulsion which raged in the fifth century of our era, has, in our time, under the new names of tetanoid fever and cerebro-spinal meningitis, been met with here and in France, and in Massachusetts has, in the year 1873, laid 747 victims in the dust.

I must cease these illustrations, though I could extend them fairly over the whole chapter of disease, past and present. Suffice it if I have proved the general proposition, that disease is now as it was in the beginning, except that in some examples of it it is less virulent; that the science for extinguishing any one disease has yet to be learned; and that, as the bases of disease exist, untouched by civilisation, so the danger is ever imminent, unless we specially provide against it; that the development of disease may occur with original virulence and fatality, and may at any moment be made active by accidental or systematic ignorance.

I now come to the design I have in hand. Mr. Chadwick has many times told us that he could build a city that would give any stated mortality, from fifty, or any number more, to five, or perhaps some number less, in the thousand annually. I believe Mr. Chadwick to be correct to the letter in this statement, and for that reason I have projected a city that shall show the lowest mortality.

I need not say no such city exists, and you must pardon me for drawing upon your imaginations as I describe it. Depicting nothing whatever but what is at this present moment easily possible, I shall strive to bring into ready and agreeable view a community not abundantly favoured by natural resources, which, under the direction of the scientific knowledge acquired in the past two generations, has attained a vitality not perfectly natural, but approaching to that standard. In an artistic sense it would have been better to have chosen a small town or large village than a city for my description; but as the great mortality of states is resident in cities, it is practically better to take the larger and less favoured community. If cities could be transformed, the rest would follow.

Our city, which may be named *Hygeia*, has the advantage of being a new foundation, but it is so built that existing cities might be largely modelled upon it.

The population of the city may be placed at 100,000, living in 20,000 houses, built on 4,000 acres of land—an average of twenty-five persons to an acre. This may be considered a large population for the space occupied, but, since the effect of density on vitality tells only determinately when it reaches a certain extreme degree, as in Liverpool and Glasgow, the estimate may be ventured.

The safety of the population of the city is provided for against density by the character of the houses, which ensure an equal distribution of the population. Tall houses overshadowing the streets, and creating necessity for one entrance to several tenements, are nowhere permitted. In streets devoted to business, where the tradespeople require a place of mart or shop, the houses are four stories high, and in some of the western streets where the houses are separate, three and four storied buildings are erected; but on the whole it is found bad to exceed this range, and as each story is limited to 15 feet, no house is higher than 60 feet.

The substratum of the city is of two kinds. At its northern and highest part there is clay; at its southern and south-eastern gravel. Whatever disadvantages might spring in other places from a retention of water on a clay soil, is here met by the plan that is universally followed, of building every house on arches of solid brickwork. So, where in other towns there are areas, and kitchens, and servants' offices, there are here subways through which the air flows freely, and down the inclines of which all currents of water are carried away.

The acreage of our model city allows room for three wide main streets or boulevards, which run from east to west, and which are the main thoroughfares. Beneath each of these is a subway, a railway along which the heavy traffic of the city is carried on. The streets from north to south which cross the main thoroughfares at right angles, and the minor streets which run parallel, are all wide, and, owing to the lowness of the houses, are thoroughly ventilated, and in the day are filled with sunlight. They are planted on each side of the pathways with trees, and in many places with shrubs and evergreens. All the interspaces between the backs of houses are gardens. The churches, hospitals, theatres, banks, lecture-rooms, and other public buildings, as well as some private buildings such as warehouses and stables, stand alone, forming parts of streets, and occupying the position of several houses. They are surrounded with garden space, and add not only to the beauty but to the healthiness of the city. The large houses of the wealthy are situated in a similar manner.

The streets of the city are paved throughout in the same material. As yet wood pavement set in asphalte has been found the best. It is noiseless, cleanly, and durable. Tramways are nowhere permitted, the system of underground railways being found amply sufficient for all purposes. The side pavements, which are everywhere ten feet wide, are of white or light grey stone. They have a slight incline towards the streets, and the streets have an incline from their centres towards the margins of the pavements.

From the circumstance that the houses of our model city are based on subways, there is no difficulty whatever in cleansing the streets, no more difficulty than is experienced in Paris. That disgrace to our modern civilisation, the mud-cart, is not known, and even the necessity for Mr. E. H. Bayley's roadway movable tanks for mud sweepings (so much wanted in London and other towns similarly built) does not exist. The accumulation of mud and dirt in the streets is washed away every day through side openings into the subways, and is conveyed, with the sewage, to a destination apart from the city. Thus the streets everywhere are dry and clean, free alike of holes and open drains. Gutter children are an impossibility in a place where there are no gutters for their innocent delectation. Instead of the gutter, the poorest child has the garden; for the foul sight and smell of unwholesome garbage, he has flowers and green sward.

It will be seen, from what has been already told, that in this our model city there are no underground cellars, kitchens, or other caves, which, worse than those ancient British caves that Nottingham still can show the antiquarian as the once fastnesses of her savage children, are even now the loathsome residences of many millions of our domestic and industrial classes. There is not permitted to be one room underground. The living part of every house begins on the level of the street. The houses are built of a brick which has the following sanitary advantages:—It is glazed, and quite impermeable to water, so that during wet seasons the walls of the houses are not saturated with tons of water, as is the case with so many of our present residences. The bricks are perforated transversely, and at the end of each there is a wedge opening, into which no mortar is inserted, and by which all the openings are allowed to communicate with each other. The walls are in this manner honeycombed, so that there is in them a constant body of common air let in by side openings in the outer wall, which air can be changed at pleasure, and, if required, can be heated from the firegrates of the house. The bricks intended for the inside wall of the house, those which form the walls of the rooms, are glazed in different colours, according to the taste of the owner, and are laid so neatly that the after adornment of the walls is considered unnecessary, and, indeed, objectionable. By this means those most unhealthy parts of household accommodation, layers of mouldy paste and size, layers of poisonous paper, or layers of absorbing colour stuff or distemper, are entirely done away with. The walls of the rooms can be made clean at any time by the simple use of water, and the ceilings, which are turned in light arches of thinner brick, or tile, coloured to match the wall, are open to the same cleansing process. The colour selected for the inner brickwork is grey, as a rule, that being most agreeable to the sense of sight; but various tastes prevail, and art so soon

ministers to taste, that, in the houses of the wealthy, delightful patterns of work of Pompeian elegance are soon introduced.

As with the bricks, so with the mortar and the wood employed in building; they are rendered, as far as possible, free of moisture. Sea-sand containing salt, and wood that has been saturated with sea-water, two common commodities in badly-built houses, find no place in our modern city.

The most radical changes in the houses of our city are in the chimneys, the roofs, the kitchens, and their adjoining offices. The chimneys, arranged after the manner proposed by Mr. Spencer Wells, are all connected with central shafts, into which the smoke is drawn, and, after being passed through a gas furnace to destroy the free carbon, is discharged colourless into the open air. The city, therefore, at the expense of a small smoke rate, is free of raised chimneys and of the intolerable nuisance of smoke. The roofs of the houses are but slightly arched, and are indeed all but flat. They are covered either with asphalte, which experience, out of our supposed city, has proved to last long and to be easily repaired, or with flat tile. The roofs, barricaded round with iron palisade, tastefully painted, make excellent outdoor grounds for every house. In some instances flowers are cultivated on them.

The housewife must not be shocked when she hears that the kitchens of our model city, and all the kitchen offices, are immediately beneath these garden roofs; are, in fact, in the upper floor of the house instead of the lower. In every point of view, sanitary and economical, this arrangement succeeds admirably. The kitchen is lighted to perfection, so that all uncleanliness is at once detected. The smell which arises from cooking is never disseminated through the rooms of the house. In conveying the cooked food from the kitchen, in houses where there is no lift, the heavy-weighted dishes have to be conveyed down, the emptied and lighter dishes upstairs. The hot water from the kitchen boiler is distributed easily by conducting pipes into the lower rooms, so that in every room and bedroom hot and cold water can at all times be obtained for washing or cleaning purposes; and as on every floor there is a sink for receiving waste water, the carrying of heavy pails from floor to floor is not required. The scullery, which is by the side of the kitchen, is provided with a copper and all the appliances for laundry work; and when that is done at home, the open places on the roof above make an excellent drying ground.

In the wall of the scullery is the upper opening to the shaft of the dust-bin. This shaft, open to the air from the roof, extends to the bin under the basement of the house. A sliding door in the wall opens into the shaft to receive the dust, and this plan is carried out on every floor. The coal-bin is off the scullery, and is ventilated into the air through a shaft, also passing through the roof.

On the landing in the second or middle stories of the three-storied houses there is a bath-room, supplied with hot and cold water from the kitchen above. The floor of the kitchen and of all the upper stories is slightly raised in the centre, and is of smooth grey tile; the floor of the bath-room is the same. In the living-rooms, where the floors are of wood, a true oak margin of floor extends two feet around each room. Over this no carpet is ever laid. It is kept bright and clean by the old-fashioned bees'-wax and turpentine, and the air is made fresh and ozonic by the process.

Considering that a third part of the life of man is, or should be, spent in sleep, great care is taken with the bedrooms, so that they shall be thoroughly lighted, roomy, and ventilated. Twelve hundred cubic feet of space is allowed for each sleeper, and from the sleeping apartments all unnecessary articles of furniture and of dress are rigorously excluded. Old clothes, old shoes, and other offensive articles of the same order are never permitted to have residence there. In most instances the rooms on the first floor are made the bedrooms, and the lower the living-rooms. In the larger houses bedrooms are carried out in the upper floor for the use of the domestics.

To facilitate communication between the kitchen and the entrance-hall, so that articles of food, fuel, and the like may be carried up, a shaft runs in the partition between two houses, and carries a basket lift in all houses that are above two stories high. Every heavy thing to and from the kitchen is thus carried up and down from floor to floor and from the top to the basement, and much unnecessary labour is thereby saved. In the two-storied houses the lift is unnecessary. A flight of outer steps leads to the upper or kitchen floor.

(*To be continued.*)

NOTES

THE reorganisation of the German Seewarte at Hamburg makes very satisfactory progress. To the Third Section is assigned the duty of issuing storm-warnings for the German coasts, and the investigation of the meteorological conditions on which the warnings depend. Hitherto meteorology has been prosecuted in Germany exclusively in its climatic aspects. It is now intended, whilst keeping in view what is required for climatic researches, to give more special attention to the investigation of weather-conditions, simultaneously observed over a wide area, and to the movements and changes taking place in the great currents of the atmosphere. In carrying out these objects, stations of the first order are established at Hamburg, Memel, Neufahrwasser, near Danzig, Swinemünde, Warnemünde, Keitum in Sylt, Borkum, Wilhelmshafen, and Kiel, at which, in addition to the ordinary instruments of observation, self-registering barometers and anemometers are erected. At these places observations are made at 8 A.M., noon, and 4 and 8 P.M., of which the observations at 8 A.M. and 4 P.M. are sent by telegraph to Hamburg. To these nine stations and some others on the German coasts at which wind and weather only are noted, the Seewarte intends to add sixteen others, situated inland in different parts of Germany, in selecting which particular attention is to be given to the position of the station and the instruments, so that really good observations of wind and temperature will in each case be furnished. The action taken by the German Seewarte to secure that the observations of temperature and wind will be of such a quality that they can be used in scientific investigations of weather changes, is deserving of all praise, the more so since these observations as at present made are often of very doubtful quality and in many cases worse than useless, considered as data for weather-inquiries.

ON the occasion of the centenary of the Genevan Society of Arts, founded in 1776, that body proposes to offer a number of prizes in its various departments. A most important service which the Academy will render to horology will be the International Competition in the Regulation of Pocket Chronometers. The trials of these chronometers will take place at the Geneva Observatory, under the superintendence of M. Plantamour, the director. All chronometers intended for the competition must be forwarded to him before mid-day of February 14, 1876. All competitors not resident in Geneva should correspond with the Observatory through a resident agent, who will manage all the details. M. J. B. Grandjean, president of the Section of Horology of the class, offers his services gratuitously to makers who have no agent in Geneva. Each chronometer should be accompanied by a paper containing data to identify the chronometer, details of its construction, &c. The trial will last fifty-two days from February 15, 1876, divided into nine periods. In a hot chamber and in an ice-house (*glacière*) the chronometers will be tested by being placed in all possible positions. All chronometers not complying with the following conditions will be excluded from competition:—1. The mean variation from day to day ought not to exceed six-tenths of a second so long as the chronometer preserves the same position in the Hall of the Observatory. 2. The values which express the mean rates during each of the periods except that of the hot chamber and the ice-house, ought to agree with their mean in the limits of two seconds more or less. 3. The error of compensation determined by the comparison of the rates in the hot chamber and in the ice-house ought not to exceed two-tenths of a second of degree centigrade. 4. The difference of rates between periods six and nine (both in the Observatory Hall, horizontal position, dial above), *i.e.* before and after the proofs relative to temperature, ought not to be above one second in twenty-four hours. The value of the results obtained in the trials which con-

cern the two former conditions will have an importance double that which will be given to the two latter. No competitor can receive two prizes. A sum of 3,000 francs at least will be devoted for the purpose of awarding gold medals, or an equivalent value, to competitors who will have been judged worthy. A number of medals in silver and bronze will also be awarded. Those who wish for further details concerning this and other competitions, should apply to the Secretary of the Academy.

OUR readers will hear with regret that the well-known observatory at Twickenham belonging to Mr. Bishop, and presided over by Mr. Hind, is shortly to be dismantled and the instruments presented to the Royal Observatory at Naples. This, however, will probably not take place till the latter part of next year. Mr. Bishop has, we believe, been induced to part with his Twickenham property mainly on account of the benefit he found from residence in a southern climate. Not wishing to sell his scientific apparatus, he offered it by letter through Prof. de Gasparis to the Italian Government for the use of the Royal Observatory of Naples, where we believe an equatorial instrument of about the dimensions of the one at Twickenham was much desired. The offer was accepted in the first instance by telegram, and Mr. Bishop has this week received the formal authorisation of the Italian Minister of Public Instruction permitting the gift for the use of the Observatory at Naples. The most useful portion of the valuable library collected by Mr. Bishop's father (so long treasurer of the Royal Astronomical Society) may probably accompany the instruments.

IN 1859 Napoleon III. published a decree ordering that a prize of 20,000 francs should be presented every two years by the French Institute, each of the five academies being in turn authorised to nominate the candidate, and the choice to be ratified by the whole body of the Institute. The first laureate was M. Thiers, proposed by the Académie Francaise for 1861, on the ground of the excellency of his historical works. In 1863 the prize was proposed by the Academy of Inscriptions, and given to M. Jules Oppert, for his Assyrian discoveries. In 1865 M. Wurtz was proposed by the Academy of Sciences, for his discoveries in chemistry. In 1867 M. Henri Martin was selected by the Academy of Moral Sciences, for his History of France. In 1869 M. Guizot was elected by the Académie Francaise, using its right for the second time. In 1873 the Academy of Inscriptions selected M. Mariette, for his Egyptian discoveries. The Academy of Sciences having to exert its prerogative this year, has, it is stated, selected M. Paul Bert,. It appears that the ground of selection is his "discoveries on the effects of oxygen in the act of respiration." M. Claude Bernard declared that these discoveries are the most astounding which have been made since Priestley dicovered that gas. These conclusions will not be accepted without opposition, even in France, although the Academy is said to have ratified the award without any objection. The lamented *Zenith's* ascent was organised in order to test the accuracy of M. Bert's conclusions.

THE Natural Science Lectures at Cambridge during the Michaelmas term present several new features of interest. The list of lectures, practical courses, and classes is now, happily, so long that it is impossible for us to notice them in detail. Prof. Dewar will commence his career as a Cambridge Professor, and inaugurate a new departure in the history of the Jacksonian Chair, by lecturing on Dissociation and Thermal Chemistry. Prof. Liveing's laborious course of instruction in Spectroscopic Analysis, in which successive batches of students are taught at successive hours of the afternoon, will be resumed. Mr. Apjohn will lecture on Volumetric Analysis, at Caius Laboratory, and Dr. H. N. Martin on Physiological Chemistry at Christ's College. Prof. Liveing promises a course on the History of Chemistry in the ensuing May term. In addition to Mr. Bridge's ordinary course of practical work in Comparative Anatomy, a valuable series of lectures with practical instruction in Morphology will be given by Mr. F. Balfour, of Trinity, and Mr. A. M. Marshall, of St. John's. Dr. Michael Foster's usual course of Practical Physiology and Histology will this term meet in two sections, elementary and advanced. Prof. Hughes's courses are divided into three sets. On Tuesdays he will lecture on Physical Geography and Elementary Geology; Thursdays, on the period represented by the depositions between the Lower New Red (Permian) and the top of the chalk inclusive; Saturdays, on various unconnected vexed questions. Prof. Hughes may be expected to propound many novel views, which Prof. Hull called heresies at Bristol, as to the Permian, Rhætic, and Triassic beds.

PROF. STOKES lectures at Cambridge this term on Double Refraction and Polarisation, Prof. Challis on Practical Astronomy and Magnetism, and Prof. Cayley on a course of Pure Mathematics.

INTELLIGENCE has been received at Sydney that the expedition under the leadership of Mr. Macleay, which left Sydney in the *Chevert* about four months ago to explore New Guinea, has become disorganised, and is returning. At the same time a report has reached Sydney that a large navigable river has been discovered in New Guinea.

DURING the past week the Social Science Association has been holding its meetings at Brighton. In all the Sections much business was done in the way of reading papers and subsequent discussion, though we regret to see that the attendance, especially of townspeople, was considerably below previous years. Few of the papers call for notice by us. The most striking, if not indeed the most valuable paper read, was that of Dr. B. W. Richardson, which we print elsewhere. The inaugural address, by Lord Aberdare, dealt with the subject of "Crime." Of other papers read we may note that of Sir Charles Reed, president of the Education Section, on the subject of "Education," principally dealing with its elementary aspect. A paper was read by the Hon. G. C. Brodrick on the question, "How can the influence of the Universities be most effectively exerted in the general education of the country?" Among other methods of reform he advocated the encouragement of literary and scientific research by University grants. Mr. Brodrick evidently is of opinion that our two great Universities are still far behind the age, and this was the tone of the discussion which followed. Miss Sherriff's paper on the question, "Is a fair proportion of the endowments of the country made applicable to female education?" is worthy of attention. In the course of the paper she gave an account of the progress of the Girls' Public Day School Company.

THE Sea-Lions, the expected arrival of which we mentioned last week, reached London on Tuesday, and were forwarded to Brighton yesterday.

DR. CARPENTER has declined to stand for the Lord Rectorship of Aberdeen University.

DR. W. J. RUSSELL has been appointed Examiner in Chemistry at the Royal College of Physicians, London.

THE open Scholarship at St. Bartholomew's Hospital, value 100*l.*, has been awarded this year to Mr. C. Pardey Lukis.

WE have had forwarded to us two photographs of a mounted specimen of an almost complete Solitaire (*Pezophaps solitarius*), found, with a second, in the island of Rodriguez, in the June of this year, by Mr. J. Caldwell, the Assistant Colonial Secretary of Mauritius, and Sergeant Morris. These specimens, together with that procured by Mr. Slater, one of the naturalists to the Venus Transit Expedition, will settle some points in the oste-

ology of the peculiar extinct Columbine birds, of which so many separate bones have been obtained.

SOME interesting results were given by Mr. H. M. Taylor, Fellow and Tutor of Trinity College, Cambridge, in a paper "On the Relative Values of the Pieces at Chess," read before the British Association at Bristol. He found by a mathematical process that if a knight and king of different colours were placed on a chessboard at random, the odds against the king being in check were 11 to 1; if a bishop and a king, 31 to 5; if a rook and a king, 7 to 2; and if a queen and a king, 23 to 13. If, however, we consider only safe check (*i.e.* check in which the king is unable to take the piece), the odds are respectively 11 to 1, 131 to 13, 5 to 1, 107 to 37. From these numbers we can obtain a fair theoretical measure of the relative values of the pieces. Thus, if we take as our measure the chance of safe check, the values of the knight, bishop, rook, and queen are in the ratio 12, 13, 24, 37, while the values of these pieces in the same order as given by Staunton are 3·05, 3·50, 5·48, and 9·94, the value of the pawn being taken as unity. Mr. Taylor remarks that the value of a pawn depends so much on the fact that it is possible to convert it into a queen, that the method does not appear applicable to it.

MESSRS. H. S. KING and CO. will publish, during the forthcoming season, the following new volumes of their International Scientific Series:—"Animal Parasites and Messmates," by M. Van Beneden, Professor of the University of Louvain, and Correspondent of the Institute of France. It will contain eighty-three illustrations.—"The Nature of Light," with a general account of physical optics, by Dr. Eugene Lommel, Professor of Physics in the University of Erlangen. This work will contain a table of spectra in chromolithography and a large number of other illustrations.—"The Five Senses of Man," by Professor Bernstein, of the University of Halle.—"Fermentations," by Professor Schutzenberger, Director of the Chemical Laboratory at the Sorbonne; and a new edition of Dr. Hermann Vogel's "Chemical Effects of Light and Photography."

TWO nests of English Humble-bees were last week sent to New Zealand by Mr. Frank Buckland, for the Canterbury Acclimatisation Society. These insects are specially desired in New Zealand for the purpose of fertilising the common clover; the proboscis of the common bee is not sufficiently long to reach down to the pollen of the clover flower, while the humble-bee is enabled to do so. In this way the insect is expected to do great service to the agriculturist by largely extending the growth of the clover. The bees were packed in their own nests in two boxes, and will be under the charge of a member of the New Zealand Council, who is provided with every necessary for their welfare during the voyage. They are expected to arrive about the middle of January—midsummer at the antipodes.

THE production of silk in South America is rapidly increasing both in quantity and quality. At a local exhibition recently held at Buenos Ayres, some samples, both raw and manufactured, were shown, which compared favourably with the best silks of Asia. The climate of Brazil seems to be especially well suited for the cultivation of the silkworm, which feeds on the leaves of the *Palma christi*, a plant which grows in abundance in the country. The Government of Brazil is said to be contemplating offering subsidies for the cultivation of silkworms in the country.

ALMOST every day the French *Journal Officiel* publishes a list of professorships created by the Government in the several academies, principally in the provinces, in order to enable them to sustain any competition which may be eventually offered by the free academies. The law of the liberty of instruction will benefit unquestionably not only the public at large, but also the official universities, in raising a spirit of emulation.

A PROFESSOR of the Academy of Grenoble, M. Violle, made several balloon ascents in the Alps last summer in order to measure the degree of heat generated by the sun, and consequently the temperature emanating from that body. It is said by the *Liberté* that M. Violle is quite opposed to the idea that the degree of temperature is immense; he says that it is not much hotter than temperatures produced in the laboratories. Details will shortly be published in the *Comptes Rendus*.

THE *Geographical Magazine* for October contains a detailed account of the voyage of the Arctic Expedition from Portsmouth to Waigat, and of the work of the *Valorous*. A map of part of the North Atlantic showing the tracks of the three ships accompanies the paper, the sea being tinted according to depth. There is also a section of the Atlantic showing the soundings of the *Valorous*, and a plan of the harbour of Holsteinberg, off which the ship grounded.

THE *Times* and other London papers of Tuesday contain letters from members of the *Pandora* Arctic Expedition, under Capt. Young. The expedition reached Disco on August 7, and all was going well, though on the way out squalls and contrary winds had been met with. Capt. Young was to leave Disco on the 10th.

PROF. ED. MORREN has published a small biography of Charles de l'Escluse, commonly known as Clusius, after whom a small order of plants was named by Lindley. Born in 1526 and dying in 1609, he was for sixteen years Professor of Botany at the University of Liège. His works are comprised in two folio volumes—"Rariorum Plantarum Historia," and "Exoticorum Libri Decem," and he was one of the pre-Linnean naturalists who attempted a classification of plants founded on artificial characters.

THE first part has just been published of the long-announced "Medicinal Plants," by Messrs. Bentley and Trimen. Each part is to contain eight coloured plates of plants included in the Pharmacopœia of Britain, India, or the United States, together with letterpress comprising a full description of the plant, its nomenclature, geographical distribution, &c., and an account of its properties and uses.

IN a recent number of the *Transactions of the Academy of Science of St. Louis*, Mr. Charles Riley describes the curious habits of two insects which occur alive in the pitchers of *Sarracenia variolaris*. The first is a small moth (*Xanthoptera semicrocea*), which lays its eggs within the pitcher. The young caterpillars there weave a gossamer-like web and feed on the cellular tissue of the leaf. The putrid remains of insects previously captured, which have perished, are covered over by the excrements of these caterpillars. The second is a dipterous insect (*Sarcophaga sarraceniæ*). The mature fly is stated to drop a number of the larvæ into the pitcher, where they feed on the decaying remains of other insects, and finally burrow through the bottom of the pitcher into the ground, where they undergo their transformations.

THE additions to the Zoological Society's Gardens during the past week include a Campbell's Monkey (*Cercopithecus campbelli*) from W. Africa, presented by Miss A. J. Brown; a Brown Bear (*Ursus arctos*) from Russia, presented by Mr. A. Vale; two Vervet Monkeys (*Cercopithecus lalandii*) from S. Africa, presented by Mr. Abbett; two Grey-breasted Parrakeets (*Bolborhynchus monachus*) from Monte Video, presented by Miss Maiden; a Peewit (*Vanellus cristatus*), European, presented by Dr. William Brewer; a Brown Bear (*Ursus arctos*) from Russia, two Argus Pheasants (*Argus giganteus*) from Malacca, an Alligator (*Alligator mississippiensis*) from the Mississippi, a Common Snake (*Tropidonotus natrix*) from South Tyrol, deposited; two Graceful Ground Doves (*Geopelia cuneata*) from Australia, received in exchange; a Scolopaceous Rail (*Aramus scolopaceus*) from S. America, purchased.

SCIENTIFIC SERIALS

THE *Journal of the Chemical Society*, July and August, 1875.—These numbers contain the following papers, besides the usual number of abstracts from other serials :—On Narcotine, Cotarnine, and Hydrocotarnine (Part I.), by G. H. Beckett and Dr. C. R. A. Wright. The authors first treat of the preparation of cotarnine, then of its conversion into hydrocotarnine, and the action of oxidising agents upon the latter. Finally, there are accounts of the action of nascent hydrogen, of boiling baryta water, and of ordinary water on narcotine. As an appendix to this interesting paper we have a treatise by Dr. F. Pierce, on the Physiological Action of Cotarnine and Hydrocotarnine. It appears from this that the addition of hydrogen to cotarnine converts a base which is apparently inert into a very active substance, the change in physiological action being far more striking even than the alteration brought about in the physical and chemical properties.—On Andrewsite and Chalkosiderite, by Prof. Story Maskelyne.—An Examination of Methods for effecting the quantitative separation of Iron Sesquioxide, Alumina, and Phosphoric Acid, by Dr. Walter Flight ; this paper is very elaborate and interesting.—On a New Method of Supporting Crucibles in Gas Furnaces, by C. Griffin.—On some points in Examination of Waters by the Ammonia method, by W. H. Deering.—On the Structure and Composition of certain Pseudomorphic Crystals, having the form of Orthoclase, by J. Arthur Phillips.—On Sodium Ethylthiosulphate, by Wm. Ramsay.—On the Action of Organic Acids and their Anhydrides on the Natural Alkaloids (Part IV.) by G. H. Beckett and Dr. C. R. A. Wright. The authors treat of the action of polybasic acids on morphine and codeine, of succinic acid on morphine, of camphoric acid on codeine and morphine, of tartaric and oxalic acids on codeine, and of oxalic acid on morphine.—A note, by the same authors, on the Sulphates of Narceine and other Narceine derivatives ; giving an account of the action of nascent hydrogen, of acetic anhydride, and of ethyliodide upon narceine.—On the Action of Chlorine on Pyrogallol, by John Stenhouse and Ch. E. Groves ; the authors speak of two substances not described before, with such minuteness, and call them Mairogallol and Leucogallol.—In an appendix Mr. W. J. Lewis gives an account of the crystallographic characters of Mairogallol.—On the Action of Dilute Mineral Acids on Bleaching Powder, by Ferdinand Kopfer ; a very elaborate treatise with numerous tables and results of analysis, going far to elucidate the still somewhat doubtful chemical composition of the substance commonly known as "chloride of lime."

THE most important article in the *Journal of Botany* for September is by Mr. J. W. Clark, "On the absorption of nutritive material by the leaves of some insectivorous plants." In a very carefully conducted series of experiments, a number of flies were supplied to the bases of *Drosera rotundifolia* and *intermedia*, whose bodies had previously been soaked in lithium citrate ; care was taken that the salt did not reach any other part of the plant externally ; and after a period of about forty-eight hours the leaf-stalks were incinerated and tested by the spectroscope for lithium, a perceptible quantity of which was found ; thus appearing to prove, in opposition to Prof. Morren's view, that the leaf does actually absorb and digest. A few experiments were tried on *Pinguicula lusitanica* with the same result. The plate in this number represents an interesting new lichen, *Stigmatidium dendriticum ;* and in that for October the mode of germination of *Chara*, to illustrate a translation of De Bary's important paper on this subject. It also contains a description of a collection of Chinese ferns gathered by Mr. J. F. Quekett, and other shorter papers.

SOCIETIES AND ACADEMIES

LONDON

Royal Microscopical Society, Oct. 6.—Mr. H. C. Sorby, F.R.S., president, in the chair.—A large number of presents to the Society were announced, and special attention was directed by the Secretary to a turn-table by Mr. Cox, of the U.S. America.—A new microscope was exhibited by Messrs. Beck and Beck, and a new form of hand magnifier by Mr. Browning.—Mr. Slack made some observations upon certain Lepidoptera armed with boring probosces, by which they were said to pierce oranges and other fruit. A comparison between drawings of an Australian species appeared to show that it was identical with one originally described by Mr. M'Intire at the meeting in April 1874.—Mr. Beck exhibited a specimen of blood discs of the *Amphiuma means*, which are supposed to be the largest in existence.—A paper by Dr. R. Piggott, on the identical characters of spherical and chromatic aberration, was read by the Secretary.—Dr. C. T. Hudson gave a highly interesting description of a new Melicertian, for which he proposed the name of *M. tyro*.

PARIS

Academy of Sciences, September 27.—M. Frémy in the chair.—The following papers were read :—Meridional observations of the minor planets made at the Paris Observatory during the first half of the year 1874, by M. Leverrier.—On the formation of hail ; reply to a note by M. Renou, by M. Faye.—Twelfth note on the electric conductivity of bodies which are imperfect conductors, by M. Th. du Moncel.—Irregular variation of hybrid plants and deductions which can be made therefrom, by M. Ch. Naudin.—On the development of the pulmonary gasteropoda, by M. H. Fol.—Transformation of blood into a soluble powder ; chemical, physical, and alimentary properties of this powder, by M. G. Le Bon.—Notes towards the history of the genus Phylloxera, by M. Lichtenstein.—On the particularities presented by the phenomenon of the contacts during the observation of the transit of Venus at Pekin ; note by M. Fleuriais.—On the putrefaction produced by bacteria in the presence of alkaline nitrates, by M. Mensel.—Remarks concerning a note by M. F. Glénard on the spontaneous coagulation of blood removed from the organism, by MM. E. Mathieu and V. Urbain.—Quantities of nitrogen and of ammonia contained in beet-roots, by MM. Champion and H. Pellet.—On the internal structure of the hailstone and its probable mode of formation, by M. A. Rosenstiehl.—Extract from a letter from Colonel Buchwalder on hailstorms, presented by M. Faye.—Letter from M. E. Solvay to M. E. Becquerel on the formation of hail, presented by M. Faye.

BOOKS AND PAMPHLETS RECEIVED

BRITISH.—Journal of the Iron and Steel Institute (Spon).—Thermo-Dynamical Phenomena; or, the Origin and Physical Doctrine of Life: H. A. Hartley, of Madras (Longmans).—Animal Physiology: E. Tully Newton (Murby).—Figures of Characteristic British Fossils: W. H. Baily, F.L.S., F.G.S. (Van Voorst).—Proceedings of the Natural History Society of Glasgow.—On Improved Dwellings: Charles Gatliffe, F.S.S. (Stanford).—Materialism: J. M. Winn, M.D., M.R.C.P. (Hardwicke).

AMERICAN.—The Recent Origin of Man: J. C. Southall (Philadelphia, Lippincott and Co.)—Preliminary Report upon a Reconnaissance through Southern and South-Eastern Nevada, made in 1869, by Lieutenants Wheeler and Lockwood.—The Origin of the Sun's Heat (Troy, U.S., Scribner).—Daily Weather Reports, December 1872 and December 1873 (Signal Service U.S. Army, Washington).

FOREIGN.—Résumé de quelques Observations astronomiques et meteorologiques: J. C. Houzeau (Brussels, F. Hayez).—Matériaux pour servir à l'étudie de la Faune profonde du la Léman: Dr. F. A. Forel (Lausanne, Ronge et Dubois).—Die Fortschritte des Darwinismus: T. W. Spengel (Leipzig, E. H. Mayer).—Culturgeschichte in ihrer Natürlichen Entwicklung bis zur Gegenwart: von F. von Hellwald (Augsburg, Lampart et Cie.)—Charles de l'Escluse, sa Vie et ses Œuvres: E. Morren (Liége).—Annaes do Observatorio do Infante D. Luiz Magnetismo Terrestre, 1870 and 1874 (Lisboa).

BANCROFT'S "RACES OF THE PACIFIC STATES"

The Native Races of the Pacific States of North America. By Hubert Howe Bancroft. Vol. ii. Civilised Nations. Vol. iii. Myths and Languages. (London: Longmans and Co., 1875.)

THE publication of this great anthropological work goes on rapidly, and no doubt the two remaining volumes will be out in a few months. Every reader must be glad that the author departs more and more from his original plan of making his book a mere museum of compiled information, and now makes some attempt towards interpreting the mythical and religious puzzles of Mexico and Central America. The introductory essays on the philosophy of civilisation and religion may not be of startling originality, but at any rate they are the deliberately adopted conclusions of a writer with an unusually large knowledge of the facts. Mr. Bancroft has evidently come, like so many thinkers of this generation, under the genial influence of Emerson. To his mind, the world seems animated by a "Soul of Progress," individual men working on unknowingly, and often against their will, towards a mysterious end which is the goal of civilisation. The two apparently oppugnant agencies of good and evil tend together toward one end; "Night or day, love or crime, leads all souls to the good." At one stage of civilisation blind faith is essential to give strength to man's belief, till at another stage scepticism has to come in and destroy the scaffolding of superstition, leaving the mental fabric which has been reared by its means. War and tyranny do the work of consolidating nations and founding political institutions, till the time comes when, having done their work in promoting good, they may themselves be cast out for being evil. Institutions which were at first the essentials of civilisation become, as man advances, a drag on his progress, and have to be abolished. The union of Church and State, of superstition and despotism, a union still necessarily kept up in some of the more backward civilisations, was in barbarous ages a real means of moral and intellectual advance from a wilder and lower state. Thus we see in every phase of development the result of a social evolution, but where it is to end, whither it is tending, we cannot tell as yet, nor can we yet fully understand its guiding laws, for "like all other progressional phenomena, they wait not upon man; they are self-creative, and force themselves upon the mind age after age, slowly but surely, as the intellect is able to receive them."

One really stands in need of some such hopeful theory of social evolution, in reading the details of Mexican religion. The chapter on Public Festivals is a sickening catalogue of horrors. It begins mildly with the priests scarifying and mutilating themselves, especially by boring holes in their tongues to pass sticks through. Then comes the sacrifice of a number of sucking infants, who were carried in procession on gorgeous litters to be slain on the mountains and in the lake, some of the bodies being brought back as a delicacy for the priests and nobles. Then an account of a festival, where the human victims, having had their hearts cut out in the usual way on the sacrificial stone, were then flayed; their flesh was eaten at a banquet, and the lads of the colleges dressed up in their skins and went about singing, dancing, and asking for contributions: "those who refused to give anything received a stroke in the face from the dangling arm." A little later comes the feast of the Fire-god, where the priests carried captives naked and bound, on their shoulders up to the top of the temple, and pitched them into a huge fire of glowing coals, where they watched them writhe and crackle till it was time to rake the almost dead bodies out and cut them open; the proceedings ended with a dance and climbing a maypole. Even at the harvest festival, an occasion of jollity, when everybody danced and feasted, these sanguinary religionists brought out a criminal, put him between two immense stones balanced opposite each other, and let them fall together so as to smash him.

It is not easy, in the present condition of Sociology, to account for this monstrous development of cruelty in the Mexican religion. The people seem not to have been either wicked or hard-hearted in their private life, but to have been the same mild and rather stolid people that their descendants still remain. The Aztec criminal code was indeed of the severest, and even Draco might have scrupled to have a man beaten to death with clubs for getting drunk, or to make stealing a tobacco-pouch a capital crime. But there is nothing extraordinary in a barbarous government trying to stamp out even small offences by ferocious punishments. That these lose much of their effect by the public mind becoming too habituated to them, is a discovery which comes at a higher stage of statecraft. The state of civil society in ancient Mexico was on the whole like that of many other half-civilised communities. It was their religion which was exceptional, in the enormous frequency of human sacrifice combined with cannibalism, it being the ordinary motive for war to obtain a supply of captives for victims. The nearest parallel is to be found in nations of West Africa, where human sacrifice and cannibalism form a great part of the religious observances. The Dahoman custom of dividing the human victim, the blood for the fetish, the head for the king, the body for the people, reminds us of similar arrangements described by Mr. Bancroft in Central America. On the other hand, the religion of Mexico, unlike those of West Africa, was one in which asceticism and self-torture prevailed both among priests and people. They fasted long and severely in their religious rites, and were everlastingly drawing blood from their bodies with aloe-thorns and obsidian knives, piercing their tongues as a penance for evil speaking, and other parts of their bodies for appropriate sins. This religious ordinance is almost peculiar to the group of connected nations of Mexico and Central America, and thus has a certain ethnological interest. The Mexican combination of religious austerity and cruelty may be instructively compared with that which developed itself in mediæval Europe.

Mr. Bancroft is inclined to think that the civilisation of Mexico and Central America had sunk somewhat from its highest point at the time of the Spanish discovery. He believes in the high culture of the famous traditional Toltecs, who were of the same stock with their successors the Aztecs, both belonging to the wide Mexican race to

which modern writers apply the old designation of Nahua (Nahuatl). But his description of the Aztec civilisation at the time of the Spanish Conquest scarcely suggests a state of decay. The handicrafts of the stone-cutter, the weaver, and the goldsmith, the elaborate organisation of the priesthood and the army, of the colleges for training boys and girls, and of the guilds of merchants, were found by the Europeans in full vigour. The Mexicans not only had a system of picture-writing and kept their chronicles in it, but King Nezahualcoyotl is said to have made a law prescribing the penalty of death on historians who should record fictitious events. This same king made severe forest-laws to prevent the supply of wood in the country being exhausted, so that the people did not dare even to pick up the fallen wood. Such a state of things may indicate a certain stiffness and artificiality of law and custom, but hardly a fall from an earlier higher state. In any new discussion of the problem of American civilisation, for which these volumes afford the first ample collection of materials, we should prefer reasoning on Aztec life as Cortes saw it, to speculating on the institutions of the half mythical Toltecs of tradition.

In looking through the present volumes two observations suggest themselves. Mr. Bancroft has drawn up descriptions of the languages of the Pacific district which are of some use in defining the general structure of each, and justifying the class-arrangement which he adopts. But he only gives a few specimen words of each language, such as pronouns, numerals, incomplete parts of a verb, and perhaps a Lord's Prayer. We wish, considering the space he has spared for native myths, that he had found room for a series of concise grammars. The existing grammars and dictionaries of many of these languages, even such as Aztec and Maya, which are the spoken languages of large populations, are so scarce and costly as to be out of the reach of ordinary philologists. For instance, it is difficult to get sufficient information as to one of the most curious languages of Mexico, the Otomi, described by several writers as a real monosyllabic language imbedded among languages like the Aztec, whose formation is polysyllabic-agglutinative in the extreme. This is a most interesting phenomenon in philology, and we looked to Mr. Bancroft at least to settle the disputed point whether the Otomi tongue is really monosyllabic. There are plenty of polysyllables in it, such as *tayo*, dog; *nxuyo*, bitch; *mahetsi*, heaven; *nuga*, I. But the question is whether the statement is fully borne out, that "in words compounded of more than one syllable, each syllable preserves its original meaning." In the first two instances this is evidently true, *ta-yo*, *nxu-yo* being decomposable as "male dog," "female dog." Whether the other two words can be analysed we do not know. So interesting is the Otomi tongue for its bearing on the theory of the monosyllabic origin of language, that it would be worth while to collect and reprint everything that is known about it. For one thing thanks are due to Mr. Bancroft, that he insists on the merely accidental character of such resemblances as exist between Otomi and Chinese. Naxera's baseless theory of a connection between these two languages had publicity given to it by Prescott, and is not yet forgotten.

The collection of cosmogonic traditions in the third volume is remarkable, and may lead us to expect valuable results to science when the creation-myths of all tribes and nations of the world shall be put together and carefully analysed. Many of them are of course mere products of childish fancy. In Central California the story is that in the beginning the world was dark, so that men and beasts and birds were always stumbling and dashing against one another. The Hawk happening to fly in the face of the Coyote (Prairie-wolf), they mutually apologised, and set to improve things. The Coyote made balls of reeds and gave them with some pieces of flint to the Hawk, who flew up into the sky with them and set them alight. The sun-ball still glows red and fierce, but the moon-ball was damp, and has always burnt in a feeble, uncertain way. The Southern Californians, on the other hand, believe that the sun and moon were the first man and woman; women, descendants of the moon, are fair but fickle, for as she changes so they all change, say these savage philosophers. Such mythical fancies, of which there are numbers in this one district, fall within the province of the pure mythologist. But it is an interesting question whether, among the legends of catastrophes which altered the face of the earth and destroyed its inhabitants, there may be any dim recollections of actual events, recognisable by the antiquary or the naturalist. To take another example from California, the natives about Lake Tahoe ascribe its origin to a great natural convulsion. Their story is that their ancestors were once numerous and rich, but a stronger people rose up who defeated and enslaved them. Then the Great Spirit sent an immense wave across the continent from the sea, which engulfed both oppressors and oppressed, all but a small remnant. Those who remained of the ruling caste made the people build a great temple for refuge in case of another flood, and on the top of this the masters worshipped a perpetual fire. Soon, however, the earth was troubled again, this time with strong convulsions and thunders. The masters took refuge in their great tower, shutting out the slaves, who fled to the Humboldt River, and paddled for their lives, for the land was tossing like a troubled sea, casting up fire, smoke, and ashes. The Sierra was mounded up from the bosom of the earth, while the place where the great fort stood sank, leaving only the dome at the top exposed above the waters of Lake Tahoe.

Such is the local story, remarkable for its good descriptions of an earthquake-wave, an eruption, and a volcanic upheaval and subsidence. Whether it is founded on some fragmentary reminiscences of a real local catastrophe is a question which we leave to be answered by some geologist who has examined the district.

HUXLEY AND MARTIN'S "ELEMENTARY BIOLOGY"

A Course of Practical Instruction in Elementary Biology. By T. H. Huxley, LL.D., Sec. R. S., assisted by H. N. Martin, B.A., D.Sc. (London: Macmillan and Co., 1875.)

IN the preface to this work, Prof. Huxley tells that the object of his book is to serve as a laboratory guide to those who are inclined to study the principles of Biology as a single science, and not as one divided, except for the sake of convenience, into the two "disciplines," Zoology and Botany. To accomplish this end a certain

number of readily obtainable plants and animals have been selected for minute description, in which the most important types of vegetable and animal organisation are capable of being demonstrated. With reference to each species selected, an account of its anatomy is given, which is followed by laboratory instructions as to the manipulatory detail necessary for its complete verification. The types selected include Yeast, Protococcus, the Proteus Animalcule, Bacteria, Moulds, Stoneworts, the Bracken Fern, the Bean Plant, the Bell Animalcule, the freshwater Polype and Mussel, the Crayfish and Lobster, and the Frog. As an illustration of the form in which the laboratory directions are given, the following quotation from a portion of the dissection of the Frog will serve as a fair example:—

"DISSECTION OF THE VISCERA IN THE VENTRAL CAVITY.

"1. Lay a frog, which has been killed with chloroform, on its back, and pin it out on a layer of paraffin or beeswax, under water; divide the skin along the abdominal median line from the pelvis to the front of the lower jaw; next make a transverse incision at each end of the longitudinal one, and then throw outwards the two flaps of skin thus marked out. The following points may now be noted:—

"*a.* A great vein (*musculo-cutaneous*) on the under surface of each flap of skin, about the level of the shoulder.

"*b.* Some of the muscles of the abdominal wall, covered by a thin aponeurosis; through this latter can be seen—

"*α.* The *rectus abdominis*, running from pelvis to sternum, close to the middle line, and divided into a number of bellies by transverse tendinous intersections.

"*β.* Other muscles outside the rectus on each side.

"*c.* The *pectoral region*: part of its hard parts in the middle line, only covered by tendinous tissue; external to this, muscles running towards the shoulder-joint.

"*d.* The *muscles of the throat*: small and with a general direction from the lower jaw towards the sternum and shoulder-girdle.

"2. Raise the tissues of the body-wall with a pair of forceps, and carefully divide them, a little to the right of the median line," &c.

From what has been said above it is evident that there are two features in this volume of Prof. Huxley's which call for special notice on account of their novelty. The first of these is that Botany and Zoology are taught in combination, as parts of the science of living organisations—Biology. The second is that the subject is taught practically; in other words, with full information on how to observe the features described.

Most amateur students of so-called science, or collectors, run in a single groove of thought. They learn to recognise specific differences in those groups of animals, fossils, or plants which they honour with their patronage; they discover minute variations in individual specimens, and frequently attempt to load nomenclature with fresh names, which may or may not have to be swamped in the mass of synonyms—already but too large—according to their knowledge of the literature of the subject they affect. In the scale of scientific investigators these stand lowest. They do good; their work is indispensable; the mental effort required for its production is, however, small, and is generally associated with a want of power to grasp general principles which is frequently quite surprising. The opportunity of seeing, or, better still, possessing "type" specimens is their highest gratification; and their opinion on any point involving more than generic differences is unreliable.

A second class of student advances further. Collection of familiar forms is not the object kept in view by them. They study the literature of their subject, having previously received a sound educational foundation. They do not make fresh and independent observations themselves, but delight in verifying those of others. New facts they absorb; and by engrafting them upon their previous ideas, modify the latter—generally prematurely—in a direction which they prophesy to be the science of the future. They draw extreme deductions on insufficient evidence, and are apt to fall whilst attempting to substantiate them. These are not to be trusted in the definition of a sub-kingdom.

A third class investigate on their own account. They study the works of others; and by thoroughly digesting the new and old facts at their disposal, are in a position to modify generally accepted views on important questions by the publication of arguments as cogent as they are reliable. These original investigators have their independent views on the most general principles.

Such being the case, we may employ the scale of biological relationships as a rough standard of the mental capacities of working students. It leads us to look upon everything which tends to inclusiveness as an advance in the right direction, and everything in the opposite direction as retrograde. All biologists must therefore thank Prof. Huxley for having introduced into the preliminary training of students of Natural History the conception of the complete unity of plant- and animal-life, and of the comparative insignificance of the gulf between the two.

Prof. Huxley teaches Biology *practically*. The pupil has to see with his own eyes all that he reads about; and what is more, he has to find what he is to see. Practical education is a praiseworthy characteristic of the present age. Numbers of laboratories, in this country and on the Continent, have been recently established for the teaching of Physics, Physiology, and lastly Biology. That this practical phase must be generally adopted in scientific education becomes more certain as the scientific training itself becomes more and more a part of the preliminary education. The tendency in recent times to estimate classics at a lower value as a discipline than formerly, is one which necessitates the introduction of a substitute; of a means by which a training in the method of work shall be the mental exercise, whilst mere facts shall not have the prominence generally given them in the scientific lecture-room. As a training, practical biology offers all the requirements, at the same time that it leaves those who have pursued it, after they have finished their education, in a position peculiarly favourable for the prosecution of original investigation on their own account. From this view of the subject we have also therefore to thank Prof. Huxley for having added Biology to the list of those sciences which are taught practically as well as theoretically.

It has also special advantages in this direction. No expensive outlay is necessary for the purchase of apparatus; a well-lighted room, together with a microscope,

scalpels, forceps, and scissors, being nearly all that is essential to a biological laboratory. These can be procured by anyone; and the student when thus equipped with Huxley and Martin's "Practical Biology" in his hands, need only look around for some of the most easily obtainable animals, upon getting which he can start work in good earnest.

In the descriptive portion of the work there is one point to which we cannot help referring, which is in connection with the circulation of the blood. It is an explanation, originally given by Brücke, we believe, of the manner in which the mixed arterial and venous blood in the single ventricle of the frog is distributed in such a manner that the venous blood mostly enters the lungs. "It fills (during the systole) the conus arteriosus, and, finding least resistance in the short and wide pulmonary vessels, passes along the left side of the median valve into them. But as they become distended *and less resistance is offered elsewhere*, the next portion passes on the right side of the longitudinal valve into the aortic arches." The words italicised by us are those which it is difficult to comprehend, for it is evident that if the pulmonary artery offers less resistance at the commencement of the systole, it will do so all through the revolution in proportion to the relative calibre of its capillaries and those of the system generally; and then there is no reason why the valve should flap back.

OUR BOOK SHELF

Rotomahana, and the Boiling Springs of New Zealand. A Photographic Series of Sixteen Views, by D. L. Mundy. With descriptive notes by Ferdinand von Hochstetter, Professor of the Polytechnic Institution of Vienna. (London: Sampson Low and Co., 1875.)

THE autotype illustrations which form the main feature of this handsome volume are triumphs of the photographic art, and reflect the highest credit upon their author, Mr. Mundy. The photographs are on a scale quite large enough to give one a satisfactory idea of the main features of the various scenes intended to be portrayed; and by the judicious introduction into most of the views of the human figure, a good idea of the scale of the photographs is at once afforded.

The remarkable region illustrated by Mr. Mundy's series of photographs lies just about the centre of the North Island of New Zealand, in the south of the province of Auckland. The culminating or rather originating point of the phenomena described, Prof. Hochstetter regards as the still active volcano Tongariro, in the north of the province of Wellington. From this volcano three lines of volcanic action are supposed to proceed in a north-easterly direction by Lake Taupo to Lakes Rotorua, Rotoiti, and Rotomahana respectively, the last-mentioned line proceeding inwards as far as the marine volcano Whakari, in the Bay of Plenty; this line also, near its source, includes the hot springs at the head of Lake Taupo, about forty miles to the north of Tongariro. Another line, which follows to some length the outflow of the river Waikato from Lake Taupo, is marked by the hot springs and steam jets of Otumaheke and Orakeikorako, on the river's banks, and those of the Pairoa mountain range. The third line of action forming eruptions of this kind is exhibited in the hot springs of Rotorua and the solfataras of Rotoiti, which terminate these specimens of volcanic action on land, being situated near the sea-coast. While all along these three lines evidences of volcanic action are visible in the shape of hot springs, solfataras, geysers, mud-lakes, &c., the chief interest centres in Rotomahana, where the most beautiful and marvellous effects of this action are displayed. Though on a much smaller scale, the phenomena greatly resemble those which are seen in such profusion in the Yellowstone region of North America.

Mr. Mundy devotes most of his photographic views to the illustration of the phenomena to be witnessed in and around Rotomahana. This is one of the smallest lakes in the region, being scarcely a mile in length and a quarter of a mile in breadth; it is 1,088 feet above the sea, and the temperature of the lake itself varies from 60° to 100° Fahr. On the margin of the lake are many boiling springs, and around it are a great variety of phenomena similar to those which are witnessed in Iceland and in North America. It is impossible in a few words to give any adequate idea of these phenomena, and we must therefore refer our readers to Mr. Mundy's beautiful illustrations, and Prof. Hochstetter's brief but clear descriptions. One of the photographs gives a fine view of Lake Rotorua, about twelve miles north of Rotomahana, and the last four are devoted to the illustration of Lake Taupo and the phenomena to be seen in its neighbourhood. Rotomahana, we may state, is about forty-five miles N.N.E. of Lake Taupo, and about double that distance from Mount Tongariro.

Lake Taupo lies at a height of 1,250 feet above the sea, and no bottom has been found at a depth of 200 fathoms. Prof. Hochstetter conjectures that its waters, which have only one visible outlet, the Waikato, but many tributary streams, has a subterranean outlet to the north. It is this, he believes, which gives rise to the curious phenomena which abound in the region to which Mr. Mundy's photographs refer; the water, after being heated by underground volcanic fires, generates high-pressure steam that forces its way to the surface, bearing the characteristics of the rocks with which it has come into contact: the New Zealand springs, we should say, are divided into two distinct classes, the one alkaline, and the other acid. Whatever may be the value of Prof. Hochstetter's explanation of the phenomena, there is no doubt about the value of Mr. Mundy's illustrations of a district which seems to be all that now remains of a once extensive active volcanic region. While as a collection of well-executed views of great interest the work deserves a wide circulation, to the student of geology it is of great value, as affording a far more satisfactory idea of an important feature of the physical geography of New Zealand than any mere description can convey.

Elementary Lessons in Botanical Geography. By J. G. Baker, F.L.S., Assistant Curator of the Herbarium at Kew. (London: L. Reeve and Co., 1875.)

A WANT has long been felt of a small text-book for the use of lecturers and students dealing with the distribution of plants on the face of the globe. A work of this kind necessarily contains a large amount of detail and a formidable array of plant-names. These features of the present little volume are less objectionable when its special purpose is borne in mind, viz., the instruction of gardeners; the various chapters into which it is divided being in fact the substance of a series of lectures delivered to the gardeners at Kew. A reference to these details would be out of place in a short notice; and the best idea will be conveyed by giving the author's final summing up, viz:—That each species has originated from a single centre; that species have originated in different parts of the world, and that the flora of any given tract depends largely on its geographical position; that a large portion of the present genera (or types which agree in structure down to minute detail) were in existence before the end of the Secondary period, and have passed through the very great changes in climate and the relative positions of sea and land that have occurred during the Tertiary period; and that species (or types which accord not in structure only,

but in vegetative characters—such as shape of leaves and arrangement of flowers) were dispersed in broad outline as at present, before present islands were insulated and the present general dispersion of sea and land worked out. The reader will find in the volume a very large amount of information on these subjects compressed into a small space.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*]

Ocean Circulation

HAVING carefully read Mr. Croll's papers in the *Philosophical Magazine* for September and October, I find in them the full confirmation of my statement that his "crucial-test" argument is based on the assumption of an equilibrium between the Equatorial and the North Atlantic columns; the words "to be in equilibrium" or "in order to equilibrium" being used over and over again to fix this as the essential condition of the computation by which the North Atlantic column is made out to be $3\frac{1}{2}$ feet higher than the Equatorial.

No reference to other passages in Mr. Croll's writings can countervail this fact. I pointed out at Bristol the fallacy it involves, which was at once recognised by Sir William Thomson, General Strachey, and other competent authorities. This fallacy becomes obvious in the following parallel case:—

The specific gravity of Ægean water being to that of Black Sea water as (say) 1029 to 1013, a column of Black Sea water 1,029 feet high would be required to balance a column of Ægean water 1,013 feet high; therefore (on Mr. Croll's assumption of an equilibrium) the level of the Black Sea must be above that of the Ægean in the proportion of 16 feet to 1,013 feet of depth. But that there is *not* an equilibrium between the two columns, is conclusively proved by the deep inflow of Ægean water which always accompanies the surface-outflow of Black Sea water, showing the Ægean column to be the heavier.

Now Mr. Croll has obviously no more right to assume an equilibrium between the North Atlantic and the Equatorial columns, and thereby to deduce from their relative temperatures the higher level of the former, and the consequent impossibility of the thermal circulation as making the poleward upper flow run uphill, than he would have to deduce the excess of level of the Black Sea from its lower salinity, and to assert that an inward underflow of Ægean water is impossible, as tending to raise that level yet higher.

But there is yet another serious error in Mr. Croll's computation, which, even admitting his fundamental assumption, completely invalidates his conclusion. He has entirely omitted the consideration of the *inferior salinity* of the Equatorial column; which, as it shows itself alike at the surface and at the bottom, may be fairly taken as characterising its entire height. This will make a difference *in the opposite direction* of about one foot in 1,026; sufficient, therefore, if the excess in the North Atlantic column extends to a depth of no more than 600 fathoms, to neutralise the whole $3\frac{1}{2}$ feet of elevation which Mr. Croll deduces from relative temperatures.

Mr. Croll is unable to see what the "viscosity" of water has to do with the question. Just this—that it affects his whole doctrine of "gradients." The nearer water is to a "perfect fluid," the less is the gradient required to give it horizontal motion.

If a viscous fluid be drawn from the bottom of one end, A, of a long trough $A—B$, its level at B will be lowered more slowly than at A, and will remain appreciably higher so long as the outflow continues. But in the case of a "perfect fluid" and a slow outflow, the level will practically fall simultaneously along the whole length of the trough $A—B$. I am quite aware that, *mathematically* speaking, the level must be always lower at A than at B; since there can be no movement of any particle from B towards A, unless room has been previously made for it. But if the time required for the replacement of each particle by the one next adjacent to it be infinitely small, the excess of reduction at A will also be infinitely small.

Now, according to the authorities I previously cited, water approaches so nearly to the condition of a "perfect fluid," that very small differences in its density will suffice (if constantly renewed) to maintain a vertical circulation, *without any appreciable difference in level*. And my position is, that the void created by the slow descent of water chilled by the surface-cold of the Polar area will be so speedily replaced by the inflow of water from the circumpolar area, and this again by inflow from the temperate region, as to produce a continual upper-flow of equatorial water towards the pole, without the gradient which Mr. Croll persistently asserts to be necessary.

I now leave it in the hands, not of Mr. Croll, but of competent authorities in Physics, to decide (1) whether his "crucial test" has the value he himself assigns to it, and (2) whether his doctrine of "gradients" can stand examination by the light now thrown upon it by Mr. Froude's researches. Until some physicist of equal weight with Sir George Airy and Sir William Thomson shall pronounce the doctrine I advocate to be untenable, I shall continue to believe, with Lenz, Arago, and Pouillet, that it is the only one which can account for the phenomena of Deep-sea temperature.

That the temperature of the upper stratum of the ocean is often affected by the Wind-circulation, and is especially thus modified in the North Atlantic, I have repeatedly pointed out. And it is scarcely fair in Mr. Croll, therefore, to continue speaking of the "wind-theory" and the "gravitation-theory" of Ocean Circulation as if they were antagonistic, instead of being not only compatible, but mutually complementary—the wind-circulation being *horizontal*, and the thermal circulation *vertical*.

As, however, Mr. Croll has now advanced so far as to admit that "physicists may differ from him in regard to whether or not the present difference of temperature between the ocean in equatorial and polar regions is sufficient to produce circulation," I am not without hope that in another year or two he may come to accept the Thermal-circulation as a "great fact;" and that he may then make good use of his knowledge and ability in elucidating the shares which are taken by the Wind-circulation and the Thermal-circulation respectively, in the distribution of terrestrial heat. WILLIAM B. CARPENTER

The Sliding Seat

MOST problems in animal mechanics are of so complicated a character as to be generally referred to direct experiment rather than to mathematical analysis.

In Mr. Wagstaffe's remarks (vol. xii. p. 369) on the analogy which exists between the movements at the sterno-clavicular articulation in rowing, and those permitted by the sliding seat, we have an argument in favour of the latter arrangement. But when the subject is regarded from the point of view assumed by a practical oarsman, the question of actual advantage still remains unanswered.

There are certain preliminaries which must be considered before we can commence to solve the problem, leading to its subdivision into several distinct problems, some of which will prove interesting to the anatomist, some to the mechanician, some to the physiologist. In the following remarks I shall attempt to indicate the preliminaries referred to.

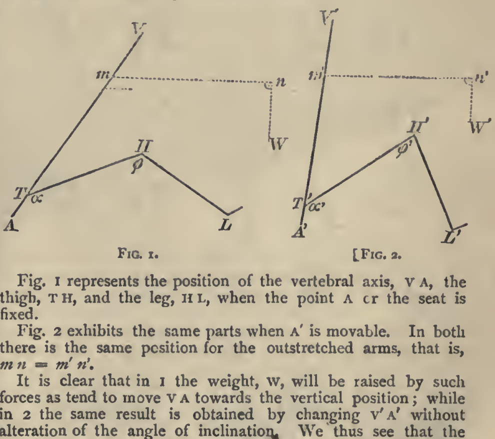

FIG. 1. [FIG. 2.

Fig. 1 represents the position of the vertebral axis, V A, the thigh, T H, and the leg, H L, when the point A or the seat is fixed.

Fig. 2 exhibits the same parts when A′ is movable. In both there is the same position for the outstretched arms, that is, $m\,n = m'\,n'$.

It is clear that in 1 the weight, W, will be raised by such forces as tend to move V A towards the vertical position; while in 2 the same result is obtained by changing V′A′ without alteration of the angle of inclination. We thus see that the angles α and ϕ will vary in definite inverse ratio, while the varia-

tion of ϕ' has almost entirely to be considered in 2. It is this which constitutes the chief difference between the sliding and the fixed seat, and which accounts for the sense of fatigue experienced in the legs in the former system.

If we examine the problems which arise from the consideration of Fig. 1 we shall find that in using the term "fixed seat" we are speaking incorrectly; that is to say, as far as there exists a force to hold A in position we have none but friction; and that practically the position of A with regard to L is determined by muscular action.

Thus in Fig. 2 the seat is really more fixed than in Fig. 1, or there is less muscular action round T′ than round T.

The advantages of the system 2 over 1 are however not simply mechanical, but the constancy of the angle α' affords greater space for the respiratory movements, and thus physiologically there is an explanation for the difference in disturbance of circulation and respiration generally experienced when comparing the two systems.

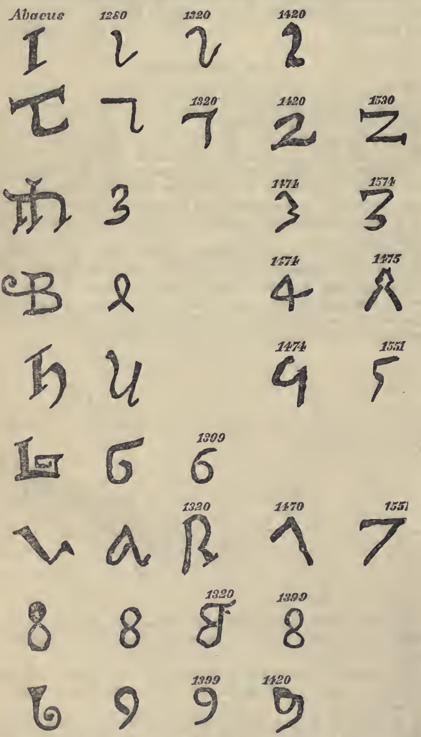
History of the Numerals

On reading the letter on the "Origin of the Numerals" (vol. xii. p. 476) I was reminded of some portions of their history which I had before noted down, and which are essential to any consideration of their origin.

The earliest forms which I have seen are those of the Abacus (Jour. Archæol. Assoc., vol. ii.), from which our later forms are mainly, if not entirely, derived. The intermediate forms are to be seen in arithmetical treatises and calendars of the thirteenth to sixteenth century, and on sundry quadrants, &c., of the fourteenth to sixteenth century, in the British Museum.

In the following table the earliest form of each letter and of



each variation is entered, with the corresponding date; the years 1280, 1320, 1420, and 1450 are only approximately stated.

Now, with respect to the primitive forms suggested by Mr. Donnisthorpe, the 2 would seem to have been two strokes at right angles (not parallel), the lower stroke of our form being only a *tail*, like that of many *medial* forms of Hebrew letters. The 3 may have been originally three vertical strokes, which were set horizontal in early times; the flat top, however, does not appear till 1574, and then only in English examples apparently. The 4 of the Abacus seems to have been deserted for cross lines connected, which are always placed diagonal till about 1474, when the first turn to the present position occurs: perhaps four strokes were intended, as we call cross-roads "four roads meet." 5 seems to have been inverted from the Abacus, and then about 1550 the straight tail was curved towards the previous figure, and the head elongated to lead to the next mark. It often occurs as a perfect though very straightened S in the sixteenth century, as it is now made in Belgium and other countries. Its form in 1280 reminds one of the Roman V written as U. 6 in the Abacus consists of six strokes; but this, from their cumbrous collocation, is probably merely a scribe's fancy. 7 has been apparently inverted (like 5) from the Abacus; its transitions are easily traced, but its origin is not so clear; some might see a trace in the Greek Z = 7. 8 has always been very near its present form, and the two squares is an explanation the character of which can only be objected to on the grounds of its inapplicability elsewhere. 9 has always had a straight tail, though it has been inverted since the Abacus form (as 5 and 7 seem changed): its origin might be looked for in the Greek θ possibly, as that letter has varied more in form than any other; or, more likely, in the Arabic Ta, or Tha (= 9), which in the Abacus it closely resembles; and it is even more similar to the Syriac Teth, a twin form to that of the Arabic. Perhaps the ancient Arabic alphabet (in its nearer approximation to its Hebrew- and Samaritan-like original) would show the origin of more of these forms, and even the simple 1 is exactly the Arabic *Elif* = 1, for their alphabetic origin is rendered highly probable from the fact that the numerical systems of the Greeks and of the Semitic nations (from whom our *Arabic* numerals probably came) were in very early times derived from the alphabet; not, like the Egyptian and Roman systems, wholly separate arrangements.

The apparent, though historically untrue, applicability of the line + line origin of all the forms of our numerals, is an interesting example of the fallibility of any theory which only looks to present conditions, apart from past facts and history.

Bromley, Kent W. M. Flinders Petrie

Scarcity of Birds

I quite agree with Mr. Barrington, who writes in Nature (vol. xii. p. 213) concerning the scarcity of birds. I find, by comparing my last year's ornithological diary with the present year's one, that I have only found about three-fourths of the number of Blackbirds' (*Turdus merula*), Thrushes' (*Turdus musicus*), Blue Titmouses' (*Parus cæruleus*), Pied Wagtails' (*Motacilla alba*), Greenfinches' (*Coccothraustes cloris*), Linnets' (*Linota cannabina*) nests that I found last year. The Hirundinidæ have been far less plentiful than usual; but the Goldfinch (*Carduelis elegans*) was the rarest bird here this summer. I did not succeed in finding a single nest, although our yearly average is fifteen. Other birds, as the Charadriidæ and the Mussel Thrush (*Turdus viscivorus*), have been very plentiful, and I found the Mountain Linnet's (*Linota montium*) nest for the first time I have ever met with it on the lowland south of the Humber. Will not the hard frost of last winter account for the scarcity of our native birds in some measure?

Adrian Peacock

Bottesford Manor, Brigg.

OUR ASTRONOMICAL COLUMN

μ Cassiopeæ and Vicinity.—Smyth (Cycle ii. p. 25) has the following remark with respect to stars near μ Cassiopeæ:—"Just 18′ south of μ is a star which, though of the 6th magnitude, is not in Piazzi. It is followed nearly on the parallel, about 11^s off, by a 9th magnitude, and both are remarkable from being red, of a decided but not deep tint." There is no star of the 6th magnitude near this position at the present time, nor so far as we know is there any record of such an object having been visible since the epoch of Smyth's observations, 1832·71.

It may, however, prove to be a variable star of long period, like the 8th magnitude orange-coloured star remarked by the same observer near Procyon in the autumn of 1833, the existence of which is supported by the observation of Mr. Isaac Fletcher, as described in Smyth's *Sidereal Chromatics* and elsewhere, and we believe by the experience of the Rev. T. W. Webb. There is now a star of the 9th magnitude, following μ Cassiopeæ, 17^s·2 and 15′ 38″ south; this is clearly Argelander's star + 53°, No. 228 of the "Durchmusterung," there estimated 9·5, a considerably fainter object than an average 9th magnitude in Bessel's scale; its place would appear to correspond better with that of Smyth's star following his 6th magnitude, nearly on the parallel, than with that of the missing one. Probably this small star may be variable also; its place for the beginning of the present year is R.A. 0h. 59m. 58·3s.; N.P.D., 35° 41′ 27″.

Smyth thought his 6th magnitude star, omitted by Piazzi, might have had "something to do with the mistakes of Flamsteed respecting μ, alluded to by Mr. Baily." These mistakes seem rather to have originated in the confusion of the stars θ and μ, and although Baily doubted if the place of the latter, which he gives from Halley's edition of 1712, could be depended upon, it will be found to agree very well with that of μ carried back from the position in the Greenwich Catalogue of 1860, with Mädler's proper motions.

Should any reader of this column have had the curiosity to look for Smyth's reddish stars, perhaps he will communicate the result of his examination of their neighbourhood.

THE DOUBLE STAR Σ 2120.—Mr. J. M. Wilson has favoured us with the following measures of this star, made at the Temple Observatory, Rugby, by himself and assistants :—

1872·48	Pos. 262°·9	Obs. 4	Dist. 3″·78	Obs. 2
73·50	,, 261°·7	,, 6	,, 3″·65	,, 2
74·62	,, 258°·5	,, 4	,, 4″·2	,, 2

Comparing these measures with the formulæ for rectilinear motion already given in NATURE, the following differences are shown :—

1872·48	Pos. $(c - o)$ − 0°·4	Dist. $(c - o)$ + 0″·65
73·50	,, − 0°·3	,, + 0″·91
74·62	,, + 1°·8	,, + 0″·51

Mr. Wilson has had a suspicion of variation in the magnitude of the companion, but thinks this may be owing to atmospheric circumstances.

THE MINOR PLANETS.—It is notified from Berlin, in M. Leverrier's *Bulletin International*, that the small planet detected by M. Perrotin at the Observatory of Toulouse, on the evening of Sept. 21, in R.A. 23h. 16m. 8s. and N.P.D. 95° 12′, is a new one, and will therefore be No. 149. The brighter members of this group now near opposition are Bellona, Clotho, and Thyra. Clotho will be between the 8th and 9th magnitude; the calculated places are, for Greenwich midnight, as follows :—

		h. m. s.		° ′
Oct. 23 ...	R.A.	3 34 47 ...	N.P.D.	90 36·0
,, 27 ...	,,	3 32 50 ...	,,	91 17·0
,, 31 ...	,,	3 30 30 ...	,,	91 55·8
Nov. 4 ...	,,	3 27 51 ...	,,	92 31·6
,, 8 ...	,,	3 25 0 ...	,,	93 3·4

TRANSIT OF COMET 1826 (V.) OVER THE SUN'S DISC.—It was remarked by Gambart that the comet discovered by Pons on the 22nd of October, 1826, the "comet in Bootes," as it was called at the time, must pass over the sun's disc on the morning of November 18, and he was at some pains in correcting the elements of the orbit, with the view of deciding whether the comet had left the disc, before it was examined by himself and Flaugergues, the only two observers who were at stations partially free from cloud on the morning of the transit. A letter from Gambart addressed to Sir John Herschel, at that time president of the Royal Astronomical Society, conveying an intimation of the expected phenomenon, arrived in London on the evening previous to the transit, and, as stated in vol. iii. of the Memoirs of the Society, "the news of so rare a phenomenon was immediately spread, and few astronomers in or near the metropolis failed to be prepared for it;" the sun, however, was totally obscured at rising, and for the whole day, by clouds and rain. A dense fog appears to have prevailed very generally over the continent of Europe, so that, as mentioned above, Gambart at Marseilles and Flaugergues at Viviers alone obtained a view of the disc during the interval in which it was expected the transit would take place.

The following particulars of the transit founded upon a new calculation from the corrected elements of Gambart, closely representing the observations between Oct. 26 and Dec. 11, may possess interest for the astronomical reader.

The comet's true geocentric positions, for Greenwich mean time, were :—

		R.A.	N.P.D.
		° ′ ″	° ′ ″
Nov. 17.	17h. ...	233 7 5 ...	108 51 48
,,	19h. ...	233 7 52 ...	109 11 50
,,	21h. ...	233 8 38 ...	109 31 26

Whence, correcting for aberration and taking the sun's places from Carlini's tables, the following differences of R.A. and N.P.D. of comet and sun's centre result :—

	h.		′ ″		′ ″
Nov. 17..	17	Diff. R.A.	+ 5 31	Diff. N.P.D.	− 16 48
,,	18	,,	+ 3 19	,,	− 7 19
,,	19	,,	+ 1 7	,,	+ 2 2
,,	20	,,	− 1 6	,,	+ 11 17
,,	21	,,	− 3 19	,,	+ 20 26

And as referred to the centre of the earth, we find :—

		h. m.	
Ingress	Nov. 17 at	16 59·9	at 19° from sun's N. point towards E.
Egress	,,	20 22·5	at 184° ,, ,, ,,

At Marseilles, the egress would take place at 20h. 59m. apparent time, the equation of time being 14m. 43s. additive to mean time.

As is well known, neither Gambart nor Flaugergues were successful in detecting this comet upon the sun's disc, but though visible at one time to the naked eye, it was not of any considerable degree of brightness.

FAYE ON THE LAWS OF STORMS*

Mechanical Theory of Whirling Movements.—Before we enter on the mechanics of these phenomena, it is necessary to clear the way by the removal of certain ideas which constantly recur to the mind of the reader, and by distracting his attention render any clear unbiassed perception of the subject altogether impossible. This preliminary discussion will embrace the three following points: the part played by electricity in the formation of whirlwinds and cyclones, the significance to be attached to the indications of the barometer, and the part played by currents of aspiration in the modern theory of the trade winds.

1. Part played by Electricity.—Certain physicists, dissatisfied with the views we are about to refute, and struck with the electrical phenomena which so often accompany hurricanes, typhoons, &c., have supposed that electricity is the determining cause. We shall perhaps give a clear idea of this theory by reverting to the electrical explanation of hail, the phenomena of hail being intimately bound up with that of whirling movements. It is well known that hailstones are composed of layers of ice alternately opaque and transparent; in breaking them we see in their texture the evidence of successive and alternate

* Continued from p. 501.

actions to which they have been subjected. Hence, it is argued, they must have been suspended in the air by some force to allow time for these alternate actions to take effect. Is the force in question not that of electricity? Let us suppose two clouds, superimposed the one above the other, to be charged with opposite electricities; if the crystals of ice which are often to be met with in the upper regions of the atmosphere happen to be in the interval between the two clouds, they will be attracted by the nearest, and thereafter repelled as soon as they have received by contact the electricity with which it is charged. Instantly being attracted by the other cloud, they rush towards it and are immediately charged with the opposite electricity; and this alternate play, during which the hailstones receive successive accretions from the vapour abstracted from the clouds and congealed by the cold of the original hailstone or of the space intervening, will go on till the hailstones acquire a weight too great for them to be any longer suspended, or till an electric discharge has destroyed the opposite electricities which have accumulated on the surfaces of the clouds. At this instant the hailstones fall to the ground by the simple effect of their own weight.

To the same cause the formation of waterspouts has been attributed. Let us suppose a low cloud highly charged with electricity and producing by induction on the water of the sea a powerful accumulation of statical electricity of the opposite sign on its surface. The mutual attraction of these two electricities, the cloud on the one hand, the sea on the other, while powerless to produce contact, will nevertheless give rise to two opposing protuberances in the oppositely electrified bodies. At that point the electricities will acquire a tension the greater as the protuberances continue to assume forms more elongated. As the attractive action goes on increasing, these two protuberances will gradually approach each other between the sky and the earth, and will ultimately unite, the protuberance descending from the sky passing over a greater space than the other. Then, by the conductor thus quickly formed of water and an elongated fragment of cloud, the electricity of the upper regions will escape into the ground, exerting a destructive action over all obstacles in its way. It is also to be noted that the instant when the waterspout is thus completed, thunder ceases to roll in the clouds, the reason being that the electricity has found a silent mode of escape. M. Peltier, the accomplished physicist to whom science is indebted for many ingenious researches on atmospheric electricity, endeavoured to reproduce in miniature the phenomenon thus described; but in bringing a highly electrified conductor close to the surface of a sheet of water, he was unable to show any other sensible mechanical effect than a more rapid evaporation.

We shall not, however, insist on the electrical theory of waterspouts. The theory is now rejected, equally with the electrical theory of hail, because if a few waterspouts have exhibited traces of an electrical action, the greater part of the observed facts show nothing of it. Waterspouts and typhoons are mechanical phenomena, in which electricity plays not the principal part, but a part altogether subordinate. There was a time when the tendency was to explain everything in meteorology by electricity. Whenever any question became obscure, electricity was resorted to as a convenient explanation, and any difficult point was considered as cleared up by an adroit appeal to some laboratory experiment—such as the explanation of the theory of hail from the dance executed by pith-balls between two brass plates. It came, however, to be recognised that, in seeking to identify meteorological phenomena with laboratory experiments, the risk was run of losing sight of the real circumstances of nature and putting in their stead those of the laboratory. The clouds of Volta are real plates of brass, and the spark of the induced conductors, as they are brought near each other, always forgets to manifest itself when the two fragments of waterspouts unite together.

2. Barometer.—The question of the barometer is more difficult. The diminution of pressure which precedes and accompanies cyclones has always been considered as a proof of aspiration. It is certain that the continual lowering of the barometric column—a lowering the maximum of which occurs in the very centre of the hurricane—is a phenomenon so constant as to serve as an infallible warning to sailors. In certain seas and at certain times of the year, the sailor ought to keep his eye on the barometer as much as the compass. But what is the significance of this diminution of pressure? Does it prove that the air over our heads is rarefied? If a vertical column of air was rarefied, the equilibrium would be re-established not at its lower part only, that is to say at the expense of the lower stratum; to effect this, a solid envelope would be necessary to isolate the column through its entire length, leaving only a free opening at its base. But the column, on the contrary, being everywhere in communication with the atmosphere, the equilibrium would be quickly restored by a simultaneous afflux of the strata at all heights, and not merely by the afflux of the lower stratum alone. This, however, is not how things take place. The diminution of the barometer does not indicate a vacuum in the upper regions, but is the result of a movement. Involuntarily, when we speak of the barometer, we always regard pressure in the statical condition, as if the atmosphere was constantly in equilibrium, whilst in reality it is in continual motion. If there was reason to believe that the different layers of air do not mix in crossing each other, it could not be denied that the aqueous vapour in its continual ascent from the ground and the sea does not traverse the successive strata on its way to the more elevated regions of the atmosphere, to be there condensed into minute crystals of ice. And when under the action of other causes, the whole strata of the atmosphere flow almost horizontally, like vast rivers, between strata absolutely immoveable, producing everywhere condensation of vapour and heavy rains, it is doubtful if even the statical principle of the equality of pressure could in every sense be employed; the barometric pressure and its variations ought no longer to be interpreted from the statical point of view only, especially if it arises from gyratory movements on a vast scale. There is here a question belonging to the dynamics of fluids which mathematicians have not yet explained; but in the meantime we ought not to forget the essential distinction between dynamical and statical pressure so as to suppose that every rapid fall of the barometer indicates a sudden rarefaction of air overhead, and consequently aspiration from above downwards.

3. Trade Winds.—The question of the trade winds is connected with the preceding subject. If the air be considered only by itself, it will arrange itself in a state of equilibrium, in homogeneous layers of varying densities, which decrease with the height. These layers will be bounded by ideal level surfaces enveloping the globe, and which may here be regarded as spheres. If the action of the sun, whose heat-rays are specially absorbed by the lowest strata and by the aqueous vapour, is felt more energetically over the torrid zone than in higher latitudes, the inferior strata will expand, and pressing upwards will raise the upper strata to a higher level. The equilibrium being thus disturbed, it will tend to re-establish itself by a general flow towards the coldest regions after the manner of ocean currents, or like immense rivers which have for their beds level surfaces, of which we are about to speak.

On the other hand, the temperate and cold zones receiving this overplus of air, their lower strata taking a movement inverse to the above, set in towards the large space of the equatorial regions where the density of the air is less; and leaving out of view the effects of the

earth's rotation, which diverts these currents from the direction of the meridians, we have there the true cause of the trade winds of the high regions, of which the lower trade winds are only the counterpart and the result. The lower trade winds are ordinarily attributed to an equatorial rarefaction and to the indraught which results from it. On this account, the indraught being direct and ceasing with the day, the lower trade winds ought to show, just as sea and land breezes, an alternation from day to night, of which there exists no trace. In considering the trade winds, on the contrary, as the indirect result of the draining effected in the region of the upper strata, we see that the intermediate mass plays the part of the air receiver of a hydraulic machine, which, by annihilating differences of velocity, produces a steady flow, but which placed under the direct action of the motive power would have been intermittent.

The theory of indraught or aspiration represents, on the contrary, vast regular currents of the atmosphere as shown by Fig. 12. We here see at the equator a sort of

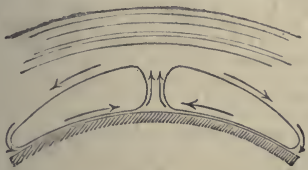


FIG. 12.

chimney towards which the air is drawn, and up which it ascends, and thereafter takes a course to north and to south. The proof that matters do not take place altogether in this way, and that the expansion of the air on all sides in the zone most highly heated by the sun does not there upset the order and the statical superposition of the strata, is astronomical refraction, whose laws are the same at the equator as in temperate regions; there is in addition the perfect regularity and the smallness of the barometric oscillations—conditions little compatible with those of a colossal updraught, or even with the behaviour of the trade winds, which no one has ever seen at the confines of the zone of calms begin to assume a vertical direction.

If we have at length succeeded in dispelling the idea of vertical aspiration from which has been deduced the direct cause of all aërial currents and all tempests, and the idea of electricity considered as the chief agent in the mechanics of the atmosphere, and lastly the confounding, so frequently, of statical pressure in a fluid mass in repose with dynamical pressure in a medium traversed throughout by movements the most capricious, we shall have no difficulty in accepting the following considerations, for the subject being in this way simplified, the result is a simple question of pure mechanics.

Vortices or Eddies with their Axes vertical to the Current of Water.—If the question exclusively concerned pure mechanics or mathematics, we should be stopped at the very threshold of the inquiry, because mechanics does not yet embrace the study of gyratory movements in liquids or fluids. We have not up to the present moment succeeded in submitting to analysis exact problems of hydrodynamics, unless in very special cases in which we may consider fluids as composed of elements of volume containing always the same molecules, of such sort that their masses are invariable and that the molecules situated at the surface or on any of the sides will always remain at the surface or at the same side. Besides, the trajectories of the liquid filaments ought never to present those re-entering or spiral-like curves which we, however, so frequently remark. If we set out with these restrictive hypotheses, the question cannot be attacked by analysis. In other words, we are forced absolutely to exclude all that relates to the movements with which we are now dealing.

But where analysis is still powerless, experiment and observation remain for our guidance. Whirling movements make their appearance not only in gases; they are equally found in liquids, where they are more manageable, since they can be followed by the eye and even produced at pleasure. We shall therefore commence with the movements which are observed in liquids after we have drawn a vital distinction between the different whirling movements with which we are dealing. Air and water present in fact very complicated gyrations, some ebullient transitory, and without any stability of figure, others perfectly regular and persistent. They are distinguished by a very simple geometrical figure: the second class have their axis always vertical; the others turn round axes diversely inclined. A moment's reflection will enable us to account for the difference. In the case of a horizontal gyration the spires keep clear of the surrounding layers past which they whirl, or only very slightly graze them in their course. In the first case all motion of the layers disappears; that of the surface even no more exists; because at the surface of separation between the water and the air the eddying spires issue from the liquid mass and cut through or carry away to the interior the air placed above so as to produce the phenomena of spray, froth, foam, and emulsion.

Let us then confine ourselves to whirling movements round a vertical axis, which the student of hydraulics knows and observes, and which can be reproduced at will and studied experimentally. These are, in truth, regular persistent movements which obey laws very simple and precise. The general law which embraces all these phenomena is as follows:—When there exists in a current of water differences of velocity between the filaments in lateral juxtaposition, there tends to be generated, by reason of these inequalities, a regular gyratory movement round a vertical axis. The spires described by the molecules are sensibly circular, with their centres about the axis. These are, speaking more exactly, the spires of a helix, slightly conical and descending, so that in following a molecule in its movements it is seen to turn rapidly in a circle round the axis, which it imperceptibly approaches, descending with a velocity very much less than the linear velocity of rotation. Evidently the centrifugal force which results from this gyratory movement must be everywhere counterbalanced by the pressure of the surrounding liquid; there is then inside these eddying spires, at least at their upper orifice, a slight lowering of the pressure which discloses itself at the surface of the liquid by a feeble conical depression centered about the axis of rotation.

The two following characteristic properties are demonstrated by analysis:—(1) The entire whirl may be regarded as separated from the surrounding fluid, which remains immoveable, by a surface of revolution whose meridian curve has its concavity turned downwards. In other words, the exterior figure of the whirling mass is in the form of an inverted cone pointing downwards. (2) The angular velocity of a molecule increases in proportion as it approaches the axis; it is inversely proportional to the square of its distance from the vertical axis. Hence the linear velocity increases in simple inverse proportion to its distance from the axis. If we consider how great the breadth of the whirling cone in the current of the water occasionally is, relatively to the size of the lower orifice, we shall understand how a gyration which appears sluggish at the surface and at the circumference becomes violent at the base of the funnel-shaped eddy.

These two laws, it must be here observed, are applicable not only to liquids but also to gases. They are easily verified by the experiment of throwing a little dust into water in which an eddy has been formed, when the

funnel-shaped figure and circulatory movement of the entire mass and the increase of velocity towards the centre will be at once seen.

The descending movement of these whirls may be examined by the preceding analysis, but observation has long since placed the matter beyond doubt. Everyone knows how much eddies in the current of a river are dreaded by bathers; when a swimmer has the misfortune to be caught in one he is drawn down by a rapid rotation even to the bottom of the water. There, the expert swimmer, knowing how to reserve his strength in place of expending it in useless efforts, extricates himself by resting on the bottom, and, disengaging himself from the eddy, rises quickly to the surface. Not only may men be thus engulphed, but masses of floating ice, or even small vessels, are drawn to the bottom by whirlpools, and thereafter are extricated and rise to the surface only by the obstacle afforded by the bottom, and by the contraction downwards, more and more marked, of the whirling mass of water.

These phenomena can be artificially produced in a large mass of still water, at a part where a rapid movement of gyration is communicated by a suitable mechanical appliance.* If we strew dust on the surface, in order to render the phenomena visible, it is seen that gyration is propagated in the form of a cone from above downwards, even to the bottom of the vessel, drawing the dust along with it. Count Xavier de Maistre, who has published in the *Bibliothèque Universelle de Genève* some interesting experiments on this subject, has shown that a layer of oil placed over the water of the funnel-shaped eddy is drawn towards the bottom by a gyratory movement; then, when it comes in contact with the obstacle presented by the base, the oil reascends in globules all round the eddy which it has quitted. There is thus here a double vertical movement—the first regularly descending along the spires of a conical helix, the second ascending and exhibiting in its ascent no geometrical figure, but rising to the surface irregularly *round about* the eddy. It is natural that the liquid thus drawn to the bottom should thereafter ascend more or less, not, be it noted, in the eddy down which it had been carried, but outside it, through the surrounding liquid.

This gyratory movement, which thus concentrates towards the point of the eddy the sum of the moving forces which the funnel-shaped whirl embraces in its vast expanse, ought to produce at its base a certain amount of mechanical work, and observation confirms this idea. The powerful whirlpools of our rivers plough up their beds and thus expend on the soil the force which they have acquired near the surface at the expense of the inequalities of velocity of the general current. And as all currents of water possessing some little depth present like inequalities of velocity among their lateral filaments, on account of the friction of the water against the banks, numerous whirlpools are constantly found whose action consists in finally absorbing these inequalities and regulating the flow of the water, so that the general velocity of the river is perceptibly reduced.

Vortices or Eddies with Vertical Axes in Gases.—All these phenomena are found in gaseous masses traversed by horizontal currents. In currents of this sort, inequalities of velocity will equally give rise to whirling movements round a vertical axis, and, as may be constantly observed, these gyrations will still assume the figure of a truncated cone in an inverted position, which becomes visible when any circumstance occurs to interfere with the transparency of the air. Equally as in the case of water, the gyration of a molecule will be the more rapid the nearer it approaches the centre. The analysis which confirms, or rather explains these phenomena is as applicable to gases as to liquids. Need it be said that waterspouts, from their appearance alone, range themselves in this category? The mechanical identity of whirls formed whether in liquids or in gases is found in all the details—such as the descending movement of waterspouts whose point is seen gradually approaching the earth, and in the abrading force which whirlwinds thus exert on the ground in breaking and beating down objects which obstruct their course—acting thus like a plate fixed perpendicularly at the end of a vertical axis whirling rapidly round. This action evidently ceases when the lower orifice of the waterspout rises a little; it recommences with energy each time that the whirling cone is lowered so as to be brought into contact with any opposing object.

We have only further to prove another characteristic of eddies in a stream of water not less general, in order to complete the study of the analogous phenomena in fluids. At the instant when there is formed in a moving mass of water one of these gyrations which are solely due to inequalities in the general current, it is evident that the eddy thus formed and isolated by an invisible sheath, so to speak, will follow the mean velocity of the current, because nothing can bear away the chief part of the velocity to the molecules which compose the eddy. We shall see it follow the line of the stream, preserving its axis in a vertical position and continuing a longer or a shorter time, or until resistances of every sort have exhausted its force. It will follow the same line of the stream as that taken by a floating object without losing its circular form, and without ceasing to act on the bottom, if it extend so far down, as long as its store of energy is inexhausted.

A distinction must be made between these travelling eddies and the great eddies in deep still water which are ceaselessly formed and re-formed at a post fixed at the turning of narrows of a river. When in such places the current makes itself felt it incessantly bears away with it the spires thus formed; the phenomenon is unceasingly renewed, giving rise to those stationary eddies in rivers which have no analogy to those of the atmosphere, and which appeared to play an important part in deepening the beds of rivers.

(*To be continued.*)

* These experiments must not be confounded with the experiment of water poured into a vessel to which a movement of rotation round a vertical axis has been communicated. In this case the free surface becomes hollow whilst the water rises along the sides of the vessel. A condition of equilibrium is soon established totally different from the dynamical phenomena we are here discussing. Thus the central depression is parabolical and not conical, and the angular velocity of the fluid molecules is constant, whereas it varies in the movements of eddies in the inverse proportion of he distance from the axis of rotation.

THE LARGE REFLECTOR OF THE PARIS OBSERVATORY

M. WALLON, the French Minister of Public Instruction, presided on the 7th inst. at the sitting of the Council of the Observatory, and at the end of the *séance* he made an official inspection of the large refractor. On the 9th the representatives of many of the Parisian papers were present at the Observatory by invitation of M. Leverrier; the weather, unfortunately, was very tempestuous.

The telescope was left under its iron house, but every detail was carefully explained by M. Leverrier, assisted by M. Wolff, the chief astronomer for physical observations. M. Leverrier praised very highly the skill displayed by the constructors, MM. Eichens and Martin.

The weight of the moveable part is nine tons; the mirror is 120 centimetres in diameter, with a focal distance of 6·80 metres. The weight of the mirror is only half a ton, instead of four tons, which would be necessary for a metallic one; its cost amounts to 2,000*l*.

The telescope is suspended like a refractor in an ordinary equatorial. The ocular is placed in front.

On the 8th minute stars were observed by M. Wolff with a magnifying power of 500, which has been found to answer excellently. An ocular multiplying 1,200 times, and perhaps another, 2,400, will be constructed. A micrometer is being made.

The seeker is in front, and can be rotated with the

ocular and the small plane mirror round the axis of the tube by a very simple process. The reason of this arrangement is to facilitate the use of the large iron winding staircase. This enormous metallic structure is moved by special machinery on two circular iron rails. It is always placed on the same side of the tube as the counterpoise, which would render observations impossible if the ocular and seeker were not rotated round the axis of the tube. The height of the iron staircase is about twelve metres, and its weight six tons. The observations are made in open air, and when the weather is propitious the cabin protecting the apparatus is removed by machinery. It is an iron casement (weight twelve tons), moveable on rails. In less than a quarter of an hour the telescope can be directed on any object, however minute.

The clock is finished, but not adjusted. The machinery for moving in right ascension is finished and works admirably. The handle and screws for minute motions in declination are finished and working most nicely. So does the gear for connecting and disconnecting the tube with the clock.

The cost of the reflector is 8,000*l.* It was built in six years, but the work was interrupted several times, first by the dismissal of M. Leverrier, secondly by the war and the Commune.

M. Leverrier is justly proud of having completed the large refractor, to which a very few details only are wanting—the adjustment of the clock, the handles for slight equatorial motions, and the machinery for large declination motions. He asked M. Wallon to give orders for the construction of the large refractor, and it was granted at once. A sum of 8,000*l.* has been already voted by the National Assembly for that purpose. It will be seventeen metres in length, and the construction will be completed in three years, if the work is not interrupted by any political or other commotion.

LIEUT. WEYPRECHT ON ARCTIC EXPLORATION

We have already (vol. xii. p. 460) referred to Lieut. Weyprecht's paper on the Principles of Arctic Exploration, read at the German Scientific and Medical Association. A full report of the paper has now come to hand. Lieut. Weyprecht rightly maintains that the polar regions offer, in certain important respects, greater advantages than any other part of the globe for the observations of natural phenomena—magnetism, the aurora, meteorology, geology, zoology, and botany. He shows that hitherto immense sums have been spent and much hardship suffered for the mere purpose of extending geographical and topographical knowledge, while strictly scientific observations were regarded as holding only a secondary place. While admitting the importance of geographical discovery, he maintains that the main purpose of future Arctic expeditions should be the extension of our knowledge of the various natural phenomena which may be studied with so great advantage in these regions.

After showing in some detail the kind of observations which would yield valuable results, Lieut. Weyprecht lays down the following general propositions:—1. Arctic exploration is of the highest importance to a knowledge of the laws of nature. 2. Geographical discovery in these regions is of superior importance only in so far as it extends the field for scientific investigation in its strict sense. 3. Minute Arctic topography is of secondary importance. 4. The geographical pole has for science no greater significance than any other point in high latitude. 5. Observation-stations are to be selected without reference to the latitude, on account of the advantages they offer for the investigation of the phenomena to be studied. 6. Interrupted series of observations have only a relative value.

Suppose that stations were established at Novaya Zemlya, 76°; Spitzbergen, 80°; West or East Greenland, 76°-80°; N. America east of Behring Strait, 70°; Siberia at the mouth of the Lena, 70°, there would thus be a girdle of observatories around the entire Arctic region. A station in the neighbourhood of the centre of magnetic intensity is much to be desired. By means of the stations already existing in the neighbourhood of the polar circle, a connection would be established with our own region. The cost of one geographical exploring expedition would supply the means of keeping up these stations for a year. The object of these expeditions would be, with similar instruments and according to similar instructions, to record simultaneous observations as far as possible throughout a year. In the first line would be placed the various branches of Physics and Meteorology, as also Botany, Zoology, and Geology; and first in the second line, detailed geographical exploration. Were it possible to establish stations for simultaneous observation in the Antarctic regions, results of much higher value might be expected. Were the cost of these yearly expeditions divided among various countries, it would fall very lightly upon each.

While we think the curiosity of a healthy kind which seeks to know the configuration of the entire surface of our globe, we are sure every man of science will admit the value of Lieut. Weyprecht's propositions. There has, without doubt, been hitherto too much weight attached to merely reaching a high latitude, and too little provision made for strictly scientific observation. Lieut. Weyprecht's suggestions deserve the serious consideration of all civilised countries; were they adopted as a ground for action, a new era in polar exploration would be begun, and results of far higher value than any hitherto obtained might with certainty be expected.

NOTES

It is rather disappointing that Capt. Young's Arctic Expedition in the *Pandora*, which arrived at Portsmouth on Saturday, should have returned home prematurely without accomplishing any part of the work for which it was organised—the discovery of additional Franklin relics and the complete navigation of the North-west Passage. Under the circumstances, however, Capt. Young has adopted the wisest possible course. Better that the expedition should spend a comfortable winter at home, and set out early next year to renew the attempt in which they have just been baffled. Disco was reached on August 7, Upernivik on the 13th, and Cape York on the 16th, after a splendid passage through the much-dreaded Melville Bay. Carey Islands were visited to deposit letters for the *Alert* and *Discovery* and to obtain a despatch from Capt. Nares, as previously agreed on. The despatch, however, was not discovered till the return voyage. From Carey Islands the *Pandora* proceeded up Lancaster Sound to Beechey Island, which was reached on the 26th. Here Capt. Young inspected "Northumberland House," which was built as a storehouse by the *North Star* (Capt. Saunders) in 1850. It was found that the house had been broken into by bears, and many of the stores damaged, but those in casks and barrels had sustained scarcely any injury. The yacht *Mary* and two lifeboats left by Sir John Ross were in such good condition that, with a few repairs, they could still be made seaworthy. After putting the stores in order, Capt. Young proceeded up Peel Strait for the purpose of reaching King William Land. After considerable manœuvring with the ice, and some difficulties arising from the uselessness of the compasses so near the magnetic pole, La Roquette Island, near Bellot Strait, was reached on August 30. The ground thus far gone over was pretty well known from the explorations of previous expeditions, and Capt. Young was close to his former encampments when travelling from the *Fox* in 1859. But now an impenetrable pack of ice across the channel barred all further progress, and after vainly trying to find a

passage, Capt. Young prudently determined to retreat, which he did on Sept. 3. Carey Islands were reached on Sept. 11, and Capt. Nares' record discovered. The *Pandora* arrived at Disco on the 20th, passed Cape Farewell on Oct. 2, and, as we have said, reached Portsmouth on Saturday. Both on the outward and return voyage very rough weather was encountered, although after leaving Disco until Bellot Strait was reached, the weather was on the whole very favourable. The following is Capt. Nares' record referred to :—"H.M.S. *Alert*, at Carey Islands, 3 A.M., 27th July, 1875.—*Alert* and *Discovery* arrived here at midnight, and will leave at 6 A.M. for Smith's Sound, after depositing a depot of provisions and a boat. We left Upernivik on the evening of the 22nd inst., and Brown Islands on the evening of the 23rd. Passing through the middle ice during a calm, we arrived at Cape York on the 25th inst. The season is a very open one, and we have every prospect of attaining a high latitude. All are well on board each ship." Thus the latest news from our Arctic Expedition is entirely favourable.

Two long letters from Mr. Stanley, the leader of the *Daily Telegraph* and *New York Herald* African Expedition, appear in the *Telegraph* of Friday and Monday last. As might be expected, they are full of interest, and contain many geographical details, too summarily stated, however, to be condensed intelligibly, or appreciated without a special map. Such a map Mr. Stanley seems to have sent home, and we hope it will be published as soon as practicable. Both letters are written from the "village of Kagehyi, district of Uchambi, country of Usukuma, on the Victoria Niyanza" (so he spells the name), dated March 1 and May 15 respectively. An intervening letter has not come to hand. The lake was reached after a march of 720 miles from the coast, in 103 days. That the expedition has had to encounter more than the usual difficulties and hardships of African exploration may be inferred from the fact that Stanley has lost considerably more than half his men, including two of his white companions, Frederick Barker and Edward Pocock. Disease carried off the greater number, though many were lost in a fierce fight with the Waturu, a people of the Leewumbu Valley. The principal additions to our knowledge made so far by the determined leader of the expedition is a pretty full account of the country and the people from Western Ugogo northwards to Nyanza, and a survey of over 1,000 miles of the shores of the lake, which apparently is studded with islands. The Shemeeyu River, known by other names in the upper part of its course, which Stanley seems mainly to have followed, and which he regards as the chief tributary of the Nyanza, enters the lake at the village of Kagehyi. Stanley calculates its length roughly at 350 miles. At 400 miles from the coast he came upon the base of the watershed of a number of streams which feed the river, and which he evidently regards as at least one of the Nile sources. According to Stanley's observations, and they seem to have been carefully made, as computed by Capt. George, the height of the Nyanza above sea-level is 3,740 feet—68 feet higher than Speke made it out to be. He has made some other corrections on Speke's observations, especially in the matter of latitude. Speke he makes out to be fourteen miles wrong in his latitude along the whole of the coast of Uganda. The mouth of the Katonga, for example, which in his map is a little south of the equator, Stanley makes by meridian altitude to be in N. lat. 0° 16′. We sincerely hope the indomitable leader of this expedition will be able successfully to accomplish the large task he has set before him—the exploration of the whole of the lake region of Central Africa.

PROF. FAWCETT's address at the opening of the winter session of the Birmingham and Midland Institute on Monday was, as might be expected, instructive and impressive. The tone of it was mainly that of our article last week on the Yorkshire College of Science, that the object of education should be to develop an intelligence which will be cultured all round, and which may be applied to any work in life. Prof. Fawcett spoke mainly of elementary education and of the education which the working classes may obtain in such an institution as the Birmingham and Midland. He advocated the study of botany and political economy from a disciplinary and practical point of view, and very properly discouraged the notion that a good education ought necessarily to make anyone discontented with his position; it would simply dignify labour of all kinds, and make the life of the artisan brighter and nobler. A somewhat similar tone as to what middle-class education should be, and what a college or middle-class school should be, pervaded the address of the Dean of Durham at the opening of the fifth session of the Newcastle College of Science. In an efficient curriculum science will find its proper place, withal a place of the highest importance.

THE Organising Committee for the International Exhibition of Electricity has held its first general meeting at the Palais de l'Industrie, Paris, under the presidency of Colonel Laussedat, one of the delegates appointed by the French Minister of War. The committee approved the regulations proposed by Count Halley d'Arroz, the originator of the scheme, appointed him general director, and divided the exhibition into eighteen groups. Amongst these are the History of Electricity, a section in which will be collected, as far as possible, the instruments which were used by Davy, Faraday, Volta, Arago, Ohm, Oerstedt, Ampère, and others, in making their discoveries. The eighteenth group will be Bibliographical; a library as complete as possible will be formed of all the books and papers published in the Transactions of the several Academies, and scientific periodicals relating to electricity. A requisition will be sent to the administration of the National Library, asking them to offer, for 1877, their Systematic Catalogue of Electricity. The President of the French Republic will be the head of the Committee of Patronage, and a sub-committee has received instructions to open negotiations with foreign *savants* and Governments.

THE catalogues of the various departments under the Science and Art Department at South Kensington have long been noted both for the extent and accuracy of the information contained in them, as well as for the low price at which they may be obtained. It is with pleasure we note that the catalogues of the contents of the Bethnal Green branch are not behind those of the mother institution in point of detail and careful working out. That relating to the special collection of waste products brought together by Mr. P. L. Simmonds is before us, and we recommend all those who are interested in the subject to obtain this little book, which costs only threepence and contains a fund of information on various matters connected with products of the vegetable, animal, and mineral kingdoms. The usual sequence of the three kingdoms of nature is somewhat altered here, the vegetable products being placed first, and for this reason, that "vegetable products have given more extensive and profitable employment and results, in the utilisation of formerly wasted substances and the recovery of residues from manufactures, than either animal or mineral substances." Nothing is too small or unimportant to rescue from simple destruction if it can be turned in any way to serve the purpose of man. As an illustration we may mention the fact of the application as fire-lighters of the central portion of the ear of the Indian corn after the seeds have been taken out; also of the cones of the Scotch Fir (*Pinus sylvestris*), which are sold in France under the name of *Allumettes des Landes*. These are novel applications of what would otherwise be pure waste substances; but there are others which, though waste from one manufacture, are used to adulterate others. From vegetable marrow, melon, and other cucurbitaceous seeds, many of the so-called sugared almonds of the confectioners are made. In China, the seeds of the water-melon are very largely

used as food; they are carried from place to place in junks laden entirely with them; they contain a quantity of oil of a sweet or bland nature. In the manufacture of olive oil, much more economy is exercised than was formerly the case. In the olive-growing countries the pulpy portion of the fruit, which was formerly thrown away after being pressed, is now bought up at the rate of from thirteen to sixteen shillings per ton, and submitted to chemical action and powerful steam pressure, by which means about twenty per cent. more oil is obtained. This oil is of course of an inferior quality to that obtained from the first expression. After this remaining oil is extracted, the seeds, which are crushed in the process, are finally burnt as fuel or used as manure. The foregoing notes will show the kind of matter dealt with in the Official Catalogue of Waste products.

FROM the Report, dated June 1875, of Mr. George King, Superintendent of the Calcutta Botanical Gardens, we see that during the past year many important improvements have been effected in the Gardens. Among other things a fine raised terrace has been constructed, on which a large new plant-house is now being erected. This noble conservatory, when finished, will, it is expected, be the greatest addition to the Garden which has been made for years, and will give facilities for the cultivation of delicate plants hitherto unknown in Calcutta. This building is 200 feet in length by 66 feet broad. The collections in the two orchid houses and in the other conservatories have been much increased during the year, considerable additions having been received from Sikkim, the Khasi Hills, the Andamans, and Burmah, also a few plants from the Neilgherries. A number of plants were also sent to the Garden by Mr. Lister, the second gardener, who accompanied the Duffla field-force as a botanical collector. "But," Mr. King justly remarks, in reference to this, "when the floral wealth of Assam, of Eastern Bengal, and of Burmah is considered, not to mention the west and south of India, the collection in this Garden appears miserably small. In an imperial institution such as this, the natural productions of the whole Indian empire should, as far as the climate will permit, be represented. I see no way of forming such a typical collection until a good trained European collector be attached permanently to the establishment. At present I have to rely for supplies of plants from distant parts of India on correspondence with private parties, who, although usually very willing to help, are unfortunately often unskilled in botany or gardening, and neither know what plants to send nor how to pack them safely for transit. The only experts, not employed in the Garden, whose services I can command for collecting, are the manager of the Cinchona plantation and his assistants, and their efforts are of course confined to Sikkim. Had I a collector as one of the regular garden staff, I could send him about to distant districts of which the flora is little known or poorly represented in the Garden, and the result would be that in a few years a very fine collection might be got together both of living plants in cultivation and of dried specimens in the Herbarium. Another great advantage would be that this Garden would be put in a position such as it has not hitherto occupied for exchanging plants with similar institutions all over the world. The cost of maintaining such a collector would not be great, and the extremely liberal manner in which the Gardens have been supported by Government during the past year leads me to hope that this desideratum will soon be supplied."

THERE is being printed for the National Library of Paris two volumes of catalogues of French History. The series will be completed in fourteen volumes. There are also being printed two new volumes of the catalogue of Medicine, containing all the thèses supported before the several French schools for a number of years. These two volumes will make the catalogue of Medicine complete in four volumes.

WE learn from the *Journal of Botany* that Prof. Kerner, o Innsbrück—to whose valuable contributions to botanical literature we have frequently called attention, especially relating to the distribution of plants as affected by climatal and geological conditions—will shortly succeed the venerable Fenzl as Professor of Botany at the University of Vienna.

A PAPER by Dr. T. Spencer Cobbold has been reprinted from the *Veterinarian* of this month, on the destruction of elephants by parasites, with remarks on two new species of entozoa, and on the so-called earth-eating habits of elephants and horses in India.

MR. SCLATER has issued an appendix to his "Revised List of the Vertebrated Animals in the Zoological Gardens," containing the names of the additions since the year 1871, among the most important of which are the superb series of Rhinoceroses, five species in all; the Chinese Water Deer of Swinhoe; the Mourning Kangaroo; the Red Oven-bird; Bouquet's Amazon, and three fresh species of Cassowary.

THE principal papers in this month's part of Petermann's *Mittheilungen* are: An account of a journey to Patagonia, by Dr. Karl Berg, of the Public Museum of Buenos Ayres, in which particular attention is given to the natural history of the country; "Chinese Travellers of the Middle Ages to Western Asia," by Dr. E. Bretschneider, of Pekin; "Travels on the Araguaya, Brazil, in January 1865," by Dr. Conto de Magalhães; "Contributions to a Knowledge of the Oasis El-Chargeh," with a map, by Dr. G. Schweinfurth; and a short paper, with map, on Weyprecht's survey of the North Coast of Novaya Zemlya in September and October 1872.

THE *Bulletin* of the French Geographical Society for September contains a careful paper by M. Jules Girard on the Elevations and Depressions which have been observed along the coast of France. This part also contains the conclusion of the Abbé Petitot's valuable contribution to the Geography of the Athabaskaw-Mackenzie region of North America, and a paper by M. E. Allain on the Statistics of Brazil.

THE French Government is sending to China a doctor, M. Durand Fardel, in order to study the important question of contagious diseases, and to elucidate the so much vexed question of quarantines.

IN the Health Section of the Social Science Congress, Prof. Wanklyn read a paper on the waters of the Nile, showing the amounts of chlorine and of hardness at different periods. The rise of the Nile commences at the end of May, and lasts through June, July, and August, up to about the middle of September, when the decrease continues till Christmas. From Christmas till May the amount is tolerably constant. Just at the time of the beginning of the rise of the waters the chlorine is 1·8 grains per gallon, but at the time when the Nile has attained its greatest size it is only 0·3 gr., and it remains very little above that proportion to the end of the year. In marked contrast with the variableness of the chlorine is the constancy of the hardness. Prof. Wanklyn's explanation is that the storm-water which adds so much to the bulk of the Nile sweeps over the country without penetrating far below the surface, and such water passing over a country long ago denuded of salt could convey but little chlorine. He thinks that the débris carried down mechanically by the flood-water contains abundance of finely divided carbonate of lime, so that the storm-water would always be saturated by carbonate of lime. Hence the constant hardness. The water which feeds the Nile, apart from the storm-water, contains 1·8 grains per gallon; and it is the accession of storm-water with chlorine that causes the relative reduction. Similar features will probably be found in other large rivers which have a flood period.

DURING the meeting of the Social Science Congress at Brighton, Mr. Booth threw open for three days his private museum which is in the course of arrangement. He has built on the Dyke Road a spacious hall of brick, lighted entirely from above, and around this are being placed 306 cases which contain groups of birds shot by himself and Mrs. Booth in Britain. There is one point about the fixing of the cases worth mentioning. A framework is constructed about three feet from the wall into which the glazed cases fit. This prevents any damp from the walls, too frequent in museums, and allows of the easy moving of the cases if needed. As these cases are arranged in three tiers only and there is abundance of light, every bird can be well seen, and the width of the hall is sufficient to admit of viewing the groups from different positions. The most important feature next perhaps to the careful stuffing of the birds, is the fidelity with which the characters of the habitat are reproduced. With birds which change their plumage during the year, two, and where needed, three illustrations are given each with the proper *entourage*. As a collection illustrating our British birds in their native haunts, this is probably unique. There is no attempt at zoological classification, however, since the position of the cases is influenced rather by their relative size and the general picturesque effect of the hall. Whoever the taxidermist is, the collection does him great credit. It is stated that when complete the collection will be thrown open to the public for the benefit of the local charities.

THE observations obtained by Prof. Violle (referred to last week, p. 527) in reference to the solar temperature, were obtained not by ballooning, but by the actual ascent of the Alps.

UNDER date Oct. 19, the *Times* Paris correspondent states that an earthquake which lasted several seconds is reported as having been felt at Moutiers-et-Brides-les-Bains, near Chambery. This phenomenon coincided with great barometrical depression. Snow has fallen on the mountains of the Puy de Dôme.

DR. PIETRE SANCTA has just started a new French periodical, the *Journal d'Hygiène*, with the object of realising, as far as possible, in France the ideal of a "city of health." The journal also treats of climatology, mineral waters, wintering and seaside resorts, and kindred subjects.

THE pair of Sea-lions which arrived at Brighton last week are, we are informed, specimens of Steller's Sea-lion, about six feet long. The species, which was originally described by G. W. Steller in a work which also contains the account of the huge extinct Manatee-like Rhytina, attains a length of sixteen feet, and has long hair surrounding the neck of the adult male, whence its name. Its under-fur is very little in quantity, so that the skin is of no use for "sealskin."

ON Monday the New Ladies' College, known as Newnham Hall, at the back of the Colleges at Cambridge, was formally opened and received into its rooms twenty-seven students. The resident mistress is Miss Clough, the sister of the poet.

A LETTER in Tuesday's *Times* describes a terrible hurricane and rain and thunder-storm which swept over the island of St. Vincent and other West India islands on the 9th September. In twelve hours the almost incredible quantity of nearly nineteen inches of rain fell.

A COURSE of twelve Gilchrist Lectures, on the Principles of Physical Geography, in connection with the School Teachers' Science Association, is being given at the Foresters' Hall, Wilderness Row, on alternate Friday evenings. The first lecture was given on the 8th inst., and the next will take place tomorrow. The lecturers are Dr. W. B. Carpenter, F.R.S., Mr. J. Norman Lockyer, F.R.S., and Prof. Martin Duncan, F.R.S.

THE evening lectures last session in connection with the Yorkshire College of Science were largely attended, and we are glad to see they are to be continued this session. Professors Rucker, Thorpe, and Green are to lecture on special departments of Physics, Chemistry, and Geology respectively, and Mr. L. C. Miall on "The Principal Forms of Animal Life."

THE following is the programme of the Glasgow Science Lectures Association for the coming Session:—Nov. 11, "Navigation," by Sir Wm. Thomson, F.R.S.; Nov. 24, "Coals and Coal Plants," by Prof. W. C. Williamson, F.R.S.; Dec. 8, "Recent Researches into the Chemical Constitution of the Sun," by J. Norman Lockyer, F.R.S.; Dec. 22, "Kent's Cavern—its testimony to the Antiquity of Man," by Wm. Pengelly, F.R.S.; Jan. 27, "Mountain Architecture," by Prof. Geikie, F.R.S.; Feb. 16, a lecture by Prof. Huxley, F.R.S., subject not yet announced.

FROM the thirteenth quarterly report of the Sub-Wealden Exploration, it appears that another effort is to be made to reach a depth of 2,000 feet. The engineer has reported favourably on the possibility of completing that distance by attaching a crown to the 3-inch tubes, and, after boring to 1,824 feet, to recommence with a $2\frac{1}{2}$-inch crown.

THE additions to the Zoological Society's Gardens during the past week include two Persian Gazelles (*Gazella subgutturosa*) from Persia, presented by Mr. Archibald Gray; a Ruddy Ichneumon (*Herpestes smithii*) from India, presented by Mr. W. R. Best; a Common Kestrel (*Tinnunculus alaudarius*), European, presented by Mr. J. H. Willmore; a Golden-crowned Conure (*Conurus aureus*) from S.E. Brazil, presented by Col. McArthur; two Crested Porcupines (*Hystrix cristata*), two Servals (*Felis serval*) from S. Africa, a Scarlet Ibis (*Ibis rubra*) from Para, a Common Boa (*Boa constrictor*) from S. America, deposited; a Derbian Wallaby (*Halmaturus derbianus*) born in the Gardens.

A CITY OF HEALTH*

II.

THE warming and ventilation of the houses is carried out by a common and simple plan. The cheerfulness of the fireside is not sacrificed; there is still the open grate in every room, but at the back of the fire-stove there is an air-box or case which, distinct from the chimney, communicates by an opening with the outer air, and by another opening with the room. When the fire in the room heats the iron receptacle, fresh air is brought in from without, and is diffused into the room at the upper part on a plan similar to that devised by Capt. Galton.

As each house is complete within itself in all its arrangements, those disfigurements called back premises are not required. There is a wide space consequently between the back fronts of all houses, which space is, in every instance, turned into a garden square, kept in neat order, ornamented with flowers and trees, and furnished with playgrounds for children, young and old.

The houses being built on arched subways, great convenience exists for conveying sewage from, and for conducting water and gas into, the different domiciles. All pipes are conveyed along the subways, and enter each house from beneath. Thus the mains of the water-pipe and the mains of the gas are within instant control on the first floor of the building, and a leakage from either can be immediately prevented. The officers who supply the commodities of gas and water have admission to the subways, and find it most easy and economical to keep all that is under their charge in perfect repair. The sewers of the houses run along the floors of the subways, and are built in brick. They empty into three cross main sewers. They are trapped for each house, and as the water supply is continuous, they are kept well flushed. In addition to the house flushings there are special openings into the sewers by which, at any time, under the direction of the sanitary officer, an independent flushing can be carried out. The sewers are ventilated into tall shafts from the mains by means of a pneumatic engine.

* An Address by Dr. B W. Richardson, F.R.S., at the Brighton meeting of the Social Science Association. Revised by the author. Concluded from p. 525.

The water-closets in the houses are situated on the middle and basement floors. The continuous water supply flushes them without danger of charging the drinking water with gases emanating from the closet; a danger so imminent in the present method of cisterns, which supply drinking as well as flushing water.

As we walk the streets of our model city, we notice first an absence of places for the public sale of spirituous liquors. Whether this be a voluntary purgation in goodly imitation of the National Temperance League, the effect of Sir Wilfred Lawson's Permissive Bill and most permissive wit and wisdom, or the work of the Good Templars, we need not stay to inquire. We look at the fact only. To this city, as to the town of St. Johnsbury, in Vermont, which Mr. Hepworth Dixon has so graphically described, we may apply the description Mr. Dixon has written: "No bar, no dram shop, no saloon defiles the place. Nor is there a single gaming hell or house of ill-repute." Through all the workshops into which we pass, in whatever labour the men or women may be occupied—and the place is noted for its manufacturing industry—at whatever degree of heat or cold, strong drink is unknown. Practically, we are in a total abstainers' town, and a man seen intoxicated would be so avoided by the whole community, he would have no peace to remain.

And, as smoking and drinking go largely together, as the two practices were, indeed, original exchanges of social degradations between the civilised man and the savage, the savage getting very much the worst of the bargain, so the practices largely disappear together. Pipe and glass, cigar and sherry-cobbler, like the Siamese twins, who could only live connected, have both died in our model city. Tobacco, by far the most innocent partner of the firm, lived, as it perhaps deserved to do, a little the longest; but it passed away, and the tobacconist's counter, like the dram counter, has disappeared.

The streets of our city, though sufficiently filled with busy people, are comparatively silent. The subways relieve the heavy traffic, and the factories are all at short distances from the town, except those in which the work that is carried on is silent and free from nuisance. This brings me to speak of some of the public buildings which have relation to our present studies.

It has been found in our towns, generally, that men and women who are engaged in industrial callings, such as tailoring, shoe-making, dress-making, lace-work and the like, work at their own homes amongst their children. That this is a common cause of disease is well understood. I have myself seen the half-made riding-habit that was ultimately to clothe some wealthy damsel rejoicing in her morning ride, act as the coverlet of a poor tailor's child stricken with malignant scarlet-fever. These things must be in the ordinary course of events, under our present bad ordinary system. In the model city we have in our mind's eye, these dangers are met by the simple provision of workmen's offices or workrooms. In convenient parts of the town there are blocks of buildings, designed mainly after the manner of the houses, in which each workman can have a work-room on payment of a moderate sum per week. Here he may work as many hours as he pleases, but he may not transform the room into a home. Each block is under the charge of a superintendent, and also under the observation of the sanitary authorities. The family is thus separated from the work, and the working man is secured the same advantages as the lawyer, the merchant, the banker now possesses: or, to make the parallel more correct, he has the same advantage as the man or woman who works in a factory and goes home to eat and to sleep.

In most towns throughout the kingdom the laundry system is dangerous in the extreme. For anything the healthy householder knows, the clothes he and his children wear have been mixed before, during, and after the process of washing, with the clothes that have come from the bed or the body of some sufferer from a contagious malady. Some of the most fatal outbreaks of disease I have met with have been communicated in this manner. In our model community this danger is entirely avoided by the establishment of public laundries, under municipal direction. No person is obliged to send any article of clothing to be washed at the public laundry; but if he does not send there he must have the washing done at home. Private laundries that do not come under the inspection of the sanitary officer are absolutely forbidden. It is incumbent on all who send clothes to the public laundry from an infected house to state the fact. The clothes thus received are passed for special cleansing into the disinfecting rooms. They are specially washed, dried, and prepared for future wear. The laundries are placed in convenient positions, a little outside the town; they have extensive drying grounds, and, practically, they are worked so economically, that home-washing days, those invaders of domestic comfort, are abolished.

Passing along the main streets of the city we see in twenty places, equally distant, a separate building surrounded by its own grounds—a model hospital for the sick. To make these institutions the best of their kind, no expense is spared. Several elements contribute to their success. They are small, and are readily removeable. The old idea of warehousing diseases on the largest possible scale, and of making it the boast of an institution that it contains so many hundred beds, is abandoned here. The old idea of building an institution so that it shall stand for centuries, like a Norman castle, but, unlike the castle, still retain its original character as a shelter for the afflicted, is abandoned. The still more absurd idea of building hospitals for the treatment of special organs of the body, as if the different organs could walk out of the body and present themselves for treatment, is also abandoned.

It will repay us a minute of time to look at one of these model hospitals. One is the *fac simile* of the other, and is devoted to the service of every five thousand of the population. Like every building in the place, it is erected on a subway. There is a wide central entrance, to which there is no ascent, and into which a carriage, cab, or ambulance can drive direct. On each side the gateway are the houses of the resident medical officer and of the matron. Passing down the centre, which is lofty and covered in with glass, we arrive at two side-wings running right and left from the centre, and forming cross-corridors. These are the wards: twelve on one hand for male, twelve on the other for female patients. The cross-corridors are twelve feet wide and twenty feet high, and are roofed with glass. The corridor on each side is a framework of walls of glazed brick, arched over head, and divided into six segments. In each segment is a separate, light, elegant removable ward, constructed of glass and iron, twelve feet high, fourteen feet long, and ten feet wide. The cubic capacity of each ward is 1,680 feet. Each patient who is ill enough to require constant attendance has one of these wards entirely to himself, so that the injurious influences on the sick, which are created by mixing up, in one large room, the living and the dying; those who could sleep, were they at rest, with those who cannot sleep because they are racked with pain; those who are too nervous or sensitive to move, or cough, or speak, lest they should disturb others; and those who do whatever pleases them; these bad influences are absent.

The wards are fitted up neatly and elegantly. At one end they open into the corridor, at the other towards a verandah which leads to a garden. In bright weather those sick, who even are confined to bed, can, under the direction of the doctor, be wheeled in their beds out into the gardens without leaving the level floor. The wards are warmed by a current of air made to circulate through them by the action of a steam-engine, with which every hospital is supplied, and which performs such a number of useful purposes, that the wonder is how hospital management could go on without this assistance.

If at any time a ward becomes infectious, it is removed from its position, and replaced by a new ward. It is then taken to pieces, disinfected, and laid by ready to replace another that may require temporary ejection.

The hospital is supplied on each side with ordinary baths, hot-air baths, vapour baths, and saline baths.

A day sitting-room is attached to each wing, and every reasonable method is taken for engaging the minds of the sick in agreeable and harmless pastimes.

Two trained nurses attend to each corridor, and connected with the hospital is a school for nurses, under the direction of the medical superintendent and the matron. From this school nurses are provided for the town; they are not merely efficient for any duty in the vocation in which they are always engaged, either within the hospital or out of it, but from the care with which they attend to their own personal cleanliness, and the plan they pursue of changing every garment on leaving an infectious case, they fail to be the bearers of any communicable disease. To an hospital four medical officers are appointed, each of whom, therefore, has six resident patients under his care. The officers are called simply medical officers; the distinction, now altogether obsolete, between physicians and surgeons being discarded.

The hospital is brought, by an electrical wire, into communication with all the fire-stations, factories, mills, theatres, and other

important public places. It has an ambulance always ready to be sent out to bring any injured persons to the institution. The ambulance drives straight into the hospital, where a bed of the same height on silent wheels, so that it can be moved without vibration into a ward, receives the patient.

The kitchens, laundries, and laboratories are in a separate block at the back of the institution, but are connected with it by the central corridor. The kitchen and laundries are at the top of this building, the laboratories below. The disinfecting-room is close to the engine-room, and superheated steam, which the engine supplies, is used for disinfection.

The out-patient department, which is apart from the body of the hospital, resembles that of the Queen's Hospital, Birmingham: the first out-patient department, as far as I am aware, that ever deserved to be seen by a generous public. The patients waiting for advice are seated in a large hall, warmed at all seasons to a proper heat, lighted from the top through a glass roof, and perfectly ventilated. The infectious cases are separated carefully from the rest. The consulting rooms of the medical staff are comfortably fitted, the dispensary is thoroughly officered, and the order that prevails is so effective that a sick person, who is punctual to time, has never to wait.

The medical officers attached to the hospital in our model city are allowed to hold but one appointment at the same time, and that for a limited period. Thus every medical man in the city obtains the equal advantage of hospital practice, and the value of the best medical and surgical skill is fairly equalised through the whole community.

In addition to the hospital building is a separate block, furnished with wards, constructed in the same way as the general wards, for the reception of children suffering from any of the infectious diseases. These wards are so planned that the people, generally, send sick members of their own family into them for treatment, and pay for the privilege.

Supplementary to the hospital are certain other institutions of a kindred character. To check the terrible course of infantile mortality of other large cities—the 76 in the 1,000 of mortality under five years of age, homes for little children are abundant. In these the destitute young are carefully tended by intelligent nurses; and mothers, while following their daily callings, are enabled to leave their children under efficient care.

In a city from which that grand source of wild mirth, hopeless sorrow and confirmed madness, alcohol, has been expelled, it could hardly be expected that much insanity would be found. The few who are insane are placed in houses licensed as asylums, but not different in appearance to other houses in the city. Here they live, in small communities, under proper medical supervision, with their own gardens and pastimes.

The houses of the helpless and aged are, like the asylums, the same as the houses of the rest of the town. No large building for the poor of pretentious style uprears itself; no men badged and badgered as paupers walk the place. Those poor who are really, from physical causes, unable to work, are maintained in a manner showing that they possess yet the dignity of human kind; that, being worth preservation, they are therefore worthy of respectful tenderness. The rest, those who can work, are employed in useful labours which pay for their board. If they cannot find work, and are deserving, they may lodge in the house and earn their subsistence; or they may live from the house and receive pay for work done. If they will not work, they, as vagrants, find a home in prison, where they are compelled to share the common lot of mankind.

Our model city is of course well furnished with baths, swimming baths, Turkish baths, playgrounds, gymnasia, libraries, board schools, fine art schools, lecture halls, and places of instructive amusement. In every board school drill forms part of the programme. I need not dwell on these subjects, but must pass to the sanitary officers and offices.

There is in the city one principal sanitary officer, a duly qualified medical man elected by the Municipal Council, whose sole duty it is to watch over the sanitary welfare of the place. Under him as sanitary officers are all the medical men who form the poor-law medical staff. To him these make their reports on vaccination and every matter of health pertaining to their respective districts; to him every registrar of births and deaths forwards copies of his registration returns; and to his office are sent, by the medical men generally, registered returns of the cases of sickness prevailing in the district. His inspectors likewise make careful returns of all the known prevailing diseases of the lower animals and of plants. To his office are forwarded, for examination and analysis, specimens of foods and drinks suspected to be adulterated, impure, or otherwise unfitted for use. For the conduction of these researches the sanitary superintendent is allowed a competent chemical staff. Thus, under this central supervision, every death and every disease of the living world in that district, and every assumable cause of disease, comes to light and is subjected, if need be, to inquiry.

At a distance from the town are the sanitary works, the sewage pumping works, the water and gas works, the slaughter-houses and the public laboratories. The sewage, which is brought from the town partly by its own flow and partly by pumping apparatus, is conveyed away to well-drained sewage farms belonging to the city, but at a distance from it, where it is utilised on Mr. Hope's plan.

The water supply, derived from a river which flows to the south-west of the city, is unpolluted by sewage or other refuse, is carefully filtered, is tested twice daily, and if found unsatisfactory is supplied through a reserve tank, in which it can be made to undergo forther purification. It is carried through the city everywhere by iron pipes. Leaden pipes are forbidden.

In the sanitary establishment are disinfecting rooms, a mortuary, and ambulances for the conveyance of persons suffering from contagious disease. These are at all times open to the use of the public, subject to the few and simple rules of the management.

The gas, like the water, is submitted to regular analysis by the staff of the sanitary officer, and any fault he may detect which indicates a departure from the standard of purity framed by the Municipal Council is immediately remedied, both gas and water being exclusively under the control of the local authority.

The inspectors of the sanitary officer have under them a body of scavengers. These each day, in the early morning, pass through the various districts allotted to them, and remove all refuse in closed vans. Every portion of manure from stables, streets, and yards, is in this way removed daily and transported to the city farms for utilisation.

Two additional conveniences are supplied by the sanitary scientific work of this establishment. From steam-works steam is condensed, and a large supply of distilled water is obtained and preserved in a separate tank. This is conveyed by a small main into the city, and at a moderate cost distilled water can be supplied for those domestic purposes for which hard water is objectionable. The second sanitary convenience is a large ozone generator. By this apparatus ozone can be produced in any required quantity, and is made to play many useful purposes. It is passed through the drinking water in the reserve reservoir whenever the water shows excess of organic impurity, and it is conveyed into the city for diffusion into private houses for purposes of disinfection.

The slaughter-houses of the city are all public, and are separated by a distance of a quarter of a mile from the city. They are easily removable edifices, and are under the supervision of the sanitary staff. The Jewish system of inspecting every carcase that is killed is rigorously carried out, with this improvement, that the inspector is a man of scientific knowledge.

All animals used for food—cattle, fowls, swine, rabbits—are subjected to examination in the slaughter-house, or in the market, if they be brought into the city from other depots. The slaughter-houses are so constructed that the animals killed are relieved from the pain of death. They pass through a narcotic chamber, and are brought to the slaughterer oblivious of their fate. The slaughter-houses drain into the sewers of the city, and their complete purification daily, from all offal and refuse, is rigidly enforced.

The buildings, sheds, and styes for domestic food-producing animals, are removed a short distance from the city, and are also under the supervision of the sanitary officer; the food and water supplied for these animals comes equally with human food under proper inspection.

One other subject only remains to be noticed in connection with the arrangements of our model city, and that is the mode of the disposal of the dead. The questions of cremation and of burial in the earth have been considered, and there are some who advocate cremation. For various reasons the process of burial is still retained: firstly, because the cremation process is open to serious medico-legal objections; secondly, because, by the complete resolution of the body into its elementary and inodorous gases in the cremation furnace, that intervening chemical link between the organic and inorganic worlds, the ammonia, is destroyed, and the economy of nature is thereby dangerously disturbed; thirdly, because the natural tendencies

of the people lead them still to the earth, as the most fitting resting-place into which, when lifeless, they should be drawn.

Thus the cemetery holds its place in our city, but in a form much modified from the ordinary cemetery. The burial-ground is artificially made of a fine carboniferous earth. Vegetation of rapid growth is cultivated over it. The dead are placed in the earth from the bier, either in basket-work or simply in the shroud; and the monumental slab, instead of being set over or at the head or foot of a raised grave, is placed in a spacious covered hall or temple, and records simply the fact that the person commemorated was recommitted to earth in those grounds. In a few months, indeed, no monument would indicate the remains of any dead. In that rapidly-resolving soil the transformation of dust into dust is too perfect to leave a trace of residuum. The natural circle of transmutation is harmlessly completed, and the economy of nature conserved.

Results.

Omitting, necessarily, many minor but yet important details, I close the description of the imaginary health city. I have yet to indicate what are the results that might be fairly predicted in respect to the disease and mortality presented under the conditions specified.

Two kinds of observation guide me in this essay: one derived from statistical and sanitary work, the other from experience, extended now over thirty years, of disease, its phenomena, its origins, its causes, its terminations.

I infer, then, that in our model city certain forms of disease would find no possible home, or, at the worst, a home so transient as not to affect the mortality in any serious degree. The infantile diseases, infantile and remittent fevers, convulsions, diarrhœa, croup, marasmus, dysentery, would, I calculate, be almost unknown. Typhus and typhoid fevers and cholera could not, I believe, exist in the city except temporarily and by pure accident; small-pox would be kept under entire control; puerperal fever and hospital fever would probably cease altogether; rheumatic fever, induced by residence in damp houses, and the heart disease subsequent upon it, would be removed; death from privation and from puerpera and scurvy would certainly cease; delirium tremens, liver disease, alcoholic phthisis, alcoholic degeneration of kidney, and all the varied forms of paralysis, insanity, and other affections due to alcohol, would be completely effaced. The parasitic diseases arising from the introduction into the body, through food, of the larvæ of the entozoa, would cease, and that large class of deaths from pulmonary consumption, induced in less-favoured cities by exposure to impure air and badly-ventilated rooms, would, I believe, be reduced so as to bring down the mortality of this signally fatal malady one-third at least.

Some diseases, pre-eminently those which arise from uncontrollable causes, from sudden fluctuations of temperature, electrical storms, and similar great variations of nature, would remain as active as ever; and pneumonia, bronchitis, congestion of the lungs, and summer cholera would still hold their sway. Cancer, also, and allied constitutional diseases of strong hereditary character would yet, as far as we can see, prevail. I fear, moreover, it must be admitted that two or three of the epidemic diseases, notably scarlet fever, measles, and whooping-cough, would assert themselves, and, though limited in their diffusion by the sanitary provisions for arresting their progress, would claim a considerable number of victims.

With these facts clearly in view, I must be careful not to claim for my model city more than it deserves; but calculating the mortality which would be saved, and comparing the result with the mortality which now prevails in the most favoured of our large English towns, I conclude that an average mortality of eight per thousand would be the maximum in the first generation living under this salutary *régime*. That in a succeeding generation Mr. Chadwick's estimate of a possible mortality of five per thousand would be realised, I have no reasonable doubt, since the almost unrecognised though potent influence of heredity in disease would immediately lessen in intensity, and the healthier parents would bring forth the healthier offspring.

As my voice ceases to dwell on this theme of a yet unknown city of health, do not, I pray you, wake as from a mere dream. The details of the city exist. They have been worked out by those pioneers of sanitary science, so many of whom surround me to-day, and specially by him whose hopeful thought has suggested my design. I am, therefore, but as a draughtsman, who, knowing somewhat your desires and aspirations, have drawn a plan, which you in your wisdom can modify, improve, perfect. In this I know we are of one mind, that though the ideal we all of us hold be never reached during our lives, we shall continue to work successfully for its realisation. Utopia itself is but another word for time; and some day the masses, who now heed us not, or smile incredulously at our proceedings, will awake to our conceptions. Then our knowledge, like light rapidly conveyed from one torch to another, will bury us in its brightness.

> By swift degrees the love of Nature works
> And warms the bosom, till at last, sublim'd
> To rapture and enthusiastic heat,
> We feel the present Deity, and taste
> The joy of God to see a happy world!

THE INTERNAL HEAT OF THE EARTH

PROF. MOHR, of Bonn, has contributed to the *Neues Jahrbuch für Mineralogie*, &c. (1875, Heft 4), a very important paper on the causes of the internal heat of the earth. After indicating some of the objections which may be urged against the Plutonistic theory of the origin of the earth's internal heat, he discusses the data obtained by the thermometric investigation of a boring about 4,000 feet deep, through pure rock salt, at Speremberg, near Berlin.

The proposition from which he starts is as follows:—If the interior of the earth is still fused, then with every increase in depth, as we approach this furnace, a less space must be necessary to produce the same increase of heat. The heat passes outwards by conduction from a smaller into a constantly enlarging sphere, and supposing the conductivity of the materials to be uniform, the temperature of the outer coats of the sphere must gradually diminish in proportion as their volume increases; or, in other words, the increase of heat per 100 feet must become greater and greater in proportion as we descend.

Now the results of the thermometric investigation of the Speremberg boring give the following numbers:—

For a depth of		Increase per 100 feet.
700 feet	15·654° R.	—
900 ,,	17·849 ,,	1·097
1100 ,,	19·943 ,,	1·047
1300 ,,	21·039 ,,	0·997
1500 ,,	23·830 ,,	0·946
1700 ,,	25·623 ,,	0·896
1900 ,,	27·315 ,,	0·846
2100 ,,	28·906 ,,	0·795
3390 ,,	36·756 ,,	0·608

The third column is a diminishing arithmetical series of the first order, showing equal differences of 0·050° or $\frac{1}{20}$° R. for every 100 feet. By applying this principle to the gaps left above 700 feet and between 2,100 and 3,390 feet, Prof. Mohr gets the following table of increase of heat for the whole depth:—

Depth.	Increase per 100 feet in depth.
100 to 200 feet	1·35 ° R.
200 ,, 300 ,,	1·30 ,,
300 ,, 400 ,,	1·25 ,,
400 ,, 500 ,,	1·20 ,,
500 ,, 600 ,,	1·15 ,,
600 ,, 700 ,,	1·10 ,,
700 ,, 900 ,,	1·097 ,,
900 ,, 1100 ,,	1·047 ,,
1100 ,, 1300 ,,	0·997 ,,
1300 ,, 1500 ,,	0·946 ,,
1500 ,, 1700 ,,	0·896 ,,
1700 ,, 1900 ,,	0·846 ,,
1900 ,, 2100 ,,	0·795 ,,
2100 ,, 2300 ,,	0·745 ,,
2300 ,, 2500 ,,	0·695 ,,
2500 ,, 2700 ,,	0·645 ,,
2700 ,, 2900 ,,	0·595 ,,
2900 ,, 3100 ,,	0·545 ,,
3100 ,, 3300 ,,	0·495 ,,
3300 ,, 3390 ,,	0·445 ,,

and from this series he concludes that at a depth of 5,170 feet the increase will be *nil*, because, as he says, "the end of the increase will come when the last increase of 0·445° R. is absorbed by the deduction of 0·05° R., therefore after $\frac{0·445}{0·05}$ or 8·9 strata of 200 feet, and therefore 1,780 feet deeper than 3,390

feet,* and he adds that even if the diminution of the increase of heat with depth took place at the rate of only $\frac{1}{100}$° R. instead of $\frac{5}{100}$° R., the region of constant temperature would be reached at 13,500 feet.

A similar diminution of the increase of heat with depth was observed in the case of the boring at Grenelle; but here the depth reached was far less, and the diverse character of the rocks passed through caused doubts to be entertained as to the accuracy of the result.†

In these results Prof. Mohr finds a strong confirmation of all the objections that have been urged from other sides against the Plutonistic theory. "The cause of the increasing heat in the interior of the earth," he says, "must lie in the upper strata of the earth's crust. . . . The theory of volcanoes must of course adapt itself to the above results, and the fluidity of the lavas is not a part of the incandescence (no longer) present in the earth, but a local evolution of heat by sinkings which have always been produced by the sea and its action upon solid rocks, as indeed all volcanoes are situated in or near the sea. This local superheating of the volcanic foci contributes greatly to the internal heat of the earth. For the internal nucleus of the earth can lose but little heat outwards on account of the bad conductivity of the siliceous and calcareous rocks, whilst, in the lapse of ages, it must propagate uniformly all the heat-effects of the volcanoes, and thus a constant elevated temperature must prevail in the interior, and therefore we come to the conclusion that increase of heat in the interior of the earth which is everywhere met with is the result of all preceding heat-actions, uniformly diffused by conduction in the internal nucleus of the earth." Further causes of terrestrial heat are, according to Prof. Mohr, the formation of new crystalline rocks from sun-warmed, infiltrated fluids, and also chemical processes such as the evolution of carbonic acid by the contact of oxide of iron with the remains of organisms, the formation of pyrites and blendes by the reduction of sulphates in contact with organic matters, the decomposition of lignite and coal, &c.

* In this calculation Prof. Mohr seems to have made a slight slip. If the increase of heat diminishes at the rate of 0·05° R. per 100 feet, it is hard to see why strata of 200 feet should be taken as the units in the calculation. Taking 100 feet as the unit of space, the zero point should be reached at 4,280 feet.

† See Vogt's "Lehrbuch der Geologie," Bd. I. p. 29.

SCIENTIFIC SERIALS

THE *Journal of Anatomy and Physiology*, which in future will appear quarterly instead of twice a year, and has two additional editors, both physiologists, Dr. Foster and Dr. Rutherford, contains several important memoirs. The first is by Mr. Frank Darwin, on the primary vascular dilatation in acute inflammation, in which, from a study of the effect of irritants on the web of the frog's foot, he concludes, in opposition to Cohnheim, and in accordance with Schiff, that local irritants produce these effects on vessels by acting on the peripheral terminations of the vaso-motor nerves; that they do *not* cause dilatation by direct paralysis of the tissues of the arteries, and that when the vaso-motor nerves include both inhibitory and constrictor fibres, both are stimulated by them, the attendant alteration in the calibre of the vessel being the result of the victory of the one set over the other.—Mr. F. M. Balfour has an important article on the origin and history of the urinogenital organs of Vertebrates, in which the independent discovery by Semper and himself of the segmental-organ condition of the primitive Wolffian bodies and kidneys in Elasmobranchiata is fully described, and the mode of development of the Mullerian duct explained. The way in which the segmental organs, opening externally in Annelids, have a ductal termination in Vertebrates is discussed. It is analogous to the manner in which the gill-sacs of Petromyzon, opening externally; those of Myxine have a single external orifice. The paper deserves careful perusal.—Dr. Ogston writes on articular cartilage, and illustrates his observations with six plates. After a description of healthy cartilage, the changes developed in scrofulous arthritis and chronic rheumatoid arthritis are discussed. The paper is more pathological than physiological.—Mr. W. H. Jackson and Mr. W. B. Clarke describe elaborately the brain and cranial nerves of the Shark *Echinorhinus spinosus*, from two specimens transmitted from Penzance to the Oxford Museum, to which are appended accounts of the digestive and urogenital organs.—Mr. J. Priestley demonstrates that the so-called corneal cells described by Dr. Thin as being brought into view by the action of saturated caustic potash solution at 110° F. are, in reality, those of the corneal epithelium.—Mr. E. C. Baber repeats Tillmann's observations on the fibrillar nature of the matrix of hyaline cartilage, confirming them, but differing as to the reagents which best demonstrate them.—Prof. Turner has an important memoir on the structure of the diffused, the polycotyledonary, and the zonary forms of placenta, which contains the substance of his course of lectures on that subject at the Royal College of Surgeons last summer.—Prof. Rutherford replies to Mr. Lawson Tait's comments on his freezing microtome, satisfactorily demonstrating the value of the instrument.—Dr. Stirling describes his way of preparing skin for histological examination by the rather crude method of partial artificial digestion.—Finally, Mr. J. N. Langley writes on the action of Jaborandi on the heart, discussing its slowing action, which he was the first to determine.—Dr. Stirling's Report on Physiology concludes the number.

THE current number of the *Quarterly Journal of Microscopical Science* commences with an illustrated memoir, by Mr. D. J. Hamilton, "On Myelitis, being an experimental inquiry into the pathological appearances of the same," in which the effect of traumatic injury of the cord is investigated microscopically.—The second paper is an abridged translation by Dr. W. R. M'Nab, of a paper by Dr. Oscar Brefeld, from his "Botanische Untersuchungen über Schimmelpilze," Heft. II., on the life-history of Penicillium.—This is followed by an article "On the Resting-Spores of *Peronospora infestans*, Mont, by Mr. Worthington Smith, with photographic illustrations.—After this Dr. Klein describes the Structure of the Spleen. He finds "that the pulp of the spleen of the rat and the cat is similar to that of the dog, whereas that of the monkey is similar to that of man; also that in the pulp the matrix, instead of being composed of fine fibres, has the appearance of honey-combed membranes, which only when seen in profile have the appearance of fibres. All the author's observations support the view of the splenic circulation adopted by W. Müller, Frey, and others, that the venous radicles represent merely a labyrinth of spaces in the splenic parenchyma. He agrees with those who find that there is a gradual passage from the matrix of the pulp to that of the adenoid tissue of the arterial sheaths and the Malpighian corpuscles.—Mr. C. H. Golding-Bird describes a simple differential warm stage by which a fairly uniform temperature may be maintained for a long time. To the central copper stage proper are fixed a tongue of copper and an iron wire, round both of which, for part of their extent, bell-wire is wound.—Mr. W. H. Poole describes the effect of the double-staining of tissues with hæmatoxylin and aniline. The nuclei stained by hæmatoxylin are made of a richer colour by the second reagent, whilst the protoplasm surrounding them is much bluer than the nuclei themselves.—Mr. J. M'Carthy makes some remarks on Spinal Ganglia and Nerve-fibres.—Dr. Klein has a note on a Pink-coloured Spirillum (*Spirillum rosaceum*).—The last paper is by Mr. Frank Darwin, on the Structure of the Proboscis of *Ophideres fullonica*, an orange-sucking moth, in which the peculiar conformation of the apex of that organ is described and figured, as is the interlocking of the two halves of its component maxillæ.—Notes, chronicle, and proceedings of Societies complete the number.

THE *Transactions of the Linnean Society of London* will in future be published, like the *Journal*, in two series, Zoological and Botanical. Three parts have recently been issued. The third and concluding part of vol. xxix. completes the account of the Botany of the Speke and Grant Expedition, by Prof. Oliver and Mr. J. G. Baker, and is illustrated by sixty-four plates, making 136 for the whole volume. The first part of the first volume of the second series (Zoology) includes Mr. W. K. Parker's paper On the Skull of the Woodpeckers; Dr. Willemoes-Suhm's, On the Crustacea of the *Challenger* Expedition; and Prof. Allman's, On the structure and systematic position of *Stephanoscyphus mirabilis*, the type of a new order of Hydrozoa: and the first part of the new Botanical series is occupied by Mr. Miers's papers on *Napoleona*, *Omphalocarpum*, *Asteranthos*, and on the Auxemneæ. An account of all these papers was given at the time of their delivery before the Society.

THE *Geological Magazine*, Nos. 133, 134, 135.—The principal original articles are instalments of long articles on volcanoes, by Mr. Judd; on *Cretaceous aperrhaïdæ*, by Mr. Starkie Gardner; on meteorites, by Dr. Walter Flight. Carl Pettersen contributes a sketch of the geology of Northern Norway, in No. 135. A list of previous writers is given. Five groups of stratified rocks are recognised: 1. The primitive; 2. The Tromsö mica slate group, probably the equivalent of the Cambrian; 3. Slates

of Balsfjord, age very uncertain, perhaps late Cambrian; 4. Alten group, regarded as Silurian; 5. Golda group, Devonian. The groups of the Secondary period are quite unrepresented. Throughout the Quaternary period the land has been subjected to an upheaving of about 120 metres, and this elevation has been continued down to the historic time. As to whether the land is still rising, there is no positive evidence existing. In any case it is certain the elevation during the last thousand years has been insignificant. When it is stated in so many quarters as a geological fact that the northern part of Norway rises about one-third of a metre in a century, this rate is evidently much too great. The unstratified rocks met with are also described. To No. 135 there is a supplement of forty-four pages, containing a report with plates of Mr. Tylor's lecture to the Geologists' Association on denuding agencies.

THE *Proceedings of the Natural History Society of Glasgow*, vol. ii. Part I. contains among the most interesting of its articles a paper by Mr. John A. Harvie Brown on the birds found breeding in Sutherlandshire, and another by the same author in conjunction with Mr. E. R. Alston, F.Z.S., on the mammals and reptiles of the same county. These form an excellent addition to Mr. Selby's on the same subjects.—Mr. J. Gilmour writes on the introduction of the Wild Turkey (*Meleagris gallipavo*) into Argyllshire; as does Mr. D. Robertson on the Sea Anemonies of the shores of the Cumbraes, &c.—Mr. J. Coutts describes the post-tertiary clay-beds at Kilchattan Bay, Isle of Bute.—Mr. R. Gray notes points in the distribution of the Capercaillie in Scotland; on the occurrence of the Crane in Rossshire; on the Wood Pigeon, &c.—Lord Binning gives notes on the food of the Wood Pigeon.—Capt. H. W. Fielden, now naturalist to the Arctic Expedition, writes on the Gaur or Indian Bison, and gives notes on a tour through the Outer Hebrides.—Mr. J. S. Dixon gives notes on the discovery of an ancient canoe at Little Hill, Cadder Moor.—Dr. Grieve records dredging notes from the Bay of Rothesay.—There are other short papers by Mr. W. Galt, Mr. J. Young, Dr. D. Dewer, Prof. A. Dickinson, Mr. J. Ramsey, Mr. D. Robertson, Rev. J. L. Somerville, &c.

Zeitschrift der Oesterreichischen Gesellschaft für Meteorologie, Sept. 1.—Mr. Blanford's researches on solar radiation and spots, described in a former number of NATURE, form the subject of the first paper.—In the concluding part of Dr. Theorell's description of his printing meteorograph, he states that, with certain precautions, the instrument may be kept for a long period in good working order. One has been in use at Upsala during the last three years and a half, and has lost nothing of its original precision. In a note appended to the inventor's description, Herr Osnaghi mentions some alterations which have been made in the Vienna instrument; thus the power to register great velocities of wind, in which it was formerly wanting, has been conferred upon it. Since the completion of these alterations the meteorograph has worked constantly and regularly.—In the "Kleinere Mittheilungen" we have an interesting extract from a letter written by Director Hoffmeyer, on the causes of the cold weather in May 1874. Up to the 21st of the month the synoptic charts show a maximum of pressure over N.W. and W. Europe, stretching like a great screen between the Atlantic and Central Europe, from Spitzbergen almost to Algiers, the minima coming partly from the Arctic seas, partly from the Western Mediterranean, with gradients steep towards N. and W. Such a distribution of pressure must give rise to a cold Polar stream flowing over the greater part of Europe. In Vienna the cold was greatest between the 16th and the 18th, and then the high pressure began to travel eastwards. This movement of the maximum produced a great change. The Atlantic minima, instead of moving northwards along the west coast of Greenland as hitherto, now pressed eastwards, reached Iceland and the Azores, and soon the pressure was lowest in the very district where a few days before the maximum existed. At the same time temperature rises in Central Europe. In June a similar succession of barometric changes occurred, and the maximum of pressure in the N. W. was again attended with cold at Vienna. Herr Hoffmeyer observes that areas of high pressure are much more quiet and longer lasting than minima, which travel rapidly, change their shapes, and throw off secondary disturbances. He thinks the present system of averages insufficient for the purposes of generalisation, and regards the researches of Köppen on the properties of winds in different conditions of atmospheric distribution as a step in the right direction.

THE July number of the *Bulletin Mensuel de la Société d'Acclimatation de Paris*, which is always more than a month behind date, opens with the Secretary's Annual Report on the proceedings of the Society in 1874.—Special attention has been given to the training of wild animals, such as zebras, for domestic purposes, and to the breeding of hybrids, such as those between the horse and zebra, ass and zebra, &c. Complete success is said to have attended the attempts to tame the zebras in the Gardens of the Society. The efforts of the Society are largely assisted by the experiments carried out by such gentlemen as M. Cornély, M. Mairét, M. Moreau, and others, who have succeeded in rearing many of the rarer forms of foreign animal life, and useful plants.—New Caledonia is the subject of a lengthy paper by M. Germain, who considers that that country would easily support many useful animals which do not exist there. By their introduction the country would be greatly benefited, while its importance would also be increased by additional facilities being given for utilising its indigenous produce. It is peculiarly rich in timber, which affords shelter to many kinds of useful birds.—The cultivation of the Alfa Plant (*Stipes tenacissima*), which grows wild in Algeria, is strongly recommended in the South of France, where there are large tracts of land well suited to its growth.—The cultivation of new varieties of silkworms is steadily progressing in France, and the improved breeds which have been introduced have greatly assisted in remedying the evils of the silkworm disease.

THE *Schriften der Naturforschenden Gesellschaft in Danzig* (vol. iii. heft 3).—From this publication we notice the following papers:—Researches on the Prehistoric Times of West Prussia, by Dr. Lissauer.—On the Petrefacts found in the Diluvial Deposits near Danzig, by Herr Conventz.—On the Culture of the Caterpillars of *Gastropaeha pini*, by G. Brischke.—On a Humming *Acilius sulcatus*, by the same.—Report on the investigations of Antiquities made in the neighbourhood of Neustettin during 1873, by Major Kasiski.—On the Spiders of Prussia, (seventh treatise), by A. Menge, with tables. This paper is the most valuable one in the publication, and gives proof of the wonderful diligence and energy of its author.

La Belgique Horticole, September and October.—In the current number of this magazine, usually devoted almost entirely to horticulture, are several articles of more than common interest. The paper of De Candolle's is reprinted entire which has attracted a good deal of attention, on the different effects on the growth of the same species of the same temperature in different latitudes. Prof. E. Morren, the editor, has two articles on the "carnivorous" habits of *Pinguicula* and *Drosera*. Following Mr. Darwin's lead in a careful series of experiments on two Alpine species of the former genus, *P. alpina* and *longifolia*, and the common *D. rotundifolia* of the latter genus, he finds the same results as regards the secretion of a fluid which causes rapid decay of the substances in contact with it, but is not prepared to admit any process of actual digestion or assimilation on the part of the plant. M. Ch. Royer has also an interesting note on the cause of the sleep of plants.

SOCIETIES AND ACADEMIES

LEEDS

Naturalists' Field Club and Scientific Association, September 15.—Mr. Henry Pocklington, F.R.M.S., in the chair.—Mr. James Abbott exhibited a number of interesting plants collected in the West Riding, including *Potentilla norvegica*, which grows abundantly on the banks of the Leeds and Liverpool Canal between Armley and Kirkstall, and appears to have been thoroughly naturalised. It was first gathered about 1860, by Mr. Wm. Kirkley, but not satisfactorily determined at the time. In 1868 it was found, also apparently native, in Burwell Fen, Cambridgeshire, by Mr. G. S. Gibson, and recorded by him in the *Journal of Botany* for that year (vol. vi., p. 302; also see "Babington's Manual," seventh edition). In 1874 Mr. Abbott noticed it in great abundance, and in 1875 it was sent to Kew to be named. It turned out to be a Scandinavian form, though in what manner it reached the Leeds district is as yet unaccounted for. Mr. C. P. Hobkirk, of Huddersfield, reports that it grows on the canal banks in his neighbourhood, where he found it in 1873. Mr. Abbott also reported the capture of the Clouded Yellow Butterfly (*Colias edusa*) near Adel Dam, six miles north of Leeds, on the 5th September. This ordinarily southern form seems this year to have extended its range far to the northward. *Vanessa antiopa*, also recorded from Kirkstall Road, Leeds, in September.

PARIS

Academy of Sciences, Oct. 4—M. Frémy in the chair. The following papers were read:—On the Observatory of the Office of Longitudes at Montsouris, by M. Mouchez.—On the dredging of the roadstead of Port Said, second note by M. de Lesseps.—New researches on beats of the heart in the abnormal state, and on the registration of these beats and of those of the arteries, by M. Bouillaud.—On disordered variation of hybrid plants, and deductions which may be made from it, by M. Naudin.—On the carpellary theory, according to the Irideæ, by M. Trecul.—Results of observations of solar protuberances and spots, from 23rd April to 28th June, 1875 (fifty-five rotations), by P. Secchi. Four tables are given; deductions to follow.—On the *Hemisepius*, new genus of the family of Sepians, with some remarks on species of the genus *Sepia* in general, by M. Steenstrup.—Results obtained from attempts at industrial applications of solar heat, by M. Mouchot. The apparatus (in work at Tours) consists of a silver plate mirror, in form of a truncated cone, turning with the sun; a cylindrical annular boiler at focus, with blackened surface; and a glass envelope admitting the sun's rays, but preventing their exit when transformed into obscure rays. One very hot day, five litres of water were vaporised in the hour, representing 140 litres of steam per minute.—On the mechanical properties of different vapours at saturation in a vacuum, by M. Antoine.—On the different quantities of heat produced by the mixture of olive oil with concentrated sulphuric acid, according as the boiling of the acid is more or less recent, by M. Maumené.—On the existence of ferruginous and magnetic corpuscles in atmospheric dust, by M. Tissandier. Drawings are given.—On the formation of clouds, by M. Hureau de Villeneuve.—On sexualised Phylloxera and the winter egg, by M. Balbiani.—MM. Chablaix, Corteggiani, and Pourcherol, also presented notes on Phylloxera.—M. Marsanne submitted a memoir on "Process and apparatus for production of signals, fires, and electric lights."—M. Malessart presented a second note on the problem of aviation.—M. Tellier called attention to an experimental voyage about to be made to La Plata for transport of meat preserved by cold.—M. Petit presented a note relative to the transformation of starch by diastase, and the production of a new saccharine matter.—The Secretary notified a brochure by M. Cossa, on the syenite of Biellese.—On the eclipse of the sun of 28–29 Sept. 1875, by M. Angot.—On the reduction of a ternary cubic form to its canonic form, by M. Brioschi.—On the value of the coefficient of expansion of steam from superheated water, by M. Croullebois.—Influence of stripping off the leaves on the vegetation of the beet, by M. Violette. It diminishes the root's weight and yield of sugar, increasing the proportion of other matters.—On two new meteorites of the desert of Atacama, and on the meteorites found hitherto in this region of South America, by M. Domeyko.—On clouds of ribbon-form, by M. de Fonvielle.—Observations of a bolide at Couiza (Aude) on the night of 30th Sept. 1875, by M. Amigues.—The thunderstorms of 1875, by M. d'Arbaud-Blonzac.

Oct. 11.—The following papers were read:—Results of observations of solar protuberances and spots from April 23 to June 28, 1875 (55 rotations) concluded, by P. Secchi. The daily number of protuberances and surface of spots steadily diminished. The great metallic eruptions ceased when the large spots disappeared. Two maxima of protuberances in each hemisphere disappeared, leaving only the minima of the equatorial zones. Protuberances diminished in height. Faculæ disappeared from round the poles and were confined to the zone of spots and protuberances.—M. Girardin presented a new edition of his work, "On Dung and other Animal Manures."—M. Favre gave an extract from his memoirs "On the transformation and equivalence of chemical forces."—On the rotatory polarisation of quartz, by MM. Soret and Sarazin.—New note on the processes of magnetisation, by M. Gaugain.—On the formation of hail, by M. Planté. Electricity suddenly brings the water of clouds to a state of extreme division, facilitating congelation in a medium of low temperature. Terrestrial magnetism, or the permanent electric current of the globe, causes the gyratory movement of electrified cloud masses.—Researches on the ammonia contained in sea-water, and in that of salt marshes in the neighbourhood of Montpellier, by M. Andoynaud.—On commercial analysis of sugars, and the influence of salts and glucose on crystallisation of sugar, by M. Durin.—On the hypsometric distribution of living molluscs in the Central Pyrenees, by M. Fischer.—On the necessity of surrounding the lower part of vine-stocks with coal-tarred powders, by M. Girard.—Five other communications relative to Phylloxera.—M. Lehmann presented a further note on a system of propulsion for steamships.—M. Le Breton submitted to the judgment of the Academy various apparatuses for the ascension of liquids.—M. Holzner showed specimens of carrot-roots, bearing pucerons apparently of a new species.—The Director-General of Customs presented a general tableau of the commerce of France with its colonies and foreign powers during 1874.—The Secretary called attention to a memoir by MM. Nobel and Abel on explosives, and one by M. Volpicelli, defending Melloni's electrostatical theory.—Remarks on the use made, in antiquity, of solar heat, on occasion of M. Mouchot's recent note, by M. Buchwalder.—On the electric conductivity, of pyrites, by M. Dufet. This is true metallic conductivity very variable with the physical structure of the specimen, but in a given crystal, depending neither on the direction, the intensity, nor the duration of the current.—On the toxical effects of alcohols of the series $C^nH^{2n+2}O$, by M. Rubuteau.—On the new tellurised minerals lately discovered in Chili, by M. Domeyko.—Perforation of a quartzous grit by the roots of trees, by M. Meunier.

BOOKS AND PAMPHLETS RECEIVED

BRITISH.—Report of the Meteorological Commission of the Royal Society.—Ganot's Elementary Treatise on Physics. Seventh Edition, Revised and Enlarged. Translated by E. Atkinson, Ph.D., F.C.S. (Longmans).—Ultima Thule; or, a Summer in Iceland: R. F. Burton (Nimmo).—Proceedings of the Bath Natural History and Antiquarian Field Club. Vol. iii. No. 2.—Elementary Lessons in Botanical Geography: J. G. Baker, F.L.S. (Reeve).—Numerical Examples in Heat: R. E. Day, M.A. (Longmans).—Zoology for Students: C. Carter Blake, D.Sc., with Preface by Richard Owen, C.B., F.R.S. (Daldy, Isbister).—Pollution of Rivers: Wm. Hope, V.C.—Food Manufacture *versus* River Pollution: Wm. Hope, V.C.—The *Challenger's* Crucial Test of the Wind and Gravitation Theories of Oceanic Circulation: Jas. Croll.—Notes on some Comparative Microscopic Rock-Structure of some Ancient and Modern Volcanic Rocks: J. Clifton Ward, Assoc. R.S.M., F.G.S. SIXTH REPORT OF THE SCIENCE COMMISSION

THREE times within the last twelve years a Royal Commission has reported on the science teaching of our higher schools. In 1864 the Public Schools Commission announced that from the largest and most famous schools of all it was practically excluded. In 1868 the Endowed Schools Commission declared that the majority of school teachers had accepted it as part of their school work. The Science Commissioners of 1875, in their Sixth Report, on Science Teaching in Schools, testing this statement by inquiry, reports that of 128 endowed schools examined by them not one-half has even attempted to introduce it, while of these only 13 possess a laboratory, and only 10 give to the subject as much as four hours a week. And this statement is curiously illustrated by the statistics of the recent Oxford and Cambridge School Examination, which show that out of 461 candidates for certificates from 40 first-class schools, while 438 boys took up Latin, 433 Greek, 455 Elementary Mathematics, 305 History; only 21 took up Mechanics, 28 Chemistry, 6 Botany, 15 Physical Geography.

In a volume whose research and condensation make it not only a monument of conscientious toil, but an invaluable handbook to all who are labouring to work out practically the great problem of which it treats, the Commissioners investigate the obstacles which have caused the endowed schools to defy the weighty recommendations of former Commissions, the unanimous verdict of educational authorities outside the scholastic profession, and the increasingly urgent demands of English public opinion. They find the schoolmasters' excuses to be threefold; absence of funds, want of time, and scepticism as to the educational value of science in comparison with other subjects. A large portion of the Appendix is devoted to the consideration of these difficulties; to sifting the allegations on which they rest, and to balancing against them the experience of those teachers who have faced and successfully met them. Showing in detail the comparatively trifling cost at which indispensable apparatus can be obtained, the Commissioners nevertheless admit the rarity, in the present state of English culture, either of independent science teachers suited to the larger schools, or of men, such as poorer schools desiderate, combining literary with scientific knowledge. This, however, is an evil of the past rather than of the future, since not the least amongst the advantages expected from a reformed system of school teaching is the creation of a race of able teachers, general as well as special. The relative value of science as an implement of mental training is next discussed. Its peculiar excellence is briefly vindicated, as cultivating in a way attainable by no other means the habits of observation and experiment, of classification, arrangement, method, judgment; and its suitability to the capacities of the very youngest boys is testified to by Faraday, Hooker, Rolleston, Carpenter, and Sir W. Thomson. Lastly, it is shown that, if this be so, the argument from want of time is no argument at all; that the hours are already wasted which condemn the half of a boy's faculties to stagnation and render education one-sided and incomplete; and that the claims of different branches of instruction may be easily adjusted by economy of time, improvement in methods, and excision of superfluous studies.

On a review of all these objections and of the answers offered to them, and taking into account the dicta of former Commissioners and the practice of other countries, the Report advises that literature, mathematics, and science should be the accepted subjects of education up to the time at which boys leave school, and should all three be made compulsory in any School Leaving-Examination or University Matriculation; but that after entering the University students should be left to choose for themselves amongst these lines of study, and need pass no subsequent examination in subjects other than the one which they select. As regards the teaching of science, they recommend that it should commence with the beginning of the school career; that not less than six hours a week should be devoted to it, and that in all school examinations as much as one-sixth of the marks should be allotted to it.

These recommendations possess the two great excellences of authoritativeness and clearness. They are supported by a host of experienced witnesses, as well as by the eminent names whose signatures follow them. Their ideal of school education is simplicity itself. The supremacy of Classics is to be dethroned; the artifices of stratification and bifurcation are to be discarded; literature, mathematics, and science are to share a boy's intellect between them from the very first, until a leaving-examination which shows his progress to have been satisfactory in all three sets him free to follow his inclination by pursuing exclusively the subject which suits him best; happy since eminence in that one will not have been purchased by entire ignorance of all the others. Unfortunately, though most necessarily—for this Report concerns schools only—the curtain drops upon this interesting moment of transition, shutting out of view the influence which University Scholarships and Exhibitions exercise upon school work, and thus ignoring an obstacle to the realisation of the programme far greater than want of money, want of time, or want of appreciation, in the schools themselves.

What is the avowed object and purpose of the higher English school education? Is it the even and progressive development of young minds? the strengthening in equal proportion of the faculties of imagination, memory, reason, observation? the opening doors of knowledge in the plastic time of youth, which if not opened then will be fast closed in later years by the pressure of active work, or habitual exclusiveness, or energies paralysed through disuse? Nothing of the kind. It is constructed entirely with the aim of winning certain prizes; for scholarships with which a costly University bribes men to come to it for education; for class-lists leading up to College Fellowships; for the lucrative posts of military and civil service. In all these, but most of all where the Universities can determine the ordeal, one principle of success has been established, and that principle is one-sidedness. The candidate for India, for Woolwich, for Cooper's Hill, must at an early age select certain subjects and throw overboard all the rest. The childish aspirant to the entrance scholarships of a public school is placed in the hands

of a crammer at eight years old, that at thirteen he may turn out Latin verses as a Buddhist prayer-mill turns out prayers, and may manifest, as a distinguished head-master has lately said, to the eye of a teacher searching for intelligence, thoughtfulness, promise, intenseness, "a stupidity which is absolutely appalling." His scholarship won, he is pledged to pursue a course whose benefits are tangible and its evil consequences remote. The Universities have stamped upon all the schools one deep certainty, that for a boy to be "all round," as it is called, is the irremissible sin; that a schoolmaster who teaches with reference to intellectual growth and width of culture sacrifices thereby all hope of the distinctions which make a school famous and increase its numbers. If a classical scholarship is desired, science and mathematics are abandoned: nay, the palm of literary excellence is conceded even to men ignorant of the noblest literature in the world, their own birthright and inheritance, and knowing less of the history and structure of the English language than a fourth form boy knows of Greek. If mathematical success is aimed at, literature and science are ignored; if the few science scholarships existing tempt candidates from any of "the thirteen schools which possess a laboratory," mathematics in part and literature altogether must be given up. It would be waste of words to point out the fatal tendency of this separative process; to show how mere linguistic training needs the rationalising aid of scientific study, or how exclusive science hardens and materialises without the refining society of literature; yet such divorce is inevitably due not to the convictions of schoolmasters, not to the influence of parents, not to the prepossessions of the public, but to the irresistible force of the University system, which makes narrowness of intelligence and imperfect knowledge the only avenues to distinction or to profit.

It is true that an attempt to alter this involves little short of a revolution; but by all accounts a revolution is at hand. It is not for nothing that a parliamentary investigation into the expenditure of college endowments should have been supported by members of the colleges themselves, or that a proposal to distribute college scholarships and exhibitions by a central authority in accordance with the results of the leaving-examination should have emanated from eminent university teachers. For it cannot be too strongly urged that college scholarships stand on very different ground from university prizes or degrees. It is easy for Parliament to lay down rules which shall control the latter once for all; it is not easy to bind the actions of some forty different foundations, each electing its own scholars according to its own idiosyncrasies, or in obedience to the changing wills of bodies in a perpetual state of flux. It may still be audacious, but it is no longer novel, to suggest that, supposing future legislation to retain the college scholarships at all, they should be awarded by the authority of Government, in strict connection with leaving-examinations which Government shall conduct, and in reward not of special but of general proficiency. For this the scheme of the Commissioners virtually contends; into regions beyond this the Report before us necessarily does not enter.

It will be seen that we accept, and recommend all teachers to accept, the scheme of the Commissioners unreservedly as a working basis of educational improvement. It may not be ideally perfect; it may invite opposition on points of detail; but it is the resultant of all the intellectual forces which have hitherto been brought to bear upon the subject; and while agreeing with all its witnesses on the principle that wide general training should precede specialisation of study, it attains extreme simplicity of arrangement by allotting the first of these to the Schools and the last to the Universities. Do not let us forget that the cry which has arisen hitherto from all the head-masters on the point of scientific teaching has been a cry for guidance; for commanding and intelligent leadership; for authoritative enlightenment as to the relative value and the judicious sequence of scientific subjects; for information as to text-books, apparatus, teachers. For the first time this cry is met by an oracle whose authority no one will question, and whose completeness of delivery all who study its utterances will appreciate. Schoolmasters anxious to teach science, and doubtful how to set about it, will meet all the facts which can enlighten them in the Appendices to the Report. They will find lists of accredited text-books, specimens of examination papers, varieties of school time-tables, priced catalogues of apparatus, syllabi of lectures and experiments, botanical schedules and tables, plans and descriptions of laboratories, workshops, museums, botanic gardens; programmes and reports of school scientific and natural history societies. They will learn how costly a temple could be built to Science at Rugby, and how modestly it could be housed at Taunton. They will see how Mr. Foster teaches physics, how Mr. Hale teaches geography, how Mr. Wilson teaches *Erdkunde*. And they will accept all this as coming from men who have a right to speak, and who wield an experience such as has not been amassed before. On any legislative change which impends over the system and the endowments of the higher English education, the body of scientific opinion is strong enough, if united, to impress its own convictions; disunion alone can paralyse it. All who feel the discredit of past neglect, its injury to our national intellect, and its danger to our national prosperity, will do well to support by unqualified adhesion the first attempt that has been made to probe its causes, and the first consistent and well-considered scheme that has been put forth for its removal.

W. TUCKWELL

DREW'S "JUMMOO AND KASHMIR"

The Jummoo and Kashmir Territories. A Geographical Account. By Frederick Drew, F.R.G.S., F.G.S., Associate of the Royal School of Mines. (London: Stanford, 1875.)

THE author of this work was for ten years, from 1862, in the service of the Maharaja of Kashmir, his primary duty apparently being the investigation of the mineral resources of the territory. During this period his duties led him to visit many parts of the Maharaja's dominions, and thus he had unusual opportunities of becoming well acquainted with the various districts and peoples under the sway of that ruler. Mr. Drew's previous training had qualified him to take intelligent advantage of his position and opportunities, and the result is the present bulky work, occupying 550 pages,

It is a perfect mine of information about the Kashmirian territories, more especially about their physical and political geography and their ethnology, while occasional details are introduced as to their zoology and botany. Mr. Drew delivers a "plain unvarnished tale," and has made no attempt to work his materials up into a merely popular book. Indeed, it might have been an advantage had he exercised a little more skill in arrangement; but with this defect we are not disposed to find serious fault, as every page of the work contains valuable information, which, by means of contents and index, is, after all, easily got at. Mr. Drew has made a substantial contribution to our knowledge of one of the most interesting regions of the globe.

Most Europeans, we suspect, have but a vague notion of how much is included under the name Kashmir. After all, Jummoo has a better title to give a name to the dominions of the Maharaja, as it is in the capital of this district that he resides. Jummoo is quite near the southern boundary of the Kashmirian territories, on a branch of the Chinab river, and hence must arise many inconveniences in the government of the country.

The territory included under the sway of the Maharaja is somewhat extensive, and of great variety in climate, physical characteristics, and races, extending from the broiling plains of the Panjab to the immense glaciers and eternal snows of the highest Himalayas, and including peoples both of Aryan and Turanian affinities, and of Mohammedan, Buddhist, and Brahman faiths. Looking down, however, upon the general map which accompanies Mr. Drew's volume, it is seen that the great mass of the territory is distinctly mountainous, and that to such an extent that one wonders where there can be any room for a population at all. Besides Jummoo and Kashmir, the countries of Ladakh, Baltistan, and Gilgit are included in the Maharaja's territories, whose entire area is estimated at 68,000 square miles.

Mr. Drew's plan is first in an introduction to present a general view of the Kashmirian territories, and then in succeeding chapters to treat of the various districts. The

High Himalayan peaks east of Nubra.

main characteristics of each district and its inhabitants are described in some detail, after which Mr. Drew takes the reader along a particular route which he himself has traversed, pointing out with great minuteness all that is worthy of note by the way. As Mr. Drew records mainly his own experiences, and as he is seldom tempted aside from the record of facts, it will be seen that the work is well adapted to afford the reader a clear and full idea of a region that is well worth becoming intimately acquainted with.

Mr. Drew divides the entire territory from a physical point of view into three regions, commencing at the plain of the Panjab and proceeding northwards. These are, first, the region of the Outer Hills, composed of mountains averaging from 2,000 to 4,000 feet above sea-level; second, the Middle Mountains, averaging between 8,000 and 10,000 feet; and lastly, the region of the lofty Himalayas, the mountains in which vary in height from 15,000 to 27,000 feet. There are many points in Mr. Drew's descriptions into which we wish we could enter in some detail, many observations concerning the country and the people we should like to lay before our readers, but this is impossible; a mere enumeration of the contents of the work would occupy most of the space at our command.

Of the inhabitants especially of this curious region, so near the supposed cradle of the Aryan race, and where the Aryans and Turanians meet, and sometimes intermingle, Mr. Drew has much to say that will no doubt command the attention of ethnologists. He observed carefully and records faithfully the characteristics and ways of the varied peoples, and although these have been observed by previous travellers, still it will be found, we are sure, that Mr. Drew has made an important contribution to the ethnology of the region. The Aryan people of Kashmir he divides into five principal races: the Dogra, Chibali, Pahari, Kashmiri, and Dard; and the Turanian, which belong to the Tibetan section of that group, into Balti, Ladakhi, and Champa. As might be expected, Mr. Drew gives much information concerning the castes of the Aryan races, and what he tells us is full

of interest. He throws some light also on the probable origin of castes, and especially of the distinction between the superior and inferior castes, and produces some very good reasons for believing that they are a result of the conquest of an inferior by a superior race. Mr. Drew was governor of Ladakh for a period, and thus had a splendid opportunity of becoming acquainted with an interesting region and curious people. He of course refers to the peculiar marital institution of the Turanians in the comparatively barren districts of the Himalayas. In Baltistan the people are of the same race as the Ladakhis, but having been converted to Mohammedanism, have eschewed polyandry for polygyny, with the result that the population has increased beyond the capacity of the country to support it, rendering emigration necessary.

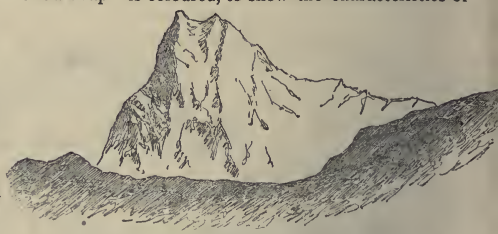
Mr. Drew presents minute studies of several places in Ladakh, especially of the salt lake district to the south of Leh. After carefully observing the geological characteristics of the district, he concludes that at one time, when glaciers were more universal than now, there must have been there one extensive and deep lake. Mr. Drew is constantly turning aside to make minute studies in geology and physical geography of this kind, and as the phenomenon investigated is generally of a typical sort, the scientific value of the book is thus much enhanced.

Of course Mr. Drew has a great deal to say about the Himalayas and their glaciers—glaciers on a scale, as he says, not to be met with elsewhere beyond the Arctic regions. Though Mr. Drew's style is unadorned, it has the merit of being always perfectly clear, so that his descriptions of glacial and other phenomena convey real and valuable information. One glacier he examined at Basha, in Baltistan, was upwards of twenty miles long, and others are to be met with of much greater extent; indeed, to judge from the map, this north-west Himalayan region is one huge net-work of glaciers. The largest of all is the Baltoro glacier, thirty-five miles long, which comes down between two lofty ridges; the northern ridge rises in one spot to the height of 28,265 feet, the peak of that height (K 2 of the Indian Survey) being the second highest mountain known in the world. And yet these glaciers are a mere remnant, the evidence seems to show, of the glacial covering which at one time spread over the Himalayan region.

One interesting excursion made by Mr. Drew was to the district in the N.E. of Ladakh, which, in the form of a great mountain-surrounded plateau, extends to the Kuenlun Mountains. This plain is divided into two by a low range of mountains running east and west, the southern half being known as the Lingzhithang Plain, and the northern half is named by Mr. Drew the Kuenlun Plain. This extensive and almost lifeless plateau has been crossed before Mr. Drew's journey, by various travellers—the unfortunate A. Schlagentweit, Mr. W. H. Johnson of the G. T. Survey, Mr. Haywood, Mr. Shaw, Dr. Cayley, and the two Yarkand Mission parties. Mr. Drew discusses the observations of some of these observers, and from observations made by himself, comes to the conclusion that the entire plateau must at one time have been under water, the mountains in the centre appearing above the surface as islands. His account of his observations on this journey are of considerable value as supplementary to those of previous observers—of the mirage, of the capricious lakelets which are still sometimes seen, of the composition of the surface of the plateau, of the remains of shingly beaches, salt deposits, and other features. This great plateau has by no means been yet fully explored, though it would be likely to yield to a competent observer important data in physical geography.

One special chapter is devoted to the various languages spoken in the territories, and their relationships well pointed out. In the appendices, also, material is provided for the comparative philologist in a Dogra grammar, various vocabularies and phrases.

A characteristic and valuable feature of the work is the series of maps which enable the reader to follow satisfactorily all the author's routes and descriptions. First of all there is a general map on the scale of sixteen miles to an inch, sufficiently minute to enable one to recognise the chief physical features, and in which the various glaciers are indicated. Then come five maps, constructed each from a different and special point of view. The "Snow Map" is coloured, to show the characteristics of



K 2 of Indian Survey, 28,265 feet, as seen from Turmik.

various regions of the territory in respect of snow, from the region of "no snow" to that of glaciers. The "Race Map" shows the distribution of the various peoples which make up the population of the country, while the "Language Map" and the "Faith Map" serve the same purpose for languages and religions respectively. The "Political Map" shows the various previously independent states and rajaships which have been gradually agglomerated into one dominion under the Maharaja of Jummoo. Besides the maps there are isometric views and sections of the principal mountain regions, and a number of illustrations of places and people. We think the illustrations, especially in the way of typical photographic portraits, ought to have been more abundant in a work otherwise so elaborate and minute; but this may be remedied in a second edition.

We have given but a faint idea of the contents of this thick volume, but perhaps we have said enough to show that henceforth it must be considered as one of the principal authorities on a country of great interest in itself, and of special interest to English people on account of its relation to our Indian dominions and government. Much has already been written on the country and on the regions which border upon it, and special studies have been made of particular parts and aspects of it—Mr. Drew refers with deserved praise to Dr. Leitner's great work on Dardistan;—but on the country as a whole, in all its aspects, political, historical, ethnological, and physical, Mr. Drew's work must be considered as a permanent and trustworthy authority.

OUR BOOK SHELF

Zoology for Students. By C. Carter Blake, D.Sc. (Daldy, Isbister, and Co., 1875.)

In this work Dr. C. C. Blake has published, as he tells us in the preface, the substance of his annual course of lectures on zoology at Westminster Hospital. Beginning with the highest form, man, he descends the whole scale of animal life, ending with the Protozoa, or Acrita. A general description of each class is followed by a more detailed account of each of the different orders which compose it. As a preface, "notes" taken from some of Prof. Owen's Hunterian Lectures on the principles of zoological classification, are, with the lecturer's permission, introduced.

The arrangement adopted is not the most modern. The Batrachina and the other Amphibia are retained as orders of the class Reptilia; the importance of the different sections of the Teleostei is considered to be as great as that of the Ganoidei or Plagiostomi; the Cirripedia are separated from the Crustacea; the "Bryozoa" are associated with the "Radiata," and the Entozoa are retained among the Articulata. More stress is laid on external peculiarities than is the custom now-a-days, among biologists, and the importance of embryology is not made prominent. Theoretical considerations are placed in the background, and illustrations are but few and far between. The fossil orders are described in their respective classes, and some of Prof. Owen's tables of the distribution in time of their different genera are introduced.

There is, no doubt, some advantage to a student with time at his disposal commencing the science upon an antiquated classification, for it enables him afterwards to more fully comprehend the history of biology, and to appreciate the rapid strides that have been made. We, however, fear that it is the object of most who take up the subject to obtain, as quickly as possible, a clear idea of its present position; and such being the case, to commence with a bygone system is only so much loss of time. The view taken by Dr. Blake will therefore detract from the value of his otherwise useful work. Another thing that will diminish its value is a certain want of accuracy which pervades it. Drawings of the feet of three birds are given, and they are all wrongly named. A scansorial foot is adjudged to a passerine bird; that of a kingfisher is said to be gallinaceous, whilst that of a steganopod is termed "foot of duck." More than once the peculiarities of two closely allied animals are reversed, as when we are told that among the Proboscidia "in one form, entirely extinct (Dinotherium), the incisors project in the form of long tusks from the upper jaw; in the existing elephants, from the lower jaw," and when "the articulated group (of the Brachiopoda are said to) possess an anal aperture, the non-articulated possess none whatever."

The chapter on the Pisces is much confused. "The living Ganoids have completely bony skeletons, but the fossil ones may have had skeletons soft and cartilaginous like those of the Sturgeons. . . . They have several holes in the arterial trunks. . . . Their optic nerves do not decussate, but merely cohere laterally." The external nares are said to be "simple" in the Rays and Sharks, or "double, as in most osseous fishes." The Ammocete is called the Sandlaunce, and it is described as a separate genus.

The same character is more than once repeated on the same or the following page, whilst others equally important are omitted. On the first page of the section describing the Reptilia, the two following sentences occur as parts of the definition of the class: "a heart with two auricles, and with the ventricle more or less completely divided;" "the heart has two auricles; the ventricle is imperfectly divided." Pentastoma is retained among the "Entozoa," instead of being placed among the Arachnida; we can find no reference to Ceratodus, a most important fish theoretically; and the brain of the Marsupials is said not to possess a corpus callosum.

Notwithstanding the imperfections above pointed out, there is much to be learnt from Dr. Blake's work; many of the descriptions are excellent; nevertheless there are so many essential facts omitted, that it will be found more valuable as an adjunct to a work like Prof. Huxley's "Introduction to the Classification of Animals," than as an independent source of information.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*]

"Instinct and Acquisition"

In Nature (vol. xii. p. 507) there appears, under the above heading, a very interesting article, being an epitome of a paper read by Mr. Spalding at the Bristol meeting of the British Association. Now that the doctrine which is maintained in this article—a doctrine with which Mr. Spalding's name is associated as almost its only experimental verifier—has proved itself so completely victorious in overcoming the counter-doctrine of "the individual-experience psychology"—and this along the whole line both of fact and theory—it seems unnecessary for anyone to adduce additional facts in confirmation of the views which Mr. Spalding advocates. I shall therefore confine myself to detailing a few results yielded by experiments which were designed to illustrate the subordinate doctrine thus alluded to in Mr. Spalding's article:—

"Though the instincts of animals appear and disappear in such seasonable correspondence with their own wants and the wants of their offspring as to be a standing subject of wonder, they have by no means the fixed and unalterable character by which some would distinguish them from the higher faculties of the human race. They vary in the individuals as does their physical structure. Animals can learn what they did not know by instinct and forget the instinctive knowledge which they never learned, while their instincts will often accommodate themselves to considerable changes in the order of external events. Everybody knows it to be a common practice to hatch ducks' eggs under a common hen, though in such cases the hen has to sit a week longer than on her own eggs. I tried an experiment to ascertain how far the time of sitting could be interfered with in the opposite direction. Two hens became broody on the same day, and I set them on dummies. On the third day I put two chicks a day old to one of the hens. She pecked at them once or twice, seemed rather fidgety, then took to them, called them to her, and entered on all the cares of a mother. The other hen was similarly tried, but with a very different result. She pecked at the chickens viciously, and both that day and the next stubbornly refused to have anything to do with them," &c.

It would have been well if Mr. Spalding had stated whether these two hens belonged to the same breed; for, as is of course well known, different breeds exhibit great variations in the character of the incubatory instinct. Here, for instance, is a curious case. Spanish hens, as is notorious, scarcely ever sit at all; but I have one purely-bred one just now that sat on dummies for three days, after which time her patience became exhausted. However, she seemed to think that the self-sacrifice she had undergone during these three days merited some reward, for, on leaving the nest, she turned foster-mother to all the Spanish chickens in the yard. These were sixteen in number, and of all ages, from that at which their own mothers had just left them up to full-grown chickens. It is remarkable, too, that although there were Brahma and Hamburg chickens in the same yard, the Spanish hen only adopted those that were of her own breed. It is now four weeks since this adoption took place, but the mother as yet shows no signs of wishing to cast off her heterogeneous brood, notwithstanding some of her adopted chickens have grown nearly as large as herself.

The following, however, is a better example of what may be called plasticity of instinct. Three years ago I gave a pea-fowl's egg to a Brahma hen to hatch. The hen was an old one, and had previously reared many broods of ordinary chickens with unusual success even for one of her breed. In order to hatch the

pea-chick she had to sit one week longer than is requisite to hatch an ordinary chick, but in this there is nothing very unusual, for, as Mr. Spalding observes, the same thing happens with every hen that hatches out a brood of ducklings.* The object with which I made this experiment, however, was that of ascertaining whether the period of maternal care subsequent to incubation admits, under peculiar conditions, of being prolonged; for a pea-chick requires such care for a very much longer time than does an ordinary chick. As the separation between a hen and her chickens always appears to be due to the former driving away the latter when they are old enough to shift for themselves, I scarcely expected the hen in this case to prolong her period of maternal care, and indeed only tried the experiment because I thought that if she did so the fact would be the best one imaginable to show in what a high degree hereditary instinct may be modified by peculiar individual experiences. The result was very surprising. For the enormous period of eighteen months this old Brahma hen remained with her ever-growing chicken, and throughout the whole of that time she continued to pay it unremitting attention. She never laid any eggs during this lengthened period of maternal supervision, and if at any time she became accidentally separated from her charge, the distress of both mother and chicken was very great. Eventually the separation seemed to take place on the side of the pea-cock; but it is remarkable that although the mother and chicken eventually separated, they never afterwards forgot each other, as usually appears to be the case with hens and their chickens. So long as they remained together the abnormal degree of pride which the mother showed in her wonderful chicken was most ludicrous; but I have no space to enter into details. It may be stated, however, that both before and after the separation the mother was in the habit of frequently combing out the top-knot of her son—she standing on a seat, or other eminence of suitable height, and he bending his head forwards with evident satisfaction. This fact is particularly noteworthy, because the practice of combing out the top-knot of their chickens is customary among pea-hens. In conclusion I may observe, that the pea-cock reared by this Brahma hen turned out a finer bird in every way than did any of his brothers of the same brood which were reared by their own mother, but that on repeating the experiment next year with another Brahma hen and several pea-chickens, the result was different, for the hen deserted her family at the time when it is natural for ordinary hens to do so, and in consequence all the pea-chickens miserably perished.

I have just concluded another experiment which is well worth recording. A bitch ferret strangled herself by trying to squeeze through too narrow an opening. She left a very young family of three orphans. These I gave, in the middle of the day, to a Brahma hen which had been sitting on dummies for about a month. She took to them almost immediately, and remained with them for rather more than a fortnight, at the end of which time I had to cause a separation, in consequence of the hen having suffocated one of the ferrets by standing on its neck. *During the whole of the time that the ferrets were left with the hen the latter had to sit upon the nest*; for the young ferrets, of course, were not able to follow the hen about as chickens would have done. The hen, as might be expected, was very much puzzled at the lethargy of her offspring. Two or three times a day she used to fly off the nest, calling upon her brood to follow; but upon hearing their cries of distress from cold, she always returned immediately and sat with patience for six or seven hours more. I should have said that it only took the hen one day to learn the meaning of these cries of distress; for after the first day she would always run in an agitated manner to any place where I concealed the ferrets, provided that this place was not too far away from the nest to prevent her from hearing the cries of distress. Yet I do not think it would be possible to conceive of a greater contrast than that between the shrill peeping note of a young chicken and the hoarse growling noise of a young ferret. On the other hand, I cannot say that the young ferrets ever seemed to learn the meanings of the hen's clucking. During the whole of the time that the hen was allowed to sit upon the ferrets she used to comb out their hair with her bill, in the same way as hens in general comb out the feathers of their chickens. While engaged in this process, however, she used frequently to stop and look with one eye at the wriggling nest-full with an inquiring gaze expressive of astonishment. At other times, also, her family gave her good reason to be surprised; for she used often to fly off the nest suddenly with a loud scream—an action which was doubtless due to the unaccustomed sensation of being nipped by the young ferrets in their search for the teats. It is further worth while to remark that the hen showed so much uneasiness of mind when the ferrets were taken from her to be fed, that at one time I thought she was going to desert them altogether. After this, therefore, the ferrets were always fed in the nest, and with this arrangement the hen was perfectly satisfied—apparently because she thought that she then had some share in the feeding process. At any rate she used to cluck when she saw the milk coming, and surveyed the feeding with evident satisfaction.

Altogether I consider this a very remarkable instance of the plasticity of instinct. The hen, it should be said, was a young one, and had never reared a brood of chickens. A few months before she reared the young ferrets she had been attacked and nearly killed by an old ferret which had escaped from his hutch. The young ferrets were taken from her several days before their eyes were open.

In conclusion I may add, that a few weeks before trying this experiment with the hen I tried a similar one with a rabbit. In this case the ferret was newly born, and I gave it to a white doe rabbit which had littered six days before. Unlike the hen, however, she perceived the imposture at once, and attacked the young ferret so savagely that she broke two of its legs before I could remove it. To have made this experiment parallel with the other, however, the two mothers ought to have littered on the same day. In this case the result would probably have been different; for I have heard that under such circumstances even such an intelligent animal as a bitch may be deceived into rearing a cat, and *vice versâ*.* GEORGE J. ROMANES

Dunskaith, Ross-shire, Oct. 10

* The greatest prolongation of the incubatory period I have ever known to occur was in the case of a pea-hen which sat very steadily on addled eggs for a period of four months, and had then to be forced off in order to save her life.

* *Apropos* to what Mr. Spalding says about the early age at which the instinctive antipathy of the cat to the dog becomes apparent, I may state that some months ago I tried an experiment with rabbits and ferrets somewhat similar to that which he describes with cats and dogs. Into an outhouse which contained a doe rabbit with a very young family I turned a ferret loose. The doe rabbit left her young ones, and the latter, as soon as they smelled the ferret, began to crawl about in so energetic a manner as to leave no doubt that the cause of the commotion was fear, and not merely the discomfort arising from the temporary absence of the mother.

Curious Australian and N. American Implement

A VERY interesting illustration of the occurrence of the same specialised implement in widely separated regions is found in the resemblance between the vermin hooks of the Australians and the same kind of weapon found among the Ute Indians. Several of the former were brought home by Wilkes' Expedition, and are found in the National Museum (Fig. 1). They

FIG. 1.—Australian vermin hook.

have highly finished handles, and the bone hook is fastened on with wrapping and gum. Of the latter, Major Powell, in his Colorado Report (1875), says, "These Indians all carry canes with a crooked handle, they say to kill rattlesnakes, and to pull rabbits from their holes" (Fig. 2).

FIG. 2.—Pai-Ute vermin hooks.

The Ute implement is very rude, consisting of a switch merely, with the bark stripped off, and a nail passed through the thick end at an acute angle, and firmly lashed with sinew. Major Powell's Fig. 45, entitled "The Human Pickle," has two of these hooks (or canes) in his hand. O. T. MASON.

Washington, D.C., Oct. 13

OUR ASTRONOMICAL COLUMN

DOUBLE STARS. (1) *p* ERIDANI.—In the year 1850 the late Capt. Jacob calculated two orbits for this binary system, the second of which represents very fairly his subsequent measures to the end of 1857, a rather severe test for elements founded upon the data available in 1850. We look in vain for measures later than Capt. Jacob's, though it may be hoped this and other interesting objects

of the southern heavens have not been entirely neglected of late years. The public observatories are perhaps too closely occupied with other work to allow of much being expected from them in a class of observation peculiarly suited to the amateur astronomer, but there must be a grand field of operations for private observers, in southern double and variable-star astronomy.

Capt. Jacob's last orbit of *p* Eridani may be written thus:—

Peri-astron passage	1819·83
Node	110° 40′
Node to peri-astron in direction of motion ...	285° 50′
Inclination	46° 36′
Excentricity	0·323
Semi-axis	4″·25

Mean annual motion, $-3°\cdot3645$, or period of revolution 107 years.

The components are of equal brightness, and hence it is to be expected some measures may be registered 180° different from others; accordingly, to work the whole series into any supposable orbit it is necessary to add 180° to Sir J. Herschel's micrometrical measures (Cape Obs., p. 276), and indeed it will be seen that he has so recorded the angles of the 20-feet sweeps, p. 174.

The errors of the above orbit are, for

1835·00	Pos. $(c-o)$	$+2°\cdot5$	Dist. $(c-o)$	0″·00
1857·96	,,	$-1°\cdot6$	,,	$+0″\cdot03$

The following are deduced from the same orbit:—

1875·0	Pos.	218°·9	Dist.	3″·92
76·0	,, ...	216°·3	,, ...	3″·89
77·0	,, ...	213°·7	,, ...	3″·86

As the measures of this star are, so far, scattered in several volumes, they are collected here for convenience of reference. Dunlop's angle was evidently registered in the wrong quadrant, as is pointed out both by Sir J. Herschel and Capt. Jacob; the correct reading appears to be 343° 6′.

			°		″
Dunlop	1825·96	Pos.	343·1	Dist.	2·5
Herschel	35·00	,,	302·3	,,	3·65
Jacob	45·88	,,	276·0	,,	4·16
,,	46·83	,,	277·0	,,	4·32
,,	49·82	,,	270·0	,,	—
,,	50·80	,,	268·73	,,	4·32
,,	51·79	,,	266·38	,,	4·30
,,	52·76	,,	264·84	,,	4·14
,,	53·99	,,	263·24	,,	4·36
,,	56·09	,,	261·12	,,	4·70
,,	57·96	,,	258·18	,,	4·49

The place of *p* Eridani for the commencement of 1876 is in R.A. 1h. 35m. 5s., and N.P.D. 146° 49′·5.

(2) O. Σ 387.—Between the epoch of Mr. Otto Struve's measures in 1844 and Baron Dembowski's in 1868, the angle in this binary has retrograded 77°, and no doubt if measures are obtained this year a very considerable further change will be manifested: yet the distance, if we except Secchi's estimate in 1856, has been found about half a second, as long as the star has been under observation. A first approximation to the elements may soon be practicable. The place of this object for beginning of 1876 is R.A. 19h. 44m. 6s., and N.P.D. 55° 0′·1. The number applies to the Pulkova Catalogue of 1850.

The Minor Planets.—No. 150 of the group of small planets has been reached, Prof. Watson, director of the Observatory of Ann Arbor, Michigan, having detected another member, apparently on the night of October 18; the place as yet doubtful, the telegrams through the French and English cables being discordant. It is stated to be of the 10th magnitude, and is therefore brighter than the great majority of planets discovered during the last few years. Considering the close scrutiny which the ecliptical region of the sky is receiving at the present day, we must surely soon be in a position to pronounce with some degree of confidence whether any trans-Neptunian planet as bright as stars of the 13th magnitude exists within 2½° or 3° from the ecliptic, and in the event of greater inclination, the scheme of Prof. Peters, on its completion, may afford an equally definitive conclusion. There have been some curious alarms in this direction, as in the autumn of 1850, during observations of the minor planet Hygeia at Washington, when an apparently slow moving object was compared with the planet on more than one evening; but although sought for diligently on the supposition of its being a distant body, was not recovered, nor, we believe, has since been seen in the observed place. The change of position was larger than could well be attributed to casual errors in micrometric observations; but there seems to be no other explanation of this case, except admitting error of observation and the existence of a variable star of long period in that spot.

NOTES FROM THE "CHALLENGER"

PROF. WYVILLE THOMSON has just sent me from the *Challenger* an account of certain results of Deep Sea dredgings in the North Pacific. In these dredgings was obtained a Gymnoblastic Hydroid of such colossal dimensions that the largest form hitherto known sinks in comparison with it into utter insignificance. Prof. Thomson has determined the Hydroid as a Monocaulus or nearly allied form, and a beautiful drawing which accompanies his letter confirms this view.

The animal itself has not yet arrived, but the letter which gives an account of its capture contains so many points of general interest, that the following extract will, I feel sure, be acceptable to the readers of Nature:—

"H.M.S. *Challenger*, N. Pacific, July 24, 1875.

. . . .

"On the 17th of June, in the North Pacific, lat. 34° 37′ N., long. 140° 32′ E., depth 1,875 fathoms, temperature at bottom 1° 7 C., bottom grey mud, the trawl brought up three or four examples of what seems to be a species of Monocaulus, or something allied to it. The point which naturally struck us most was that the hydranth in a specimen measured fresh by Moseley and myself, was nine inches across from tip to tip of the expanded (non-retractile) tentacles, and the hydrocaulus was seven feet four inches high! On the 5th of July, lat. 37° 41′ N., long. 177° 4′ W., depth 2,900 fathoms, with bottom temperature the same as before, and a bottom of red clay with manganese nodules, the trawl, which was torn to pieces by having taken in too great a weight of nodules of manganese, brought up entangled in its outer netting another fine specimen of this same form. It was put in weak picric acid, and then into weak alcohol, and you have it in the short piece of test-tube among the horsehair. This specimen was not measured, but the hydranth was carefully sketched by Mr. Wild, and I enclose you the sketch.

"These delicate things, drawn up rapidly through the water from a depth of nearly four statute miles, and transported into such totally different conditions of temperature, pressure, &c., suffer greatly from the violent change: they are in fact almost knocked to pieces, and their finer tissues are in a nearly deliquescent state, so that our great anxiety is to get them at once into some reagent which will harden them somewhat. It is wretched to see them melting away absolutely under one's eyes: when put into any of our fluids they at once contract out of all form, but that cannot be helped. I thought it best you should have them as well preserved as we could manage, so I only gave them a cursory glance and sent them on.

"The hydrocaulus is enormously extensile—it is of a pale pink colour, and our specimens, when distended in the water, were about four feet or so long: one, as I mentioned before, which Moseley and I measured, was seven feet four inches high, but that one was stretched over the surface of the trawl net, and although it must of course have been capable in life of extending to that degree, it might not have been a normal attitude. When at what

seems to be its normal state of distension, the diameter of the hydrocaulus is about half an inch. Its structure you can make out for yourself. The proximal ends of several of them were coated with mud when they came up; the longitudinal striæ were very evident in the soft tissue; fluid gravitated down the centre of the hydrocaulus, and collected in a bladder-like expansion at the base. The base of this stem was of a darker colour than the rest—a dull rose—in most of them (not in the one figured by Wild). As I did not mean to describe the creature I did not look out for processes or fibrillæ at the proximal extremity; you may find them in the spirit specimens. The total length of the hydranth when moderately extended was 1½ inches.

"The proximal range of tentacles number about a hundred, and these are about four inches long—they are almost transparent in life—of a pale pink colour in most specimens. The sporosacs are in close tufts of a maroon colour just at the base of the proximal tentacles. The specimen I looked at was a male, but the tissues were so soft—almost slimy—that I did not like to tease it too much. The walls of the body-cavity were yellowish, and seemed to contain some vertical rolls of glandular matter, and the hypostome terminates in a fringe of about forty-eight or fifty extensile tentacles round the mouth. So much for our gigantic Corymorphoid! These are the only two occasions on which we got it, or anything like it. I should have liked to get a haul or two in Behring's Sea, for there doubtless we should have had it in shallow water. I can only tell you one thing more about it—its associates. On the 17th of June, 1875, in 1,875 fathoms, it was associated with many fishes (Ophidoids, Macrurids, Scopellids—all the usual deep-sea lot), several Gasteropods, many Crustaceans (Dorippe, Galatea, Caridids, &c., and a fine Scalpellum), a few Annelids, many Echinoderms (Brisinga, Phormosoma, Ophiurids, two very fine Holothurids of a new group), species of Isis, Primnoa, Polythoa, and Actinia. On the 5th of July, in 2,900 fathoms, there were some worms (Aphroditacean), an Urchin allied to Diadema, two Holothuriæ, and one or two sponges; but the trawl-net was torn by the weight of the manganese nodules, so we had scarcely a fair sample of the fauna. In the bottle with the tube you will find among the horse-hair one or two pieces of *Heliopora cerulea* from Moseley. He sends at the same time a paper on it to the Royal."

That the enormous depths from which this colossal Hydroid has been brought up should favour the development of gigantic representatives of the diminutive forms of shallower zones, and that in the tenants of these sunless regions of the sea we should find colour not less vivid than that of their light-loving relatives, are facts full of significance.

It is also worth noticing that the sexual zooids of the great Hydroid are to all appearance simple sporosacs, instead of the medusiform zooids which are so frequent in the Gymnoblastic Hydroids of our littoral regions. Indeed, among the many Hydroids which I have examined from deep water, I have never found one which could be referred with probability to a form characterised by the production of medusiform zooids. It would seem that these zooids—delicate and active organisms which are among the most abundant captives of the towing-net in the surface-zone of the sea—are unable to endure, either before liberation from their parent Hydroid, or for a period however short in their free state, the darkness and pressure and other conditions to which the dwellers in the deep sea are exposed. GEORGE J. ALLMAN

NORDENSKJÖLD'S ARCTIC EXPEDITION

A LETTER from Prof. Nordenskjöld to Mr. Oscar Dickson, of Gothenburg, appears in the *Goteborgs Handels Tidning* of the 14th inst. It is dated "On board the *Pröven*, at anchor at the mouth of the Jenesej, 16th August, 1875." The following extracts may be of interest to our readers:—

"We are now employed as busily as possible in equipping the boat in which I, accompanied by Dr. Stuxberg, docent Lundström and three men, intend to sail up the Jenesej, with the view of returning to Europe across Siberia, while the other part of the expedition returns to Norway by sea, on board the *Pröven*.

"After the *Pröven*, on the 8th of June, was towed free of cost out of Tromsö by a little steamer of the same name, we were compelled to lie at anchor in the sound between Carlsö and Renö for five days, on account of a head wind. Finally, on the 14th, we could again weigh anchor and get to sea through Fuglö Sound. We thereupon set our course past North Cape, which we passed on the 17th, to the southern part of Novaya Zemlya.

"During spring and the early part of summer the west coast of this double island is, for some distance from the land, surrounded by a compact ice girdle, impassable at most places, which disappears later in the season, and in which, according to the experience of the fishermen, there are formed, generally at an early period, two sounds which are covered only with thin passable drift-ice, and by which the ice-free belt of water along the coast is connected with the ice-free ocean westwards. One of these open channels is usually situated off Matotschkin Scharr, and its formation is caused by the strong currents which prevail in that sound; the other is to be found about the latitude of Severo Gusinnoi Mys, or North Goose Cape. The latter was chosen by me for the *Pröven*, and was passed without any special difficulty on the 22nd of June. The expedition thus, in seven days from its departure from Carlsö, cast anchor for the first time at Novaya Zemlya, in a little ill-protected bay immediately north of North Goose Cape.

"During the voyage there were set on foot, when the state of the weather permitted, frequent soundings and dredgings, examinations of animal and diatom life in the surface of the sea, determinations of the temperature at different depths, &c. Our operations were generally very successful, and showed that in this sea we may reckon on reaping rich harvests in natural history. We also made repeated trials at different depths of a new instrument for bringing up specimens of the bottom, constructed for the expedition by Dr. Wiberg, which showed itself very well adapted for the purpose, and easily managed."

After visiting and examining various parts of the coast for many days, the *Pröven* was directed to the Sea of Kara, and on the 26th July the anchor was let go off Cape Grebeni, on Waigats Island. So violent a storm was raging, however, that a boat could not be sent out till the 30th July to land on Waigats Island. "A rich collection was here made of Upper Silurian fossils, strongly resembling those from Gotland, and therefore of special interest for Swedish geologists. Here we for the first time encountered Samoyedes, who when they sighted the vessel drove down to the shore in peculiar high sledges adapted for travelling in both summer and winter, and drawn by three or four reindeer. They immediately gave us to understand that they wished to come on board, whither they also accompanied us in our boat, and where they were soon afterwards well entertained by us.

"During our stay on the west coast of Novaya Zemlya we of course instituted numerous investigations regarding the geology, animal and vegetable life, &c., of the regions visited by us, and the number of the places on the coast where we landed rendered it possible for the scientific staff of the expedition to collect materials for ascertaining the natural relations of these regions, which are certainly far more extensive than have been brought home by any of our predecessors." At last on August 2 the sound was successfully passed, and on the *Pröven* reaching the Sea

of Kara it was found completely free of ice! "Our course was set towards the middle of the peninsula which separates the Sea of Kara from the Bay of Obi, and is named Jalmal by the Samoyedes. The wind was very moderate, so that we only advanced slowly—a circumstance by which our patience was in truth sorely tried, but which had this good result, that during our sailing forward in these waters visited for the first time by a scientific expedition, we were able daily to undertake dredgings, hydrographic work, &c. The dredgings gave an unexpectedly rich and various harvest of marine animals, among which I will specially mention here several colossal species of Isopoda, masses of Amphipoda and Copepoda, a large and beautiful Alecto, uncommonly large Ophiurids, beautifully marked Asterids, innumerable mollusca, &c. The peculiar circumstance here occurs that the water at the surface of the sea, which in consequence of the great rivers which debouch in these regions is nearly free of salt, forms a deadly poison for the animals which live in the salt water at the bottom. Most of the animals brought up from the bottom accordingly die if they are placed in water from the surface of the sea.

"Here, as on the west coast of Novaya Zemlya, were instituted, when opportunity offered, with the thermometers by Negretti and Zambra and Casella procured by you during your stay in London last spring, determinations of the temperature of the sea, not only at the surface, but also at different depths under it. These investigations yielded a specially interesting result, and perhaps may be regarded as conclusive of a number of questions regarding which there has of late been much discussion concerning the ocean currents in these regions, the direction of which, in the absence of other data, it has been attempted to determine chiefly by the temperature of the surface water. By means of numerous observations along the west coast of Novaya Zemlya from Matotschkin Scharr to Jugor Sound, and thence past Cape Grebeni to 75½° N. lat. and 82° E. long., and on to the mouth of Jenisej, I have obtained indisputable proof that in this sea the temperature of the sea-water at the surface is exceedingly variable and dependent upon the temperature of the air, upon the neighbourhood of ice, and upon the influx of warm fresh water from Obi and Jenesej, but that the temperature of the water at a depth of only ten fathoms is nearly quite constant, between $-1°$ and $2°$ C. If, in the northern part of the Sea of Kara, where the water on the surface is almost completely *free of salt*, and at this time of the year very warm, a flask filled with water from the surface is sunk to a depth of ten fathoms, the water freezes to ice. There are thus no warm ocean currents here at any considerable depth below the surface. A large number of deep-water samples have been taken by the apparatus constructed by Prof. Ekman, which is exceedingly well adapted for the purpose, and I am convinced that at the bottom the content of salt is also constant, which can be ascertained with certainty after the return of the expedition by analyses of the samples of water which have been taken.

"On the 8th August we landed for a few hours on the north-western side of Jalmal, where an astronomical determination of the position of the place was made. A great many astronomical determinations had previously been made during the expedition along the west coast of Novaya Zemlya and Jugor Sound. Traces of men, some of whom had gone barefoot, and of Samoyede sledges, were visible on the beach. Close to the shore was found a sacrificial altar, consisting of about fifty skulls of the Ice Bear, Walrus, and Reindeer bones, &c., laid in a heap. In the middle of the heap of bones there stood, raised up, two idols, roughly hewn from drift-wood roots, newly besmeared in the eyes and mouth with blood, also two poles provided with hooks, from which hung bones of the Reindeer and Bear. Close by was a fireplace and a heap of Reindeer bones, the latter clearly a remnant of a sacrificial meal. After a stay here of several hours, I sailed further north, until further advance in this direction was prevented by impassable masses of great even icefields at 75° 30′ N. lat., and 79° 30′ E. long. Afterwards I followed the edge of the ice eastwards, and finally steered our course towards the north side of the mouth of Jenisej, where the Swedish flag was hoisted and the anchor was let go on the 15th in the afternoon. We had now attained the goal which great seafaring nations had in vain striven for centuries to reach.

"The expedition will now, in accordance with the plan agreed upon, separate, inasmuch as I, accompanied by Lundström and Stuxberg, and three men, intend, in a Nordland boat brought with us for the special purpose, to sail or row up the Jenisej, in order to return by Turuchansk and Jeneseisk to Europe, while the *Pröven* returns hence to Norway, if possible going north of the north point of Novaya Zemlya."

SCIENCE IN GERMANY

(*From a German Correspondent.*)

SINCE we possess in the kinetic molecular theory, as founded by Clausius, a mechanical theory based on the atomic conception of gases, it is possible to employ the results of the chemical investigation of these bodies for physical deductions. It is only necessary to suppose for this purpose that *the same* molecules, which are the bearers of the thermal and mechanical properties of gases, act reciprocally in chemical reactions. We must point out as one of the most important confirmations of this view, that Avogardo's hypothesis, based on general physical deductions, and adopted in chemistry as the foundation-stone of its whole recent development, has lately found its mechanical confirmation in the gaseous theory of Maxwell and of Boltzmann.

Recently, however, difficulties have arisen in the further investigation of this theory, with regard to the specific heat of gases. The quantity of heat contained in a gas is defined as the total energy of its molecules, and this energy consists solely in progressive motion, if the molecule is looked upon as a mere material point. On the other hand, the pressure of the gas upon the surface-unit equals two-thirds of the kinetic energy of progressive motion contained in the volume-unit. If, therefore, we raise the temperature of the gas by one degree, the volume remaining the same, we can find by calculation the adduced quantity of heat according to the gaseous theory, from the increase of pressure determined by Mariotte-Gay Lussac's law. This quantity of heat in its relation to the mass-unit, is, as is known, called the specific heat of the gas at the constant volume (c), and calculation now shows this value to be 0·60 of the observed one. In close connection with this it was found that the proportion of specific heat at constant pressure (c') to the specific heat at constant volume (c), viz. $\frac{c'}{c} = k$ is $= 1·67$ according to the theory mentioned, but $= 1·405$ according to observation.

Clausius has shown that the theoretical value of c is certainly increased, if we take into account that according to the results of chemical researches the molecules of the gases hydrogen, oxygen, and nitrogen are *not* material points, but polyatomic, and that they are thus capable of storing, as it were, a certain quantity of energy in the shape of motion relative to a centre of gravity. But when Boltzmann lately investigated the behaviour of polyatomic gas molecules according to mechanical principles, he found c for a diatomic gas (like hydrogen, oxygen, nitrogen) to be 1·22 times more than observation shows. He found by calculation $k = 1·33$, and this value is *smaller* than the actual one (1·405). We must remark here that the supposition of a number of atoms larger than

2 would decrease k still further, and here exists for the present an unsolved contradiction between experience and the theory in its present form.

Looking at this state of things, Herren Kundt and Warburg at Strasburg thought it advisable to investigate experimentally the simplest case which nature offers to us, viz. the case of a gas which, according to its chemical behaviour, is a monatomic one. Herr Baeyer pointed out to them that mercury gas was such a gas; they therefore undertook to determine the specific heat of mercury gas. Here a contradiction to the theory did *not* become apparent; the experiment has yielded exactly the value demanded by theory for a monatomic gas, viz., $K = 1{\cdot}67$. Thus it is proved that the molecule of mercury gas, with regard to its thermal and mechanical properties, behaves exactly like a material point. It is hardly necessary to remark that, with regard to other properties, it is not at all necessary that the same molecule should behave like a material point. Thus, for instance, one glance at the spectrum emitted by incandescent mercury gas, which is crossed by many bright lines, shows us at once that the molecule of the same, with regard to the light it emits, does certainly not behave like a material point.

With regard to the way in which the experiment was conducted, we confine ourselves to the following remarks.

The k for mercury gas was determined from the velocity of sound in this gas, and this was found by means of the method of dust figures, formerly described by Herr Kundt.* A glass tube A, closed at both ends, well dried and pumped perfectly free from air, contained a certain quantity of mercury, which had been carefully weighed, and a little silicic acid. Sealed to this tube was another one, B (this a little narrower), in such a manner as to form the prolongation of A. A was placed in a four-fold box made of iron plates, which was heated by a series of Bunsen burners. This box also contained the great reservoir of an air thermometer, and, if observations were made at a temperature under 354°, several mercury thermometers besides. The end of B, projecting from the box, was sealed up, and over this end a long wide glass tube D was placed, which was closed at one end and contained a little lycopodium.

If now, after the necessary regulation in the heating arrangements, the thermometers in the box showed equal and sufficiently elevated temperatures, the tube composed of A and B was sounded by friction to its third longitudinal tone; at the same time a reading of the air thermometer was taken, and the temperature of the air in D was noted down. The powders introduced then showed in tubes A and D the sound-waves in mercury gas and in air respectively, so that afterwards the lengths of these waves could be measured with the greatest accuracy.

Let us suppose

l to be the length of the sound-wave in air,
l' " " " in mercury-gas,
t the absolute temperature of air in D,
t' " " of mercury gas in A,
$d = 6{\cdot}9783$ the density of mercury gas (air = 1),
k – the proportion $\frac{C}{c}$ of the two specific heats for air.
k' " " " " for mercury gas.

Then we have

$$k' = k\left(\frac{l'}{l}\right)^2 \frac{t'}{t} d.$$

If k for air was taken at $= 1{\cdot}405$ according to Röntgen, then by seven definite experiments, at different degrees of saturation of the mercury vapour, and three different sets of apparatus being employed, it was found on the average that

$$k' = 1{\cdot}67.$$

The results of the different experiments never deviated more than one per cent. from this value.

* See NATURE, vol. xii, p. 88.

If the specific heat c at constant volume for air is taken as $= 1$, then it follows that c for mercury

$$c = 0{\cdot}60.$$

W.

AMONG THE CYCLOMETERS AND SOME OTHER PARADOXERS

NO notes have been handed down of the conversation between Erskine and Boswell, whilst strolling in Leicester Fields, on squaring the circle. There is on record, however, Boswell's small joke, "Come, come, let us circle the square, and that will do us good."

The subject is one that has occupied the thoughts of some few from the earliest times of geometrical history, and there are some now fascinated by it at this date, when we have—

> "on the lecture slate
> The circle rounded under female hands
> With flawless demonstration."

Old Burton advises him that is melancholy to calculate spherical triangles, square the circle, or cast a nativity. A popular novelist ("Aurora Floyd," chap. iv.), describing one of her characters "who was an inscrutable personage to his comrades of the 11th Hussars," says he was, "according to the popular belief of those harebrained young men, employed in squaring the circle in the solitude of his chamber."

To say of a man that he is a circle-squarer will make an ordinary mathematician shrug up his shoulders and indicate expressively that there is, in his opinion, a screw loose somewhere. Having had some slight acquaintance with the writings of a few of the race forced upon us, we propose here to pass them under review, generally contenting ourselves with letting them speak for themselves, for thus shall we possibly most effectually confute their absurdities, at least in the judgment of our mathematical readers.

De Morgan, the great exposer of circle-squarers, trisectors, *et id genus omne*, has, after Montucla, stated ("Budget of Paradoxes," p. 96) that there still exist three ideas in the heads of this race—(1) That there is a large reward offered for success; (2) that the longitude problem depends on that success; and (3) that the solution is the great end and object of Geometry. Some eight years ago we saw a letter from a Spanish Don of La Mancha, who offered to send an infallible method of squaring the circle; and within the last four months an application came to us from Sweden, in which the author stated that he had heard that the London Mathematical Society had offered a prize for the trisection of angles, and as he had after long working at the problem obtained a solution, he was ready to transmit the same, but his organ of caution led him to fear lest his communication might get into improper hands, and so he wished to know to whom to send the aforesaid solution. We need hardly say that the Society, in this matter imitating the example of the French Academy of Sciences and of our own Royal Society, has declined to receive any communication upon either of the above-named subjects or upon that of the allied problem, the Duplication of the Cube. This decision was arrived at in consequence of a bulky mass of papers on the circle problem having been laid before the President in the end of 1871. The author had previously submitted his papers to our own examination, and after some little perplexing we were able to indicate the point at which the author had tripped. We have heard nothing further of the solution, nor seen any of the elaborate figures since. We think it fair to state that we believe this cyclometer to have been an honest man and a good geometer. He had worked at the problem, off and on, some twenty years, and attacked it by the lunes of Hippocrates of Chios.

We have consulted the "Introductorium Geometricum" of Charles de Bovelles (Bovillus) in the 1503,

1507 (?), and 1510-1517 editions; and also his "Géométrie Practique" in the 1549 and 1555 editions; and we are disposed to think that De Morgan (B. of P., pp. 31, 32) is in error, possibly in this case following Montucla (for he says he has not seen the former work, and he makes no mention of the second), though all the copies of the "Introductorium" cited above contain the *De Quadratura* which De Morgan states that he has seen. Any how, all the constructions we have seen of Bovillus give $\sqrt{10}$, and not $3\frac{1}{8}$. This will readily be seen from the following:—Bovillus inscribes a square in a circle, and then *states* that the quadrantal arc is equal to the line drawn from an angle of the square to the middle point of one of the opposite sides. In his "Géométrie" he says of Cusa (whose views De Morgan states him to have adopted): "Il ha usé de dimensions infinies, lesquelles un géométrien ne cognoist, et ne confesseroit jamais estre possibles. Nonobstant, son invention est bonne et approuvee, tant par raison que par expérience." Nor do we find any account of his quadrature agreeing with that of a peasant labourer, but he states that he too had attempted the problem by another method (than that of Cusa), and not without success. Whilst standing on a bridge at Paris he noticed the carriage-wheels passing over the road; the fact that when the wheel has performed a revolution we have a straight line whose length equals the circumference of the wheel, suggested his solution to him, and on his return home he easily got his construction, which is this: Divide a radius of the circle into four equal parts, produce this radius through a fourth of its length; join the extremity of this line with an extremity of the diameter at right angles to the radius, and with the point as centre and this distance as radius describe a circle; the portion of the tangent at the extremity of the selected radius cut off by this circle, he says, equals the semi-circumference. It will be seen that this is the same value as that given above. Bovillus, also, in a *libellus de mathematicis supplementis* (1509), gives a third construction, which leads to the same value.

Before leaving this writer we ought to state that he attributes the first construction we have given to his friend M. Achaire Barbel, a man "ingenious at new inventions of use in geometry." It is with considerable diffidence that we have ventured to go thus into detail, but it seems to us that De Morgan had fallen into error in the case of this early writer.

We propose now to take up the subject at the point where it is left in the "Budget," constantly regretting that the hand which so vigorously lashed the offenders in this line now lies cold. Here we must give place to that arch circle-squarer, Mr. James Smith. We shall deal tenderly, however, with his book, as we learn that he too has gone over to the majority and joined his former opponent. The book we have now before us is "Why is Euclid unsuitable as a Text-book of Geometry? This question answered and the Propositions of Euclid 8 and 13, Book VI., proved to be erroneous by Heterodox Geometry." (Motto—"Magna est veritas et prævalebit." London: Simpkin, Marshall, and Co., 1871.) The editor, whose name does not appear, in an address to the reader, states that Geometricus, a principal correspondent in the pamphlet, is "an intimate acquaintance and almost in daily communication with Mr. James Smith, the well-known author," &c. Geometricus became a convert to Mr. Smith's views. He has no niche in the "Budget:" were we not informed to the contrary, we should have been disposed to say that Geometricus and Mr. James Smith were one and the same person. The first fifteen pages are mainly devoted to a correspondence between Geometricus and the Rev. Dr. Jones, if that can be called a correspondence in which the writing on one side is copious and on the other confined to simple acknowledgments of receipts of letters.

The doctor was singled out for this honour in consequence of his having written an able pamphlet "On the unsuitableness of Euclid as a Text-book of Geometry." Geometricus was delighted at the appearance of this work, thinking now at last "here is a recognised mathematician, who has got out of the groove and who can see a geometrical truth by whomsoever propounded;" but alas! he is soon disappointed, and finds that, as in Mr. Smith's experience, directly a mathematician is driven into a corner, he invariably gets out of it by pleading pressing engagements, want of time, &c., "and so a great and important scientific truth—it may be—is born to blush unseen," &c. He then sends James Smith's works (which we said above had converted himself), and now the redoubtable champion of "$\pi = 3\frac{1}{8}$" himself descends into the arena, and must have given the doctor a pretty lively time of it, from the 13th of April to the 10th of June, 1871, as he assails him in six long letters, with diagrams, occupying nearly thirty-three octavo pages of print. Much of what had been written in the "Athenæum Budget of Paradoxes" is brought up and the Smithian value maintained, for though this incontrovertible solution "may not be admitted by you or Clifford (alluding to Prof. Clifford's paper 'On an unexplained contradiction in Geometry,' read before the British Association), or any such like mathematicians of the present age, I can afford *to bide my time* and trust to posterity doing me justice."

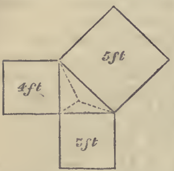
This is the main portion of the pamphlet; there is, however, occasional sparring, both on the part of Geometricus and of Mr. Smith, with the editor of (and some writers in) the *Mechanics' Magazine.* In an appendix a correspondent recommends J. S., "now poor De Morgan (who made you look so rediculous [*sic*]), has departed from this life, there are still some great men left—Prof. Sylvester. Try him, Smith; if you convert that gentleman to your $3\frac{1}{8}$, I will give in *humbly.*" Similar advice is given by the same writer in a second letter. The whole book is provocative of much amusement, and is quite of a piece with J. Smith's previous writings.

At the time of writing the previous remarks, we were under the impression that the "Budget" had exposed "Cyclometry and Circle Squaring in a Nutshell, by a member of the British Association for the Advancement of Science." This we at once found was not the case when the pamphlet was lent us by a friend. As we have devoted sufficient attention to Mr. Smith, we may shortly say that it is in octavo form, forty-four pages, and contains letters written between 24th October 1870 and January 1871; that is, immediately preceding the earliest date in the work we have noticed above. The correspondents are A. E. M. (is this the E. M. of the "Budget"?) and S. B. J. This last is another signature, we find, for the pertinacious Smith, who has figured elsewhere as "Nauticus," and wherefore not as "Geometricus"? The "Budget," though it does not discuss this *brochure* individually, has well demolished it by anticipation.

The close of the work is of a prophetical cast. "It is more than sixty years ago since an astronomer of recognised authority—who repudiated the idea that I could solve the problem of 'squaring the circle'—said to me: '*A bright day will have dawned on the astronomical world if ever the* EXACT *ratio of diameter to circumference in a circle shall be discovered.* The day will arrive when it will be said: 'In the nineteenth century of the Christian era—that remarkable century of invention and discovery—darkness still overshadowed the mathematical world. Scientific truth is, and ever has been, a plant of slow growth, but *Magna est veritas,* &c.'" It is to be hoped that the good man has not left his mantle behind, and that "Geometricus" and he were really one and the same.

Mr. John Davey Hailes has a place in the "Budget" (pp. 339, 340). He has not, so far as we know, touched upon the squaring of the circle, but possibly he is approaching that as the termination of his labours. We

have before us five slips. The first addressed "To the Scientific of University College, London, 1871. The Curve a Progressing Wheel Curve. A *wheel* four feet diameter with a *nail in its rim:* when *traversing forward*, the *nail will form a curve, and much longer than the circumference of the wheel. Query: How much longer?* and what must be the DIAMETER of a circle—*for a part of the said circle to* SHOW THE SAID CURVE?" And then there follow two other geometrical questions, the one to divide a trapezium into two equal parts. On the back is pasted (all in writing): "'A Problem within a Problem. History record (*sic*) Pythagoras discovered the demonstration of the three squares to surround a Right Angle Triangle; the Two smallest when added together to equal the largest of twenty-five square Feet. I *ask* to find the *Dimentions* to demonstrate the Three Triangles *dotted out* into proportionally *un*equal parts, that when added to each square they produce the same result; viz. Two to equal the largest Figure.



"N.B.—From the Figures 3, 4, and 5,
They can be wrought perfective."

Dated Oct. 2, 1871.

So far there is not much harm in J. D. H.

Another slip addressed, in ink, "To University College, London," is a bit of Hailesian Astronomy, and is, "Astronomy is Paradoxical." The N.B. is of interest in the light of the recent Transit Expeditions. "Those Transit of Venus measurers *that try for the distance* of the sun by Paradox, are in error. Let them try to find *the distance by demonstration. I say it can be done.*" The back of this page is devoted to "Astronomy and Longitude," and opens with the following doggrel:—

Science the Lock of Bible Truth, all the Works Divine,
Magnetic Key, unlock the Truth, and give *true Mean Time.*
In the Time of Joshua the *Sun* stood over Gibeon, the Moon over Azalon;
It was at the *Summer Solstice*, 2548 *from Adam*, DISPROVE WHO CAN?
The Sun began to go back on the Dial of Ahaz at 40′ past Noon.

This last line is in ink. We have then a rule to find true longitude at sea by time, sun, and moon. The spelling is a caution, and the calculation a fitting companion. This is dated Oct. 16th, 1870; the former page Oct. 6th, 1871. Our last document from Mr. Hailes was sent to the British Association, 1868, and is entitled "My Calculated Time of Christ's Crucifixion, A.D. 30," with a number of dates: "And now I challenge all the astronomers in the world *justly* to dispute my above-given times for the above-given events." Verily, Mr. J. D. H. believes wisdom will die with him. Stand down! you will not do much harm, Mr. Hailes.

Mr. W. Upton, B.A. (B. of P., pp. 256-258) brought out in 1872 (E. and F. Spon), "The Circle Squared: Three famous Problems of Antiquity geometrically solved—1. The Quadrature or Circle Squared. 2. Diameter definitely expressed in terms of the circumference. 3. The circumference equalised by a right line. The whole rendered intelligible for arithmeticians as well as for geometers, and adapted for the higher classes in schools of both sexes, private students, collegians, &c." We think the day is not very near at hand when this subject will occupy the minds of schoolboys; the present generation have enough to do to secure time for the study of the elements in the "Conflict of Studies" which is being now waged. Mr. Upton, if now living, must be in his 83rd year, and can hardly be expected to write much more on this subject. In his preface he acknowledges to previous failure with respect to the trisection, "but has it now complete." (De Morgan demolished his former essays; one we have seen appears to depend upon a construction familiar to practical geometers. The neatest of practical methods we believe to be that hit upon by J. J. Sylvester, F.R.S., recently referred to in the columns of NATURE.) His aim (in the quadrature) has been at *practical* utility, not rigidly subject to all the extreme niceties of mathematical strictness. The more general treatment he has not gone into on account of the expense (he has not apparently the purse of a James Smith or a "Kuklos") He pledges himself to the satisfactory fulfilment of all that the following advertisement sets forth:—"1. The *full* development of the Quadrature, analytically and synthetically, in its threefold aspect—arithmetical, geometrical, and trigonometrical; containing—2. The so greatly coveted and despaired of desideratum of equalising a circular segment by a rectilineal figure, which determines at once the complete solution of the Quadrature. 3. An appendix, with diagrams, &c." All this to be published on or before Jan. 1, 1873, or much sooner if a sufficiency of *early* subscription warrants it. This work we have not seen; we infer, then, that there were not found eighty subscribers of sufficient faith in Mr. Upton's word and sufficiently interested in the question to come down with the requisite 3*s.* 6*d.* each. What an opportunity for a liberal-minded man! A trifle of 14*l.* in the one scale, and in the other a vexed question set at rest. Nor is this all; he could, too, satisfactorily account for the real origin and inspired nature of mythology, but for the present he confines himself to the more immediate subject. "Certain Hebrew letters and Greek mythology, nay, even Scripture itself, seem to bear distinct allusions to matters touching upon the origin of the square and circle." He winds up with a singular excursus upon the Hebrew ל "distinctly representing the square and circle; the *level* line answering for *base* of the one and *diameter* of the other; the perpendicular for the adjoining side of the square; and the curve for a quadrant of the circle: each with an appearance of *string* at the extremity to intimate its being carried on to *completion.*" There is a "Supplement" (diagram and five pages, *free of charge*), from which an estimate of the value of the work may be got on the author's own showing: "The *precise* difference is therefore *not* equivalent to the impression of a pin's point; so that the author considers himself fully justified in looking upon the two areas as *arithmetically* equal. Moreover, in a *geometrical* solution, which is the *real* object of the problem, it is evident that so *invisible* a difference can have no possible effect."

Again, if he should be enabled to publish his proposed treatise, he can "show by three or four *distinct* but *concurrent proofs* that the circle itself not only admits of, but—more surprising still—actually suggests the formation of a right-lined figure equal in area to the circular segment belonging to each quadrant! This is what may indeed be esteemed as the *true secret*, the *virtual key* of the Quadrature; which the author will give to his readers and apply for them in the annexed diagram. He would have reserved the *fact* till he could have given it with the several proofs *complete*. But, as the fact itself, and its application to the diagram, ought to prove sufficient to produce conviction as to the truth of his assertion, he will proceed to apply it without further preface." We gather from his remarks that they turn upon the lengthening of a line by a *point* from a pencil which can make no *perceptible* difference in the geometrical construction. It seems only necessary to make this statement, and leave our mathematical readers to draw their own conclusions therefrom. (*To be continued.*)

INTERNATIONAL METEOROLOGY*

IT may be truly said that all the large questions which fall within the province of meteorology can only be adequately discussed by data collected in accordance

* Report of the Permanent Committee of the First International Congress at Vienna, for the year 1874. Printed by authority of the Meteorological Committee. (London: Stanford, 1875.)

with some well-devised scheme of international observation. What is required is the means of giving an accurate general representation of atmospheric pressure, temperature, humidity and aqueous precipitation, together with the movements of the air as indicated by the direction and force of the wind, and of the phenomena more immediately connected with these movements. Of these last, the more important are clouds, their species and motions, and electrical and auroral manifestations.

These large inquiries naturally fall into two groups. The first group is concerned almost exclusively with the great movements of the atmosphere, and it is the adequate investigation of these inquiries which is aimed at by the United States Government in their great scheme of observations made at the same *physical instant* over the whole globe. This scheme may be called *cosmopolitan*.

The second scheme may, in contradistinction to the above, be called *international*. It includes those inquiries which deal with the large and vitally important subject of comparative climatology, or a comparison of the climates of different countries and regions, and of their meteorology generally, inclusive of the great movements of the atmosphere over a restricted portion of the globe, such as the United States, the North Atlantic, or Europe. It is altogether essential to the discussion of those inquiries which fall under this head that the observations be made at the same *local time* and with instruments so constructed and placed as to give results strictly comparable with each other. It is evident that the exposure of the thermometers, including their immediate surroundings and height above the ground, must be uniform in all countries; otherwise the observations, being incomparable, cannot be used in questions of international meteorology.

Of the recurring meteorological phenomena which first and most imperatively require to be dealt with internationally, both from their importance in atmospheric physics and from their intimate bearings on animal and vegetable life, are the daily changes which take place in the temperature, humidity, pressure, and movements of the atmosphere from 9 A.M. to 3 P.M. With observations at these hours, together with the daily maxima and minima of temperatures from a network of stations well spread over Europe, we should be put in a position of being able to inquire, with some hope of success, into the influence exerted on meteorological phenomena by different latitudes and elevations; by the Baltic, Caspian, Black, Mediterranean, and Adriatic Seas, the English Channel, and the Atlantic; and by the Swiss Alps, the mountain ranges of Great Britain and Norway, the scattered hills of Ireland, the elevated plateaux of Spain, and the extensive flats of Germany and Russia. We entirely concur with Prof. Plantamour in thinking that during recent years the study of the movements of the atmosphere has been too exclusively directed with a view to the application of the results to the prediction of storms on the coasts and to the system of storm-warnings, and that other points of view have been completely abandoned (Report, p. 58). It is right, however, to add that this neglect may be excused on the ground that, as there is an entire want of uniformity in the hours and modes of observing in the systems of meteorology as pursued in the different countries of Europe, the data for the investigations of nearly all the important questions of international meteorology do not exist.

It was a widespread feeling of a requirement of uniformity of procedure in the prosecution of meteorological researches in different countries which led many to look to the Congresses of Leipsig and Vienna as likely to secure this result; and it is a matter of regret that at these meetings nothing was done to bring about uniformity in the hours and modes of observing. Doubtless the question of international observations was under discussion at Vienna, but the feeling of the delegates regarding it, as indicated by the state of the vote and the large number who abstained altogether from voting, was such that the only resolution arrived at was this, viz.: "That the best form of publication for the stations selected for international objects should be determined by the Permanent Committee, after consultation [*nach Anfrage*] with the directors of the central institutes." *

The matter accordingly came before the Permanent Committee at their meeting at Utrecht in September 1874, and after numerous explanations and a long discussion they unanimously resolved on a form for the publication of observations made for international objects (p. 7). This resolution is now being carried out by several of the countries represented at the Vienna Congress.

With reference to this resolution, however, it is to be remarked that (1) no provision was made by it for the observations being made at the same hours of the day; and as a matter of fact, the observations in the British Isles in connection with the scheme are 9 A.M. and 9 P.M.; in Russia, 7 A.M., 1 P.M., and 9 P.M.; in Norway, 8 A.M., 2 P.M., and 8 P.M.; in Italy, 9 A.M., 3 P.M., and 9 P.M.; in Austria, variously, and so on.

(2) No provision was made for securing uniformity as regards the vital question of the exposure and position of the thermometers, without which comparability is impossible.

(3) The forms adopted, both for the daily observations (p. 10) and for the monthly results (pp. 47-50) are in several respects defective, inasmuch as they do not include some of the more important data required in international inquiries.

The result will only be the printing of various sets of observations styled international, but which are not international—being, in truth, taken at their very best, merely national. By observations so made, no international question of meteorology can be satisfactorily discussed, and many international questions of the first importance, both practical and scientific, cannot even be attempted to be discussed.

When the subject was before the Vienna Congress, Plantamour urged the necessity of drawing a distinction between observations referring to the special study of the climate of each country, and those which are intended to indicate the simultaneous condition of the atmosphere over the whole surface of the earth (Report of Vienna Congress, p. 35). Until this be done, or until some such scheme as we have here indicated has been considered and agreed upon, it would be a mistake in meteorologists co-operating in carrying out a scheme which, while called international, completely fails to furnish the data required for international inquiries.

The only wise course the Permanent Committee can take at their next meeting is to rescind this resolution, as they have already virtually rescinded (p. 8) the resolution regarding rain-gauges all but unanimously passed at Vienna; and after consideration of the whole question to make provision that the instructions given them by the Vienna Congress with regard to this matter be carried out, viz., that no resolution be come to till after they have consulted the directors of the central institutes of the different countries; by which means they will furthermore be put in a position to propose a scheme which has been well matured, and therefore of such a character as will enlist in its behalf the general co-operation of meteorologists.

* Protocol of the Ninth Meeting of the Congress.

NOTES

WE can only this week join in the universal expression of regret at the death of Sir Charles Wheatstone, which took place at Paris on the 19th inst., at the age of seventy-three years. Inflammation of the chest was, we believe, the immediate cause of the sad result. The Paris Academy showed the greates

interest in Sir Charles during his illness, and previous to the removal of his body to London a religious service was held at the Anglican chapel in the Rue d'Agueneau, at which a deputation from the Academy was present. MM. Dumas and Tresca delivered addresses, which will be published in the *Comptes Rendus*. Sir Charles was buried yesterday in his family burial-place at Kensal Green. We shall give a memoir in an early number.

THE following changes are proposed to be made for the ensuing session in the Council of the London Mathematical Society:—Profs. Cayley and Sylvester, having served their term of office, become ordinary members, and the Council recommend that their places be filled up by Lord Rayleigh, F.R.S., and Mr. W. Spottiswoode, F.R.S. Dr. Henrici, F.R.S., and Mr. H. Martyn Taylor are put in nomination to fill up the vacancies caused by the withdrawal of Mr. R. B. Hayward and Mr. W. D. Niven.

THE anniversary meeting of the foundation of the French Institute by the executive directors of the first French Republic was celebrated as usual on the 25th of October. The president was M. Lefuel, a member of the Academy of Fine Arts: he was assisted by delegates of the other academies. M. Lefuel had to perform the duty of awarding the great biennial prize (see vol. xii. p. 526) for 1875 to M. Paul Bert, member of the Versailles Assembly and a Professor of Physiology at the Sorbonne, for his discoveries relating to the part played by oxygen in the act of respiration. Although the report was presented to the Academy of Sciences at a secret sitting, it is expected that it will be published shortly, as the noblest part of the award is not the gift of a handsome sum of money, but the reasons why the prize had been adjudged to the candidate. After this the report for the prize established by the celebrated Volney was read at full length, and three lectures were delivered. The last one was by M. Mouchez, the new member of the Academy of Sciences, on the Venus Transit Expedition to St. Paul. The brave captain read it in plain sailor-like fashion and with much humour, and met with a most favourable reception.

THE Congress of Meteorologists, which was to have been held at Poitiers at the end of October, has been postponed for a month, and will be held on the 19th, 20th, and 21st Nov. next. It is to be styled the "Meteorological Congress of Western Oceanic France." All the departments situated within the space bounded by the Dordogne, the Atlantic, the Loire, and the central mountains of France, together with the Council of the Observatory of Paris, will be represented on the occasion. Among the representatives who will be present are MM. Belgrand, Renou, de Touchimbert, de Tastes, de la Gournerie, Lespiault, Raulin, and Leverrier, who will preside. Delegates from the departments of the regions adjoining are invited to be present to assist in laying the basis of a common understanding among the different regions in matters referring to meteorology.

A REUTER'S telegram, dated Rome, October 23, states that Mr. J. Norman Lockyer and Major Festing had arrived there, deputed by the British Government to propose to the Italian Government to send to the Exhibition at South Kensington in 1876 a collection of the instruments used by Italian professors in recent important astronomical observations.

PROF. BOYD DAWKINS, F.R.S., who left early in June for Australia, has returned to England *viâ* the Rocky Mountains Railroad and New York. The duties of the Geological chair at Owens College have been taken during his absence by Mr. C. E. De Rance, F.G.S., of the Geological Survey of England and Wales.

THE Commission on Vivisection have been meeting constantly during the past and present weeks, and have examined a considerable number of witnesses.

IT is announced that the preliminary works for the Channel Tunnel are to be commenced this week near Calais. A shaft will be sunk to a depth of 100 metres.

As zoologists are not likely to look in the Transactions of the Society of Biblical Archæology for anything concerning their own studies, especially in a paper entitled "The Tablet of Antefaa II.," it may be as well to mention that this paper, by the learned president of the society, Dr. S. Birch, of the British Museum, in the last issued number of the Transactions (vol. iv. part i.), contains an interesting account, with numerous illustrations, of the different breeds of domestic dogs kept by the ancient Egyptians. It would appear from the drawings preserved on the walls of the tombs, that the variations of this animal in those early days were quite as well marked as those that may be seen at a modern dog-show.

THE Geographical Society of Paris held its first semi-monthly meeting of session 1875–1876 on the 20th of October; more than 190 members were present. The chair was filled by M. Delesse, the president of the central section. The correspondence was unusually long and interesting, and it is evident that geographical studies are advancing in France.

AN expedition under M. Largeau has been fitted out by the French Chambers of Commerce and private subscriptions to proceed to Rhadames from Algiers, and open communications with Soudan and Timbuctoo. The expedition is already on its way. A French paper, the *Rappel*, has sent a special correspondent with M. Largeau; this is perhaps the first time that any French journal has taken such a step.

NEWS has been received from the French Gaboon expedition under MM. Marche and Brazzi. These two gentlemen had arrived at St. Louis and selected a number of Laptots to accompany them in their excursions. The expedition is to last several years. A Government steamer was to conduct them from St. Louis to Gaboon.

A FRENCH expedition is being fitted out to make a "Tour du Monde" in ten months. The excursionists are to visit India, Japan, the interior sea of Japan, Chinese ports, Australia, &c. A special library, with instruments, will be placed on board. The members of this expedition will be exclusively of the male sex. The fare is to be 800*l*., everything included. The Geographical Society will superintend the management of the enterprise, although it will be supported by private funds and is altogether a private speculation.

THE Marquis de Compiègne, the African explorer, has ftle for Cairo, where he has been appointed by the Khedive the acting secretary of the newly-established Khedival Geographical Society.

THE *Times* special correspondent at Suez, under date Oct. 26, telegraphs as follows with regard to African exploring expeditions:—"Despatches of the 14th and 20th of August, received yesterday, report that Lieut. Gordon was in Appudo with the steamer. The Kabba Regga people were intriguing. Linant saw Stanley, who had traversed Lake Victoria from south to north alone, at M'tesas. Cameron was at Tanganyika for eight months, trying to go the western route between Uganda and Zanzibar, which was interrupted by the Karaque tribe two degrees south. Subsequent despatches report the death of Linant in a fight with the Kabba Regga people. Lake Victoria is very large, and full of isles."

WE announced some time ago that the Italian Geographical Society was organising an expedition for African exploration. The Society has already raised 70,000 lire, which it expects its honorary president, Prince Humbert, to raise to 100,000 lire (4,000*l*.) The *Times* Milan correspondent sends additional

details. The Italian expedition is to be divided into two sections; one is to set out from the Gulf of Aden for Tajurra, or Berbera, or some other port on the eastern coast of Africa, proceed to Shoa, and thence to Kaffa; and from this great slave market it would make its way through an unexplored region to the central lakes, studying the hydrographic course of the eastern Nile. The other party would take its start from Khartoum, and, exploring the region lying between Monboottoo and the Victoria Nyanza, push on, if it be practicable, as far as the great valley of Lualaba, discovered by Livingstone. The first-mentioned section of the expedition will be commanded by the Marquis Antinori, one of the vice-presidents of the Geographical Society, a distinguished ornithologist, who has spent several years in Central Africa, and whose travels in that region have won him a widespread reputation. He is now about seventy years old. The other section will be under the guidance of Ademoli, also familiar with the districts he proposes to explore, a young, brave, and strong man, known for his enthusiasm in the work of discovery, to which he has devoted himself.

FURTHER correspondence from members of the English Arctic Expedition confirms the news brought home by the *Pandora* that an unusually easy passage had been made to within 100 miles of the entrance to Smith Sound, and it is even expected that if circumstances continue equally favourable the pole may be reached this year. The expedition is not expected home, however, till the end of 1877. On July 23, the *Alert* met with the first accident; she went on shore on a small island off Kingitok, but was floated off without injury as the tide rose.

LAST week we gave an abstract of Lieut. Weyprecht's paper on the principles which ought to guide Arctic exploration. Now it is stated that the Scientific Commission appointed by the German Government has reported, we believe in consequence of this paper, against the expediency of a fresh Polar Expedition, but has recommended the establishment of stations of observation in both hemispheres.

A PAPER of considerable interest, by Dr. Daniel Wilson, has been reprinted from the *Canadian Journal*. Its title is "Hybridity and Absorption in relation to the Red Indian Race." Dr. Wilson, while of course admitting the patent fact that the American Indians, like most other barbarous races, have largely melted away before the white races, thinks that in accounting for this too much stress has been laid on mere extermination. He adduces data to prove that a very considerable proportion of red blood has been absorbed into the whites of North America, and that especially in the Canadian Dominion this shows itself in the physiognomy of all classes. It would be difficult, he believes, to find either in the United States or in Canada many Indians of pure breed. In Canada half-breeds are the almost universal representatives of the former Indian tribes, and many of them are settling down to a steady civilised life. In short, Dr. Wilson has what appears to us a well-founded belief that the aborigines of North America are being gradually absorbed into the dominant race, and that in course of time they will have become as integral a part of the population as any one of the elements which may be traced in the population of Europe, and that their physical and mental characteristics will tell upon the American character—just as Melanochroic attributes have left marked traces on the intrusive Xanthochroic European peoples. Fortunately the evidence gives good ground for believing that this influence is decidedly good, physically and intellectually. The characteristic "Brother Jonathan" face, which is generally attributed to influences of climate, soil, food, &c., Dr. Wilson is inclined to attribute to a decided admixture of Indian blood; probably both causes have had to do with it. Dr. Wilson rightly advocates the most judicious and humane treatment of the Indians both by the U.S. and Canadian Governments.

THE opening lecture of this session's Manchester Science Lectures for the People, the charge for admission to which is only one penny, was given on Tuesday last by Capt. Davis on "Arctic Discoveries." The other lectures are as follows:—Prof. Rucker on "Soap Bubbles;" R. Bowdler Sharpe, F.L.S., on "The Birds of the Globe;" Prof. J. Martin Duncan, F.R.S., on "The Great Extinct Quadrupeds;" Prof. Thorpe, F.R.S.E., on "Cavendish and his Discoveries;" Prof. Ferrier, F.R.S., on "The Functions of the Brains;" Prof. Henry E. Armstrong, on "Food;" William Pengelly, F.R.S., on "The Age of the Men of Kent's Cave." Part II.

A CIRCULAR, signed by Mr. W. Melton, who is judicial assessor on the Gold Coast, was issued last month by order of the Governor, "To the native kings, chiefs, captains, headmen, and principal men of the Gold Coast Colony," pointing out that "it is most desirable that the Gold Coast Colony should be well represented at the forthcoming International Exhibition at Philadelphia," and asking them to give all assistance in their power in sending contributions and collecting articles illustrative of the countries and districts over which they preside. Mr. Melton has issued a classified schedule of articles suitable for exhibition. Department I. Materials in their unwrought condition, mineral, vegetable, and animal. II. Materials and manufactures, the result of extractive or combining processes. III. Textile and felted fabrics, apparel, costumes, and ornaments for the person. IV. Furniture and manufactures of general use in construction and dwellings. V. Tools, implements, machines, and processes. VI. Boats and sailing vessels. VII. Apparatus and methods for the increase and diffusion of knowledge. VIII. (Not represented). IX. Plaster and graphic arts. As the arrangements are, we are told, in vigorous hands, and it is announced to the "native kings, chiefs," &c., that they may be reimbursed for any outlay they make, it is expected the collection from this colony will be extensive and interesting. In connection with this, Schweinfurth's "Artes Africanæ," just published, is of interest: we shall give an early notice of this work.

IN reference to a recent note, p. 461, we are glad to see that at the Brighton meeting of the Social Science Association a resolution was passed requesting the Council to communicate with the authorities of the Science and Art Department of the Privy Council, suggesting the desirableness of making "Foods, their uses and preparation," the subject of examination.

IT seems that a good deal of the tobacco used in the manufacture of the so-called Havana cigars in Germany comes from Colombia, principally from Jiron, Ambalema, and Palmira, and that its quality is not of the first mark. Tobacco is also cultivated in the State of Bolivar, and is exported for a similar use.

MR. AMOS SAWYER contributes a short though interesting article to the *Transactions of the Academy of Science of St. Louis* on the cause of climatic change in Illinois. During the last twenty years, he says, the climate has been slowly, but surely, changing from wet to dry; and although this change has been beneficial from a sanitary point of view, agriculturally considered it has been, and will hereafter prove to be, a great obstacle to the successful cultivation of the soil. The most important agent, in Mr. Sawyer's opinion, is what he calls the aqueous agent. The chemical and mechanical effects of this agency are constantly at work, and the result is plainly visible in the deepening of the channel of all the small streams. At the present time all the prairie land is in cultivation, or used as pasture; the ponds and small lakes have become so filled up that they contain less than

half the former amount of water; the stock now consumes the reeds and marsh-grass, exposing the water to the direct rays of the sun, thereby promoting evaporation, so that by midsummer even the mud in their basins has dried to a hard crust, and a change in the temperature during the heated term brings, as a rule, a cool, dry atmosphere instead of rain, as in former years. Mr. Sawyer goes on to describe the large increase in the consumption of water by domestic animals. In this State at the present time there are at least "three million horses, cattle, and mules, and five million hogs and sheep, and they will consume not less than *seventy million gallons* of water every twenty-four hours—quite a lake of itself." This, surely, must be a misprint, or American animals are very thirsty beings!

A CORRESPONDENT of the *Aberystwith Observer*, the Rev. James Lewis, of Llanilar Vicarage, writes as follows to that journal:—"Whilst returning from service at the parish church of Rhostie, about 8.15 P.M. on Friday, the 24th ult., in company with two members of the congregation, my attention was called to a remarkably strange phenomenon. In walking across a field on the farm of Cwmclyd, it was noticed that our footsteps were marked by a peculiar light, which could be traced back for several yards, each footprint being as distinctly marked on the ground as when one walks in snow. When we got into the adjoining field the light disappeared until we came near to the end of it, when it was observed that our footsteps were again marked by the same luminous appearance. In colour the light was similar to that of phosphorus rubbed on a wall in a dark room, or a mass of glow-worms, of which insect, however, there was no trace on the surrounding ground."

IN the *Bulletin International* of the Paris Observatory for the 21st inst. appears an interesting note by M. de Lagrenè on the thunderstorms which have occurred in the department of Haute-Marne during the seven years ending 1874. In this department the average annual number of thunderstorms is 87, of which 25 occur in July, 20 in May, and 14 in June. During the six months from October to March inclusive the mean annual aggregate is only six. The geographical position of Haute-Marne is an important one as regards these electrical phenomena, about which so very little is yet known, and this Departmental Meteorological Commission is doing good service in contributing its share in the work of collecting data on the origination, intensity, and rate of propagation of thunderstorms, and the manner in which they are influenced by the winds prevailing at the time, by the contour of the ground, and by forests.

WE have received the first number of the *Iowa Weather Review*, September 1875 (pp. 20), which has just been started by Dr. Gustavus Hinrichs, from which we learn that the system of rain observations set on foot by him, as explained in a recent notice in NATURE, is only the beginning of a more complete system by which it is hoped that the whole meteorology of this important State will be adequately and systematically observed and turned to practical account in the interests of the people. There is an idea shadowed out in the prospectus by which, if gone into and developed, the United States will be divided into meteorological districts or regions similar to what is now being done in France, and which is really the only means by which many highly important questions can be properly investigated. Dr. Hinrichs gives the monthly rainfall for the months of past years' observations, as well as the monthly means, at six places in the State, and sends a carefully compiled monthly report of his own observations made at the laboratory of the Iowa State University at Iowa City, the amounts and averages of each month being compared with the results of previous years' observations.

THE additions to the Zoological Society's Gardens during the past week include a Binturong (*Arctictis binturong*) from Malacca, presented by Captain A. R. Ord; a Wood Owl (*Syrnium aluco*), European, presented by Mr. F. Brannd; a Missel Thrush (*Turdus viscivorus*), European, presented by Mrs. Watson; a Grey Wagtail (*Motacilla boarula*), seven Picked Dog Fish (*Acanthias vulgaris*), European, purchased; a Cape Buffalo (*Bubalus caffer*) born in the Gardens.

ON THE VARIATIONS OF THE ELECTROMOTIVE FORCE OF A NEW FORM OF LECLANCHÉ'S CELL

A NEW form of Leclanché's cell has been constructed by Dr. Muirhead, and is supplied by Messrs. Warden, Muirhead, and Clark.

In this form the carbon and black oxide of manganese are packed in the outer case around a glazed porcelain jar perforated with holes about one-eighth of an inch in diameter, the jar containing a zinc plate bent into the form of a cylinder.

The advantages gained are that a much larger surface of zinc is exposed and the perforations of the jar are in no danger of being choked up by deposition of chloride of zinc.

The following results may be of some interest as showing how the electromotive force of this cell varies when it works for a considerable time through circuits of various resistances.

A circuit of known resistance was formed, through which the battery worked, and two points in this circuit were attached to the poles of a sawdust Daniell's cell, so as to form a branch circuit in which a galvanometer was included; one of these two points was then moved along the circuit until the galvanometer showed that there was no current through the Daniell; when this is the case the E.M.F. of the battery is to that of the Daniell in the same ratio as the resistance of the whole circuit to that of the part between the points of attachment of the Daniell.

A set of coils was used by which the resistance could be adjusted to ·05 ohm, and by adding one of these coils to the common part of the circuit (so that the resistance of the whole circuit did not remain quite constant) a very small change in E.M.F. could be measured.

The current through the Daniell was always very small, and as it passed sometimes in one direction and sometimes in the other, the difference between the potentials of its poles must have remained very nearly constant.

In the circuits of small resistance it became necessary to take account of the internal resistance of the cell. This was found (for these circuits) to be generally between ·45 and ·46, it was subject to slight variations between these limits, but rarely exceeded them when the battery was worked for only two or three hours, although on leaving the battery circuited through 30 ohms for 20 hours it rose as high as ·525. The lowest resistance observed was ·420 when working through 10 ohms.

The following tables give the E.M.F. of the battery in terms of the Daniell:—

When the cell had been circuited through 10 ohms for 2 min., the E.M.F. was 1·320; for 3½ min., 1·314; for 5½ min., 1·304; for 13 min., 1·292; for 23 min., 1·283; for 34 min., 1·277. For 1h. 1m., 1·266; for 1h. 31m., 1·256; for 1h. 56m., 1·254; for 2h. 11m., 1·253.

When circuited through 20 ohms for 2½ min. the E.M.F. was 1·3465; for 4 min., 1·3420; for 5½ min., 1·3385; for 13 min., 1·3315; for 18 min., 1·3270; for 30 min., 1·3215; for 46 min., 1·3155. For 1h. 1m., 1·3095; for 1h. 22m., 1·3045; for 1h. 31m., 1·3035.

When circuited through 30 ohms for ½ min. the E.M.F. was 1·3702; for 2 min., 1·3608; for 3 min., 1·3585; for 4 min., 1·3562; for 10 min., 1·3500; for 20 min., 1·3446; for 26 min., 1·3404; for 28 min., 1·3391. For the next four minutes the E.M.F. was very unsteady. For 32 min., 1·3411; for 33 min., 1·3398; for 39 min., 1·3364. For 1h. 3m., 1·3318; for 1h. 14m., 1·3292; for 1h. 28m., 1·3211; for 23h. 30m., 1·2810.

When circuited through 100 ohms for 7 min. the E.M.F. was 1·4415; for 10 min., 1·4417; for 20 min., 1·4423.

No further change was observed at the expiration of one hour.

When the cell (after being insulated for 21 hours) was circuited through 3,200 ohms, after 1 min. the E.M.F. was 1·448; after 3 min., 1·450; after 18 min., 1·454; after 38 min., 1·459.

When the cell was short circuited through itself for two minutes the E.M.F. fell from 1·407 to 1·235. (These measurements were taken with the cell working through 3,500 ohms.)

On being circuited through 3,500 ohms for 23 min., the E.M.F. rose to 1·383.

More observations were made than those here recorded, readings being taken in some cases every minute, but the only irregularity observed was that noticed when working through 30 ohms.

In these experiments we may notice that when the battery was short circuited through 10 ohms, the E.M.F. after the first two minutes fell $4\frac{1}{4}$ per cent. in $1\frac{1}{2}$ hours; through 20 ohms it fell 3 per cent.; and through 30 ohms, $2\frac{3}{4}$ per cent., in the same time. But when circuited through 100 ohms and upwards, the E.M.F. increased with the time,* the percentage increment increasing with the resistance. Hence it appears not unlikely that there may be some resistance through which the E.M.F. will remain absolutely constant; should this be found to be the case, and should this resistance always remain the same, the battery will be very valuable when required to work through such a circuit.

It may be remarked that, in accordance with the usual rule, the E.M.F. of the battery increases with the external resistance.

The cell was insulated for a considerable time previously to commencing each set of experiments. S. A. SAUNDER

Cavendish Laboratory, Cambridge

* As the coils were arranged in boxes, and so could not be kept at a uniform temperature, it was thought that this might be due to unequal heating. It was found, however, that the alteration in the ratio of the resistances due to this cause was such as to cause the E.M.F. to appear to increase less than it really did by about ·005 per cent. in one hour, which would not affect the results in the tables.

OUR BOTANICAL COLUMN

EXOTIC TIMBER-TREES IN MAURITIUS.—Amongst useful plants that have been introduced into countries distant from their native habitats, the timber-trees are of some interest, inasmuch as beyond the proof of their establishment in foreign climates and soils, some time is needed to prove what effects the change may have on the quality of the timber itself, for on this alone depends the value of the experiment in a commercial point of view. It is, however, satisfactory to learn that some well-known timber-trees that have been introduced into Mauritius through the instrumentality of the Royal Gardens, Kew, are in a flourishing state. Thus, the mahogany (*Swietenia mahagoni*), one of the oldest and most valued of furniture woods, has made a very rapid growth, forming, in three or four years after the sowing of the seeds, trees about twenty feet in height, with stems from three to six inches in diameter. In India, likewise, the mahogany thrives well, and as a proof that the wood is valuable, it may be stated that a tree blown down in the Calcutta Botanic Gardens during the great cyclone realised over 1,000 rupees. Logwood (*Hæmatoxylon campeachianum*) is reported also to grow well in Mauritius, and it moreover makes excellent hedges, far superior, it is said, to hawthorn. It has been quite naturalised on the hills and waste lands in the vicinity of Port Louis, and annually produces large quantities of seeds.

BAMBOO AS A PAPER MATERIAL.—A good deal of attention has of late years been directed to new materials for paper making. Esparto has been one of the most successful of modern discoveries, and now we are told that the supplies of that useful substance are decreasing and must in course of time fail altogether. Where then shall we look for our future supplies is a question that has agitated many minds, and which has been answered frequently by references to the numerous fibre-producing plants of both the East and West Indies, Australia, &c. We know that in India the fibrous barks of many trees, and notably that of *Daphne papyracea*, are used for paper making; while in China and Japan, where paper is used for a much greater variety of purposes than it is in England, the barks of *Broussonetia papyrifera* and *B. Kæmpferi* are made into paper of every conceivable and indeed inconceivable form; for some specimens are so much like leather that it takes a critical eye to detect it, and others are such good imitations of crape and muslin that the same care is needed to determine their true nature. That the Chinese and Japanese excel in paper-making cannot be doubted, when we consider all their manufactures, and more especially that fine quality of paper known as India proof paper, which they make from young bamboos. The bamboo as a paper material in this country is a comparatively modern introduction; indeed, we can hardly say that it has actually become a commercial article, but there seems no reason why the stems of the bamboo, which in tropical countries is one of the commonest and fastest growing plants, should not be converted into *half stuff* and sent to England in almost any quantity. To make this material better known has been the aim of Mr. Thos. Routledge, in a little pamphlet of forty pages, which he has just issued. Mr. Routledge is no doubt able to speak with authority on the details of manipulation of paper stock in a practical, if not in a scientific sense; but it is not our intention to follow him through the subject, but simply to refer to some facts quoted by him as an illustration of the suitability of bamboo as a paper-making material, and to endorse to a certain extent some of those facts and suggestions. Thus, with regard to supply, it is well known that in most tropical countries bamboos of various species flourish to a considerable extent and are to the people of immense value, furnishing them with numerous articles of daily necessity; then again their growth is so rapid as to form a constant supply. With regard to the rate of growth, we read that at Gehzireh, the gardens of the Khedive of Egypt at Cairo, it has been known to grow nine inches in one night. At Sion House, the Duke of Northumberland's, stems of *Bambusa gigantea* have attained the height of 60 feet in twelve weeks; while at Kew, *Bambusa vulgaris* is recorded as growing in favourable seasons at the rate of eighteen inches per day; and at Chatsworth the same species has attained the height of 40 feet in forty days. For the purpose of paper-making the stems should be cut down in a comparatively young state, before they become too woody, and reduced to pulp or half stuff before being sent to this country.

SCIENTIFIC SERIALS

American Journal of Science and Arts, October.—This number contains the following two papers read at the Detroit meeting of the American Association for the Advancement of Science.—Address of Dr. John Le Conte, the retiring president.—A comparison between the Ohio and West Virginia sides of the Alleghany coal-field, by E. B. Andrews.—There is also a reprint from the *Philosophical Magazine* of Mr. Mallet's paper on the temperature attainable by rock-crushing.—In an obituary notice of Sir Charles Lyell, there is introduced an extract of a letter from Dr. Mantell to Prof. Silliman, in 1841, describing how Mantell and Lyell first met.—The original articles in this number are: On the arithmetical relations between the atomic weights, by M. D. C. Hodges.—A note by L. F. Pourtales recording the corals found at the Galapagos Islands.—On instinct (?) in hermit crabs, by Alexander Agassiz. This records how young crabs reared without shells during their growth, "made a rush" for them as soon as they were placed in the tank where they were living.—On Southern New England during the melting of the great glacier, Part ii. We reserve our notice of this till the paper is completed.

Geological Magazine, October.—The original articles are: The Geology of Central Sumatra, by R. D. M. Verbeek (superintendent of the Geological Survey of Sumatra). This is stated to be the commencement of a series of articles on the subject, published with the authority and assistance of the Dutch-Indian Government. The oldest rocks in this part of Sumatra are granites, granite-syenites, and syenites. Then follow sedimentary rocks classed as of Carboniferous or Permian age. "This oldest sedimentary formation of Sumatra can be divided into two parts. The lower portion consists of clay-slates with auriferous quartz-veins, marl-slates and siliceous schists; the upper part consists only of limestone, with some small beds of schists." There are quartz porphyries and greenstones, the age of which is not known, but they are probably older than the tertiaries. The tertiaries themselves are divisible into five groups. The trachytic rocks are younger than the tertiaries. Three clearly drawn sections illustrate the paper, and a list of principal papers on the geology of Sumatra is given.—On the origin of Coums, by J. G. Goodchild. That many of these cauldron-like hollows are due to the eddying of ice is the argument of Mr. Goodchild.—Dr. Walter Flight continues his "History of Meteorites."—Dr. Thomas Wright records the occurrence of the genus *Cotylederma* in the middle lias of Dorsetshire.

Poggendorff's Annalen, No. 8.—This number commences with an investigation by Karl Müller as to the pitch of the transversal vibrations of bars of gypsum, when these are saturated with different droppable liquids. It appears that the liquid does not act as a weighting of the bar, but enters into union with the molecules of the substance, diminishing the co-efficient of elasticity; and this is manifested in a fall of pitch, the fall having

been greatest (in the cases studied) on imbibition with water, less with oil, and least with alcohol. It is greater the higher the specific gravity of the liquid. The change of pitch with alcohol and with oil was more regular than with water, and the regularity was almost perfect, if the changes of tone of the saturated bars were compared with one another, and not with the dry state.—Herren Kundt and Warburg continue the account of their researches on friction and conduction of heat in rarefied gases. Having experimented with air, hydrogen, and carbonic acid, they here show that the coefficients of friction are independent of pressure within the limits 750 mm. and 1 mm. mercury. With rarefaction under 1 mm. they could not sufficiently remove the vapour.—Dr. Oberbeck describes a method of determining the conductivity of liquids for electricity. The principle is briefly this:—Connect the ends of an induction spiral with a spark micrometer. Then, with a certain strength of inducing current, a separation of the balls may be found, at which sparks continuously pass; but on slightly increasing the interval they cease to pass. Next, connect the two ends of the spiral also with an uninterrupted branch line; it will depend on the resistance of this and the intensity of the inducing current, whether sparks will pass between the balls. If the line is short and of metallic wire, the spark current disappears, however near together the balls may be brought; but if it consist of thin tubes of badly conducting liquids,, a small approximation of the balls will reproduce the sparks. Thus the conductivity of liquids may be compared.—An improved construction of lightning conductors for telegraph-wires is described by M. Schaack. The line-wire and that of the telegraph-apparatus are connected respectively with two binding screws on pieces of wood which form opposite rims of a rectangular tin case containing water, and a loose coil of German silver wire, covered with caoutchouc, connects the binding screws through the water. The wire of the telegraph-apparatus, after passing through the apparatus, returns to the case, which is connected to earth.—There is also an account of M. Le Cour's valuable proposal for employment of tuning-forks in electric telegraphy.—M. Schneebeli continues his researches on the attraction and separation-time of electro-magnets, and takes occasion to describe Hipp's chronograph as recently improved.—Among the remaining papers may be noted one by M. Sauer, describing some interesting experiments on the visibility of ultra-violet rays, and another by M. Holz, on transformation of electric currents of low tension into disruptive discharges of higher tension.

Der Naturforscher, September.—This number contains some interesting observations made at hot springs in Italy, by M. Hoppe Seyler, on the upper temperature-limit of life. At Ischia, on Monte Tabor, he found green algæ on the widening sides of a fissure through which rose hot steam, and the thermometer showed 64°·7 C. This was higher than in the case of algæ growing in water; at Lipari, the limit of temperature for such seemed to be about 53°.—In a lecture by M. Brefeld (given in outline), on the biology of yeast cells, the author describes the process of fructification, which is asexual, and tells how all his attempts to produce it with cultivated yeast were in vain; with the natural yeast used in fermenting wine he always succeeded.—The peculiar condition of vegetation on the sides of lakes, and banks of rivers, owing to reflection of light and heat from the water, and constancy of temperature of the latter, is illustrated by Dr. Hoffmann from a number of phænological phenomena on Lake Maggiore, the lakes of Geneva, Zurich, and other localities.—M. Felix Plateau investigates the process of digestion in insects; and M. Böhm records the gases resulting from fermentation of dead marsh and water plants; finding that these gases sometimes consist of carbonic acid, nitrogen, and hydrogen, sometimes of marsh gas with the first two. There is, he thinks, a sort of conflict between the two fermenting processes.—From accounts of the aurora of Feb. 4, 1872, Donati is led to the striking result that it was observed in different regions of the earth not in the same physical moment, but everywhere at the same local hour; as is the case with celestial phenomena which do not share in the earth's rotation. The aurora appeared first in the extreme east of the southern hemisphere, in Eden and Melbourne, and shortly after in China, whence it travelled over Asia, Europe, and America. Donati attributes the phenomenon to electro-magnetic currents from the sun.—There is also a paper on the movements of Encke's comet, by Dr. von Asten; and among other subjects treated are: insular giant reptiles, diathermancy of moist air, beats of musical tones, and the formation of meteorites and vulcanism.

Zeitschrift der Oesterreichische Gesellschaft für Meteorologie, Sept. 15.—The first paper in this number, by Herr Luedicke, of Gotha, gives an account of observations made by him on the tidal action of the moon in its several phases on the atmosphere, during a period of 100 revolutions, from Jan. 1867 to Feb. 1875. The differences between the mean heights of the barometer in the four quarters are small; the greatest difference, viz., that between the second and last quarter, amounting only to ·57 mm. The various tables given by Herr Luedicke agree, however, in pointing to the following conclusion:—That pressure diminishes with the waxing and increases with the waning moon. Comparing the means of readings nearest perigee with those nearest apogee, he finds (1) that pressure is less at perigee than at apogee; and (2) that pressure in apogee is less about the time of the equinoxes, greater about the time of the solstices, than in perigee. Lastly, taking the mean variations from the monthly mean of all observations taken in apogee and in perigee, that in perigee the excesses happen at the quadratures, the deficiencies at the syzygies; and inversely, in apogee the excesses happen at the syzygies and the deficiencies at the quadratures. These variations are rather large: for instance, in apogee at the first quarter the deficiency is 3·83, at the last 5·16 mm. It appears from all his results that the effect of the moon upon the atmosphere is exactly contrary to that produced upon the ocean, pressure being lower when the moon is near than when it is far from the earth. Tables of the varieties of weather in the four quarters are given at the end of the paper.—In the "Kleinere Mittheilungen" two articles appear on Mr. Blanford's observations in India.

Bulletin de l'Académie Royale des Sciences de Belgique, tom. xl. No. 7.—In the "Classe des Science" are the following articles:—A brief note by M. Emm. Liais, on the parallax of the sun.—A note on *Drosera rotundifolia*, by M. Ed. Morren, to which is a plate showing the structure of the different kinds of glands and hairs. M. Morren describes the capture of two insects, and especially draws attention to the way in which the glands curve in "prehension," like an animal's tongue.—M. G. Dewalque contributes a short article on lightning strokes.—M. E. Quetelet records the dip of the needle at Brussels in 1875, determined on two dates—

April 14, between 10.30 A.M. and 12.30 = 66° 56′·6
May 22 ,, 11 ,, 12 = 66° 58′·8

The diminution is at the rate of 2¼ min. per annum. The declination has been determined on three days as follows:—

June 9, between 11 A.M. and 12.30 = 17° 24′·4
,, 23 ,, 10.30 ,, 11.30 = 17° 25′·1
,, ,, ,, 2 ,, 3 = 17° 26′·3

The decrease is 8¼ min. per annum. This last observation was by M. Hooreman.—M. L. Saltel contributes two mathematical papers.

THE *Journal de Physique* for September commences with a paper by M. Marey on the movements of liquid waves in elastic tubes, a phenomenon exemplified in the circulation of the blood. He applies his graphic method: passing an indiarubber tube through a series of boxes in such a way that when it expands at successive points, through passage of a wave, it presses upwards the membrane of one of the well-known monometric capsules. These successive movements are indicated, as usual, on a rotating blackened cylinder. He explains the various phenomena of positive, negative, secondary, and reflected waves, harmonic vibrations, &c.—M. Govi follows with an account of some experiments meant to prove that induced electricity of the first kind has tension. A new instrument for determining, more especially, the density of solids of which only small fragments are had, is described by M. Paquet. It is like a Baumé areometer, consisting of a pear-shaped air-vessel, weighted at the lower, narrow end with a bulb of mercury, while a thin tube rises from the upper part, surmounted by a short wider tube closed below, into which the solid fragment is put, with water. Both tubes are graduated. The density is ascertained after immersion of the instrument in water.—A valuable paper by M. de Romilly treats of the conveyance of air by a jet of air or steam, issuing from one ajutage, and entering another; several varieties of ajutage having been experimented with, and in different positions. He finds, *inter alia*, there is an integral conservation of the quantity of motion, with a conical receiver of 5 to 7 degrees, small section towards the jet-ajutage, which is placed at an exterior distance, given by the form of the jet, making a cone of about 15 degrees, the jet-orifice occupying the summit, and the receiver-orifice the base.

—M. Righi contributes a paper on an electroscope with very sensitive dry piles; its use in some experiments on electricity of contact, and on the electromotive force of heat. The journal concludes with a number of abstracts from other serials.

Bulletin de la Société d'Anthropologie de Paris, 1875.—In fascicule 4eme, tome ix. 11^{e} série, M. G. de Rialle, in considering the present state of our knowledge in regard to the races inhabiting Central Asia, invites travellers to turn their attention to the study of the Herazehs, who occupy the most easterly spurs of the chain of the Paropamisus, and who still preserve many traces of the habits and traditions of the northern steppes, from which they have probably been driven by Mongol invaders. Little is known of these people, who are dreaded by the Afghans for their bravery and ferocity, and who regard themselves as allied to the Calmuks of Cabul. In the course of the discussion on M. de Rialle's paper, Madame C. Royer drew attention to the important service which travellers might render to the sciences of Comparative Ethnology and Anthropology, if they would make young children, in whom distinctions of race are most prominently exhibited, the special objects of their observations. M. Topinard, in conclusion, called upon the members of the Central Asiatic Expedition to discover whether any survivors could still be traced of the fair-skinned people described by the Chinese as inhabiting the western portion of the central plain of Asia two or three centuries before our era, and as having green eyes and red hair. Tchihatcheff asserts that he has met with red-haired individuals among the nomad Turkomans of Asia Minor, and Desmoulins believes that they are typical representatives of the primitive Turks.—In the same number of the *Bulletin* we have a summary of the views entertained by M. A. de Bertrand and others in regard to the definition and classification of prehistoric eras. M. de Bertrand, in considering the age of the Reindeer of Thurigen, suggests that we may refer the period of the introduction of polished stone into Gaul to about 3,400 years before the Christian era, and that we may possibly assume 2,000 years as the maximum of the duration of this age. His attempted determination of these periods was strongly opposed by MM. Leguay, Roujon, and others.—Several interesting reports have been laid before the Paris Society, of the numerous caves and grottoes which have been examined in the course of 1874, by M. Louis Lartet, Lagarde, and other members. The finds at Cumières, near Verdun, have been especially rich, while the explorations made at the cemetery of Curanda (Aisne) are valuable from the great variety of objects intermingled with the human remains, but owing to the successive occupation of the ground by Gallic, Romano-Gallic, and later populations, the results yield no certain evidence of the antiquity of the earlier races, whose remains are interspersed among those of definite and determinable historical character. An examination of the remains *in situ* has, however, led M. Millescamps to the important conclusion that flint instruments were cut and used as recently as the Merovingian age in France. —M. P. Broca has proposed to adopt the word "Stéréométrie" for that branch of craniometric science which treats of the determination of cranial capacities. In his paper M. Broca explains the various methods which he has found best adapted for the purpose. He considers that, of all the substances tried, bullet-lead, although not perfectly free from sources of error, is the most reliable, the results yielded by repeated experiments varying not more than five cubic centimetres for the same skull. No absolutely correct method has as yet been devised, and hence we must content ourselves for the present with approximate results.

Sitzungsberichte der Kgl. böhm. Ges. der Wissenschaften in Prag.—The publication of this Society comprises the whole of 1874, during which period some thirty important papers were read in the Natural Science Department of the Society. We notice the following:—On the independent representation of the *n*th derivative of broken functions of a variable, by Prof. Dr. Studnicka.—On the chemical composition of microsommite, by Prof. Safarik.—On harmonic systems of points on rational curves of the third and fourth order, by K. Zahradnik.—On the discovery of diluvial animal remains in the Elbe Loess, near Aussig, by Dr. Laube.—On some minerals from Kuchelbad, near Prague, by Dr. Safarik.—On the different forms and the signification of the changes in generation of plants, by Dr. L. Celakovsky.—Researches on the hyëtography of Bohemia, by Dr. Studnicka.—On the inflorescences of Borragineæ, by Dr. L. Celakovsky.—The solution of the problem of seat and essence of attraction, by Dr. Studnicka.—On the laws regulating incandescence of wires by electric currents, by Prof. A. von Waltenhofen.—Contradiction of Stieda's criticism on the author's work "On Hair," by Dr. J. Schöbl.—On a hyæna skull, by Dr. A. Fric.—On the Myriopoda hitherto observed in Bohemia, by Prof. F. V. Rosicky.—On a new universal microscope, by Prof. Zenger.—On a new photographic process to enlarge photographs correctly and to any size, by the same.—On curves of the fourth order, by Prof. E. Weyr.—On the travels of M. Emil Holub in Southern Africa, by Prof. C. Koristka.—On a new mineral mixture, named Parankerite, by Dr. Boricky.—On the theory of Cardioids, by Dr. K. Zahradnik.—On the discovery of an Ichthyomorphous *Ceratodus Barrandei* in the gas coal of the Rakonitz deposit, by Dr. A. Fric.—On the elements of a mechanical theory of ocean currents, by Prof. G. Blazek.—On the Cladocera-fauna of Bohemia, by B. Hellich. Preliminary researches on the Annelida of Bohemia hitherto observed, by F. Vejdovsky.—On the integration of differential equations of the first order, by Dr. E. Weyr.—On the pseudoscorpiones-fauna of Bohemia, by Prof. A. Stecker.—On the coal deposit of Pilsen, by Prof. J. Krejci.—Report on the chalk deposits of Perutz, in Bohemia, and their fossil remains, by the same.—On a new simple method of determining tautozonal planes of crystals, by the same.

THE August number of the *Bulletin de la Société d'Acclimatation de Paris* contains a very instructive paper, by Dr. Vidal, on the fauna and flora of Japan. The useful indigenous animals of that country are not so numerous as the geographical position of the islands would seem to indicate; the principal are a small species of ox, goats, rabbits, and wild boars. Imported animals, such as sheep and pigs, are rare, the former, indeed, not appearing to thrive in the climate, although they exist in considerable quantities on the opposite coasts of Northern China. A species of small black bear, and monkeys, are prized by the natives as articles of diet. Horses are abundant, though the ass and the mule are unknown in the country. Birds, both useful and ornamental, are very numerous, the principal being several varieties of duck and common "barndoor fowls," pheasants, and quails; wild geese are abundant, but the domestic variety and the turkey are almost unknown. Of fish there is a plentiful supply, and the fisheries form one of the most important industries of the country. Salmon are very common and highly prized.—M. L. Faton gives a summary of experiments with several kinds of vegetables and useful and ornamental plants, which is valuable as indicating the species which best repay the trouble of scientific cultivation.—At the July meeting of the Society a letter was read from M. C. Naudin, enclosing seeds of *Cytisus proliferus* from the Canary Islands, a plant which is cultivated there for the sake of its leaves, which are used as food for cattle. M. Naudin suggests that it might be usefully cultivated in France, or at any rate at the Cape of Good Hope, and in Australia.—Another plant (*Reana luxurians*), called in Guatemala Téosinté, and cultivated there for the same purposes as the one above named, is recommended by M. J. Rossignon.

Reale Istituto Lombardo di Scienze e Lettere. Rendiconti, vol. viii. fasc. xvi. The first portion of this number contains the following among other papers:—On the hydrological map of the department of Senna e Marna, by M. Curioni.—On two benzol-bisulphuric acids and their relations to other compounds, by MM. Koerner and Monselise.—The second portion of these *Rendiconti* contains reports by M. Carcano and M. Hajech, on the work of the Institute during the year; accounts of prize awards, with reports of committees on the competitive memoirs; and an announcement of prizes to be competed for within the next three years. Among the subjects of the latter we note the following:—Actual mean longevity of man in Italy, compared with other peoples; What are the best antifermentatives and antiseptics, disinfectants and deodorizers? Indicate a good method of cremation; Respective merits of animal and human vaccination; Embryogeny of silkworm; History of the progress of the anatomy and physiology of the brain, in the present century.

SOCIETIES AND ACADEMIES

MANCHESTER

Scientific Students' Association, Oct. 20.—Mr. John Plant, F.G.S., in the chair.—Mr. Wm. Gee lectured on *Polytrichum commune* (the common Hair-moss), as a type of moss-structure, commenting on the points of differentiation between true mosses and cryptogams erroneously associated with them, tracing the life-cycle, the minute anatomy of the organs, and the

function of mosses in nature and art.—The Chairman exhibited a collection of Ammonites from the Kimmeridge Clay and from the Tertiary Sand near Alexandria.—Mr. C. Robinson showed local drift-shells; and Mr. Gee a miner's lamp-glass, tempered by the new process to withstand change of temperature, although of the usual thickness (¼ inch).

CALIFORNIA

Academy of Sciences, Aug. 2.—Mr. H. Edwards, vice-president, in the chair.—Mr. Lackington presented a paper on some new Crustaceans of the Pacific coast.—Dr. Blake made some remarks on a mineral which he had presented to the Academy a few months ago under the name of Colomite. He stated that a superficial analysis of the mineral had then led him to believe that it was a potash mica, containing a very large quantity of chromium. Since that time the mineral had been analysed by Prof. Genth, of Philadelphia, who had discovered that it contained a large quantity of vanadium, more than 20 per cent. Under these circumstances he proposed to name the mineral Roscoelite, as Prof. Roscoe, of Manchester, had so successfully investigated the properties of vanadium. The mineral occurs in a gold mine in the lower hills of the western slope of the Sierra. It is associated with a small vein of quartz, but it is principally in the mica that the gold is found, a few pounds of the mineral (a miner's panful) often yielding as much as $240 in gold. The occurrence of so large a quantity of a pentivalent metalloid in a mica offers another and perhaps the most striking anomaly presented by this class of minerals as regards their chemical composition. Dr. Blake then alluded to some physiological experiments he had performed to determine the molecular relations of beryllium. Neither the specific heat of the metal nor the vapour density of its chloride had been determined, and chemists were undecided as to whether it was a bivalent or quadrivalent element. Its physiological reactions, when introduced directly into the blood of living animals, so closely resembled those of alumina that there can be no doubt but that it belongs to the same isomorphous group, and that it is a quadrivalent element. There is also a close relation between the intensity of physiological action of this substance and its atomic weight. When compared with aluminum, as in a series of experiments conducted expressly to determine this point, the quantities of Be_2O_3, under the form of sulphate, required to kill 2,270 grammes of rabbit, when injected into the veins in divided doses (three injections), were ·059, ·061, ·050; the quantities of Al_2O_3, introduced into the veins under the same conditions were ·021, ·023, ·022; and the smallest quantity required to kill, when introduced in one injection, was, of Al_2O_3, ·016, and of Be_2O_3, ·038, showing a marked increase in the physiological action of these substances, with an increase in the atomic weights, the atomic weight of Al being 27·4 and of Be, 14. This, the author believes, is the first occasion on which physiological reactions have been used to determine the chemical properties of a substance. Should, however, the carbon compounds follow the same laws in their physiological reactions as the inorganic elements, living matter must offer a valuable reagent in investigating their molecular properties. The interesting experiments of Messrs. McKendrick and Dewar, published in the 23rd vol. of the Proceedings of the Royal Society, would indicate that such may be the case, as these gentlemen found in experimenting with the compounds of the Chinolin and Pyridin groups, that the physiological actions became stronger in going from the lower to the higher members of the series. They also observed that in the Pyridin group, when the base became doubled by condensation, not only was the physiological action more intense, but its character was completely altered, agreeing in these respects with the salts of iron with which analogous changes take place, both in the character and intensity of their physiological action, when the molecule is doubled in the change from ferrous to ferric salts, as the author has shown in the *Journal of Anatomy and Physiology*, vol. iii. p. 24.

PARIS

Academy of Sciences, Oct. 18.—M. Frémy in the chair.—Admiral Paris presented the volume of the "Connaissance des Temps" for 1877. This publication, prepared by M. Loery, is now double in size what it was twenty years ago, and much improved. The following papers were read:—New problems relative to the conditions of equality of size of rectilinear segments on the tangents of geometrical curves of any order and class, by M. Chasles.—Third note on the electric conductivity of bodies moderately conducting, by M. Du Moncel. In the polarisation currents obtained with silex of Herouville, he found that the electrodes do not simply play the part of conductor, but acquire a peculiar electric state, which they may retain for days, and even under intense heat; this state cannot alone produce a current of polarisation; the dielectric must have undergone electrification under influence of the electrodes. But once this has occurred, they may be separated for some time without losing the power of giving a current when brought together again. The phenomena are analogous to those of phosphorescence.—On the trepanation and evacuation of long bones in cases of osteitis of neuralgic form, by M. Gosselin.—Fall of a meteorite on 12th May, 1874, at Sersukow, in Russia, by M. Daubrée. It weighs ninety-eight kilogrammes, and is of the oligosidere type.—On the carpellary theory according to the Irideæ (second part), by M. Trecul.—On the rotatory power of quartz in the ultra violet spectrum, by M. Croullebois.—On the laws which govern reactions with direct addition, by M. V. Markovnikoff.—On a case of oxidation in the cold state, of acetic acid in neutral or weakly alkaline liquids, in presence of nitrates and phosphates of soda and potash, by M. Mehay.—Process for artificial cooling of considerable masses of air by contact with a cold liquid, by MM. Mignon and Rouart. In a candle manufactory at Amsterdam, they use a cooled solution of chloride of calcium, which descends on the uppermost of a series of plates rotated with the axis of a cylinder between discs projected from the cylinder-wall, thus giving a continuous finely-divided cascade. Through this passes 26,000 kilogrammes of air in an hour, and a building of 3,051 cubic metres' capacity has thus been kept, in September, at 12° or 13° C.—On the sexual generation of the Vorticellians, by M. Balbiani.—M. Petit and M. Godet presented notes on treatment of Phylloxera.—M. Hugo, one on a transformation of the law of Bode, regarding the distances of the planets.—M. Brachet, on an improvement of Gramme's machine, a modification in the microscope, and a process for rendering ordinary glass fluorescent.—M. Varssin-Chardanne submitted several memoirs on aërial navigation.—M. Marchand described his process of aërial navigation.—The Secretary quoted from a work of M. Mouchot's in 1869, where he refers to the ancient Roman method of utilising solar heat.—The Secretary also noticed a second edition of "Preliminary notions for a treatise on the construction of ports in the Mediterranean," by M. Cialdi.—Magnetic map of France for 1875, by M. Marié Davy. This note gives tables of declination and annual variation for different districts.—Observations of the Perseides, made on Aug. 10, 1875, at Spoix (Côte d'Or), by M. Gruey.—On a chloride of silver pile composed of 3,240 elements, by MM. Warren de la Rue and H. W. Müller.—On a successful case of trepanation for an osteitis of neuralgic form, in a flat bone—the frontal—by M. Pingaud.—On the frequency of earthquakes relatively to the age of the moon, by M. Perrez. He finds evidence that during the last century and a quarter, earthquakes have been more frequent at syzygies than at quadratures.—M. Rivet transmitted a note from Martinique on earthquake shocks there and the electric phenomena which preceded them in telegraph wires.—M. Montucci presented a note on the hypothesis of a terrestrial central fire, and M. Noirit one on an automatic dredger.

CONTENTS
